Key References A select list of references, which provides more general information on the species, or a work that is generally considered to be a key reference work on the species. Each reference is given in full in the Bibliography. Citations given in the text (but not cited in ‘Key References’) are also given in full in the Bibliography. In general, profiles account for all literature published up until the end of 2007. Authors and editors have endeavoured to keep the species profiles fully up-to-date throughout the long production schedule, and references published from 2008 onwards have been incorporated where possible. None the less, certain key recent papers will have been missed or omitted.

Author The name of the author, or authors, is given at the end of each profile. All profiles should be cited using the author name(s).

Tables With a few exceptions, the use of tables to present data has been avoided in Volume V of *Mammals of Africa*.

Higher taxon profiles

The profiles for orders, families and genera are much less structured than for the species profiles. Each profile usually begins with a listing of the taxa in the next lower taxon; for example, each family profile lists the genera in that family. An exception to this arrangement is where a taxon has only one lower taxon. Higher taxa profiles provide the characteristics common to all members of that taxon. Some of these characteristics (for example, number of nipples or dental formula) may not be repeated in lower taxon profiles (unless essential for identification), so readers are encouraged to consult also the higher-taxa profiles, e.g. the species profile for *Canis simensis* should be consulted in association with the genus *Canis* profile. Likewise, a generic profile, such as *Canis*, should be read in association with the family Canidae profile.

Distribution maps

Each species profile contains a pan-African map showing the geographic range of the species. The purpose of the maps is to show current known limits of distribution of the species within historical range, recognizing that within this mapped range a particular species’ distribution will not be homogeneous. Reintroductions within the former range of a species are included and mapped, but

introductions outside of the former known range are not. Note that due to the sensitivity around the location of rhinoceros populations in Africa, the maps for these species are degraded to the country level. Subspecies are only indicated in cases where the boundaries can be reasonably delineated.

Each map shows the boundaries of the 47 countries of Africa, some of the major rivers (Nile, Niger–Benue, Congo [with the tributaries Ubangi, Lualaba and Lomani], Zambezi and Orange), and Lakes Chad, Tana, Turkana (formerly Rudolf), Albert, Edward, Victoria, Kyoga, Kivu, Tanganyika, Malawi, Mweru, Bangwuela and Kariba. The map projection is Transverse Mercator, with the following parameters: False Easting: 0; False Northing: 0; Central Meridian: 20; Linear Unit: metre; Datum: Clarke 1866.

The geographic distribution of a species is indicated as:

- red shading = current range. Different colour shading denotes subspecies, where appropriate.
- × = isolated locations considered to be separate from the main geographic range(s); some locations indicated by × may include two or more closely spaced locations.
- ? = uncertain, but possible, presence.
- red arrow = recorded from the island indicated by the arrow.

Cohort FEREUUNGULATA

Fereuungulata Waddell, Okada & Hasegawa, 1999. Syst. Biol. 48: 3.

Fereuungulata is a mammalian cohort that unites the carnivores and pangolins with what were traditionally and popularly dubbed 'Ungulates', a category that sometimes, but not always, has been thought to have a relationship with whales. Use of the taxon name Fereuungulata, instead of Ferungulata (*sensu* Simpson 1945, who included also paenungulates, but not pholidotes or cetaceans) follows Asher & Helgen (2010).

The orders Artiodactyla and Perissodactyla, or more commonly the even-toed and odd-toed 'ungulates', respectively, both made their first appearance in the fossil record in the earliest Eocene, around 55 mya. Members of both orders are known across the northern hemisphere at this time, but their origin is commonly assumed to be in Asia (Beard 1998). This time period coincides with a major fall in sea level and with dispersal events among many mammalian groups.

It has been commonly assumed that artiodactyls and perissodactyls had a common evolutionary origin, in part based on their dental and post-cranial similarities, and yet many of these features can be shown to have evolved convergently, including hooves (Prothero *et al.* 1988, Prothero & Shoch 2002). Recent molecular studies have further complicated traditional efforts to fathom the evolutionary history of 'Ungulates'.

Of major significance has been the excision of 'subungulates' or 'paenungulates' (elephants, hyraxes and sirenians, plus some related extinct groups) from any possibility of close relationship. Several molecular phylogenetic studies have shown that these African groups must be removed from the same clade as the northern ungulates. As a result of these studies, Paenungulata is now a cohort in its own

right within the new supercohort Afrotheria (see Springer *et al.* 2005; and Supercohort Afrotheria in *Mammals of Africa*, Volume 1).

Another complication has been the creation of a clade to embrace both whales and artiodactyls (see Springer *et al.* 2005 for a review of the molecular evidence for higher order mammalian clade relationships). For several decades cetaceans (whales and dolphins) were presumed to have a relationship to artiodactyls, but molecular studies now place them as a suborder *within* what used to be called the Artiodactyla (the two former orders now combined in order Cetartiodactyla). However, there is still much dissension between molecular biologists and morphologists as to exactly how whales are related to other artiodactyls.

It is also not clear whether artiodactyls (= cetartiodactyls) and perissodactyls form a monophyletic group. Molecular studies (e.g. Liu *et al.* 2001, Meredith *et al.* 2011) unite a clade of Carnivora plus Pholidota (pangolins) as the Ferae (see below), and in turn show a close relationship to these ungulates. But while some studies place the Ferae clade outside of the grouping of the two ungulate orders (thus making the ungulate grouping monophyletic), others group the Ferae as the sister taxon to Perissodactyla (e.g. Waddell *et al.* 1999), although the morphological support for this grouping is slender. Some molecular studies also place bats within this clustering of carnivores

Golden Jackal *Canis aureus*.

and ungulates (as related to perissodactyls), while others have bats as the sister taxon to ungulates plus carnivores (see Meredith *et al.* 2011). In spite of such uncertainties, this work has provisionally adopted a molecular taxonomy that aligns a monophyletic clade comprising the orders Cetartiodactyla and Perissodactyla (Euungulata, after Waddell *et al.* 2001) with a monophyletic Ferae (Carnivora + Pholidota) under the cohort 'Fereuungulata' (and see Zhou *et al.* 2012).

Modern Carnivora have, in general, modified their cranial anatomy less radically than have Cetartiodactyla (the most extreme, of course, being the whales). The diversification of carnivores is sketched out in the Carnivora profile. Modern Pholidotes (pangolins), totally toothless, have made their affinities particularly difficult to fathom so the discovery by geneticists of a molecular link with carnivores has, at last, provided some sort of a lead, however distant, into the remotest origins of this most enigmatic of mammal orders. None the less, by adopting such a specialized ant and termite diet, and evolving the equivalent of mediaeval armour, the pangolins are almost as different from their nearest affines as whales are from pigs and hippos.

Many phylogenies have positioned artiodactyls and perissodactyls as 'closely related'. Today, we may well see living artiodactyls and perissodactyls as being rather similar types of mammals: horses are not so dissimilar from cows (i.e. both are largish, long-legged grazing mammals) and rhinos are not superficially remote from hippos (but note there has never been a perissodactyl equivalent for the huge radiation of omnivorous pigs among the artiodactyls). It is, thus, important to remember that during the Eocene, when most of the northern hemisphere was covered by tropical-like forests and the earliest artiodactyls and perissodactyls had begun their radiation, each lineage represented emphatically different types of mammals (see Janis 2008).

Artiodactyls were mainly small forms, rather like present-day mouse deer (Tragulidae) in both size and ecology. Their dental morphology indicated omnivorous (or, at best, soft browsing diets that included berries, buds and non-fibrous leaves). The perissodactyl equivalent of these early artiodactyls would have been the early equids ('horses'). Perissodactyls also branched out into a number of different, and larger, ecological types, most with more specialized browsing diets. These included ceratomorphs (rhinos and true tapirs) and a diversity of extinct lineages: a diversity of small 'tapiroids', the rhino-like brontotheres, and the rather horse-like chalicotheres that substituted claws for hooves.

By the late middle Eocene, around 45 mya, the northern hemisphere climate commenced cooling and drying, a trend that characterized the rest of the Cenozoic (see Morley & Kingdon, *Mammals of Africa*, Volume 1, pp. 43–56). Tropical forests started to retreat, replaced by more temperate woodlands, and this period heralded a time of great evolutionary turnover among the ungulates, among which artiodactyls apparently pulled ahead of the perissodactyls in terms of 'evolutionary success'. The first fossil ruminants (still small, tragulid-like forms) are known from this time in Asia and North America.

This change in fossil diversity has long been interpreted as reflecting some evolutionary superiority of artiodactyls, presumed to relate to the rumen-based foregut method of fermentation of fibrous vegetation in at least some clades, in contrast to the less derived mode of hindgut fermentation in perissodactyls (see Hofmann & Kingdon, *Mammals of Africa*, Volume 6, p. 84). However, the fossil record does not support the notion of a blanket competitive replacement. Moreover, it is certainly not the case that rumen-based fermentation is inevitably superior to hindgut fermentation under *all*

ecological circumstances. The rise of the more folivorous clades of artiodactyls (Ruminantia and Tylopoda) during the late Eocene, and the decline of the perissodactyls, is best explained by changes that would have taken place in vegetational quantity, quality and seasonal availability that would favor these animals' mode of feeding selection (small amounts of high-quality food: see discussion in Janis 2008).

Among the later Eocene artiodactyls a clear division emerged. As presented in these volumes, this has taken the form of four modern suborders: Suiformes (pigs and peccaries), Tylopoda (camelids), Whippomorpha (hippos and whales) and Ruminantia (modern ruminant groups, including tragulids). There is considerable debate as to how the artiodactyl suborders are interrelated, and as to where extinct groups would fit in. Hippos, long supposed to have some sort of affinity with suids, have been declared as close whale relatives by molecular biologists (with Whippomorpha as a sister group of the Ruminantia by Price *et al.* 2005). Craniodental morphologies have linked tylopods and ruminants as sister taxa in the 'Neoselenodontia', but molecular biology has broken this grouping up, and placed camelids as basal to other artiodactyls (including whales) (see Price *et al.* 2005). In any event, the modern lineages of artiodactyls gained their first evolutionary foothold during the late Eocene (about 40–35 mya). At this time some clear divisions emerged and the contemporary descendants of these early radiations are provisionally presented in these volumes in the form of the aforementioned modern suborders.

The late early Miocene, around 20–18 mya, marks another critical point in the patterns of ungulate evolution. Out of the initial diversification of perissodactyls, only four families remained: rhinocerotids, tapirs, chalicotheres (which survived into the Pleistocene) and horses. At this time, the first of the more derived equids (subfamily Equinae) appeared in North America (first appearing in the Old World around 10.5 mya). These equids were of a larger body size (pony-sized) and larger than previous forms, with high crowned (hypsodont) cheekteeth indicative of a diet that included at least a good proportion of grass, and with limbs more adapted for locomotion in open habitats.

The radiation of equids in North America has long been a well-known example of evolution (although they subsequently became extinct on that continent). In the Old World there is today only a single genus of grazing equid (*Equus*, comprising some seven, mostly allopatric, species) in contrast with the broad diversity of antelopes (although only a minority of antelope species are specialized grazers). However, horses in the middle to late Miocene of North America, including both grazing and browsing forms, were equal in their taxonomic diversity to the present day African bovids. Their decline in the latest Miocene predated the entry of bovids to North America, and was likely related to climatic changes. The genus *Equus* only reached Africa in the Pleistocene (although there was a moderate African late Miocene/Pliocene radiation of immigrant equids of the three-toed genus *Hipparion*). When zebras today, in substantial numbers, share their African pastures with grazing bovids, their present-day ecological success echoes the success that horses achieved in North America, albeit now expressed outside of their continent of origin.

In spite of possessing different digestive systems, bovids and equids represent the evolution of specialized grazers on different continental land masses, rather than two competing adaptive types with clear 'winners' and 'losers'.

Christine Janis & Jonathan Kingdon

Superorder FERAЕ

Ferae Linnaeus, 1758. Syst. Nat., 10th edn, 1: 37.

The superorder Ferae describes the recognition of a very unexpected affiliation between Carnivora and the pangolins, Pholidota, a clade that is well supported in molecular studies (Liu *et al.* 2001, Murphy *et al.* 2001a, b, Springer *et al.* 2005, Meredith *et al.* 2011, Zhou *et al.* 2012). Use of the name Ferae follows Asher & Helgen (2010); alternatively, the name Ostentoria has been applied to this clade of pangolins plus carnivorans (e.g. Amrine-Madsen *et al.* 2003).

The later radiations of Carnivora are becoming better known, and these are outlined in the appropriate profiles, but what still earlier divergence could have led to pangolins? The multiplicity of extant carnivores includes many forms that are relatively conservative and some of these, such as the Two-spotted Palm Civet *Nandinia binotata*, are omnivorous (including insects), well-clawed and also arboreal. It is very likely that the earliest proto-pangolin was also a small, sharp-clawed, tropical Asiatic tree-climber with omnivorous or insectivorous tastes, and, given the crucial role of the tail in all pangolin species, that its long tail was prehensile and scaly. The beginnings of scales, which are cornified extrusions of outer skin, can be seen on the tails of various mammals such as rats, some insectivores and some afrotherians, while the most explicitly counter-abrasive tail-scales are found among anomalurid rodents. Carnivore-like proto-pangolins could, therefore, have been well-entrenched arboreal omnivores or insect-eaters with strongly prehensile and abrasion-resistant tails. Strong tails can also serve to mitigate accidents and predation in that it is harder for their owners to be dislodged. As a fifth limb, such tails also make it easier

for animals to engage in vigorous action while climbing, foraging or fighting.

Ants and termites have probably been a major component in the canopy of tropical rainforests for about as long as there have been rainforests and many species of arboreal ants and termites build nests in or on branches, or live in symbiosis with ‘ant-plants’, *Myrmecodia* and *Hylocophytum*, that have evolved chambers to accommodate the ants (Huxley 1978). Whereas many canopy resources are ephemeral, seasonal or unreliable, ants tend to be more predictably perennial inhabitants of the tropical canopy. Even in the Palaeocene, any arboreal predator that could penetrate the ants’ physical defences and also digest their chitinous, formic acid-protected bodies would have been assured of a reliable food supply. Once embarked on such a specific diet, the earliest pangolins, probably very small animals, must have progressively modified their teeth, tongues and digestions, and lost most of their fur as scales spread from the tail to body and limbs. Eventually some forms came to the ground and some became much larger (possible affinities between pangolins are discussed in the Manidae profile).

Modern pangolins no more resemble carnivores than whales do giraffes, yet fossils, genes and biological logic continue to reveal that such affinities, even when separated by many millions of years, can become comprehensible. As evidence accumulates we can expect that the intervening adaptive steps that have taken highly derived taxa ever further from their less-specialized origins can eventually be reconstructed with some confidence.

Jonathan Kingdon

Order CARNIVORA – Carnivores

Carnivora Bowdich, 1821. An analysis of the natural classifications of Mammalia for the use of students and travellers. Paris, J. Smith, 115 + [31] pp., 16 plates.

Carnivora are highly diverse in Africa. From Lions *Panthera leo*, Cheetahs *Acinonyx jubatus*, hyaenas and mongooses to clawless otters, polecats, Cape Fur Seals *Arctocephalus pusillus* and African Wild Dogs *Lycaon pictus*, this varied array of predators, scavengers, piscivores and omnivores play keystone roles in many African habitats, from the Serengeti Plains to the Congo rainforest. Yet, it is noteworthy that the key anatomical feature usually associated with Carnivora, elaborated and restricted carnassial shear in the dentition, predates its appearance in modern forms. The carnivory indicated by this primary dental adaptation has been substantially modified in the dietary specialization of many living carnivorans, with varying degrees of hypocarnivory to hypercarnivory, reflecting a wide range of specialized diets.

Even though many carnivorans retain a relatively generalized anatomy, diversity also marks virtually every aspect of their biology.

Carnivora are remarkably diverse taxonomically, being the fourth most speciose of modern mammalian orders with >280 species (see Wozencraft 2005 for a recent classification of the order). Species diversity varies markedly among the major extant clades, from the monospecific Nandiniidae, Ailuridae and Odobenidae to the dozens of mustelid species, and with terrestrial–freshwater taxa outnumbering the marine Pinnipedia by roughly 7 to 1. Carnivoran ecological diversity embraces diurnal, crepuscular and nocturnal forms; cursors, climbers, diggers, swimmers (freshwater and marine); and flesh eaters, herbivorous forms, insect eaters, piscivores and omnivores. The breadth of their geographic and environmental range spans land to water, all continents, from pole to pole, from deserts to high mountains to rainforests. An outstanding fossil record also makes Carnivora one of the most important and widely studied groups of mammals.

While ambling plantigrade forms are common, both speed and hunting range can be remarkable in cursorial carnivorans, with the Cheetah noteworthy as the fastest mammalian short-distance sprinter. Body size (correlated with many life history and physiological attributes) among living Carnivora ranges over more than four orders of magnitude, exceeding that observed in any other mammalian ‘order’, from the tiny Least Weasel *Mustela nivalis* at just 100 g to the gargantuan Southern Elephant Seal *Mirounga leonina* at up to 4000 kg. Delayed implantation of embryos is widespread among mammals, but is particularly common in mustelids and mephitids, representing almost half of the documented mammalian cases (Thom *et al.* 2004). Although it appears to be correlated with longevity, maximum latitude of geographic range and maternal investment (after correcting for phylogeny; Thom *et al.* 2004), the

Tentative phylogenetic tree for extant African carnivora (after Flynn *et al.* 2005, Eizerik & Murphy 2009).

observation of delayed implantation in marine carnivorans (e.g. Ross Seals *Ommatophoca rossii*) and inference that it may occur in all pinnipeds, indicate that much remains to be learned about this important reproductive trait. Of course, the marine pinnipeds differ from their terrestrial relatives in many key features related to their specialized aquatic habitus, such as locomotor, metabolic and respiratory adaptations (e.g. the Weddell Seal *Leptonychotes weddellii* can remain submerged for 80 minutes during foraging dives to 700 m, while the champion diver is the Southern Elephant Seal, spending some 90% of its time submerged at depths up to 2150 m and for up to 120 minutes). Social systems also vary widely, from the many solitary species, to pair or small-group forming taxa, to the diverse array of social forms (e.g. Lion prides, colonial herpestids, or pack-hunting canids), all of which are found in Africa today.

The clade Carnivora is actually a relative latecomer to the African continent and the fossil record documents similar predator niches being first occupied by the now-extinct creodont clade Hyaenodontidae (first arriving in Africa during the late Eocene). Creodonts went extinct in Africa about 13 mya. The late arrival of Carnivora partially explains the uneven modern distribution of subclades in Africa. For example, many predominantly herbivorous forms that occur on other continents (e.g. Giant Panda *Ailuropoda melanoleuca*, Red Panda *Ailurus fulgens*) do not occur in Africa. In addition, members of the families Ailuridae, Procyonidae, Mephitidae, Eupleridae, Odobenidae and Ursidae do not occur in mainland Africa today. However, fossil bear (Ursidae) remains have been retrieved from north, north-east and southern Africa. Others, like Phocidae (one species) or Viverridae (two subfamilies), are much more diverse elsewhere. Several other entirely extinct higher-level clades also occurred in the past in Africa, such as various sabretooths and ‘false sabretooths’, Machairodontinae (Felidae) and Nimravidae, respectively, which flourished and diversified within Africa between the Miocene and about 1.5 mya, and the ‘bear-dogs’ of the family Amphicyonidae as well as the aforementioned creodonts.

Of living families, only one is found solely on mainland Africa: the monospecific Nandiniidae (recently raised to this rank based on strong genetic support for the Two-spotted Palm Civet *Nandinia binotata*

Two-spotted Palm Civet *Nandinia binotata* myology (above) and skeleton (below).

forming the outgroup to all other living feliform Carnivora, well outside of its traditional placement as a member of the Viverridae). In addition, the Eupleridae are now recognized to be a monophyletic array embracing all the carnivorans that are endemic to Madagascar (although they appear to have originated in Africa during the middle Cenozoic prior to their dispersal to the island; Yoder *et al.* 2003). Tectonic, environmental and biogeographic events and processes have profoundly influenced the global distributions of Carnivora (reviewed in Deméré *et al.* 2003, Hunt & Tedford 1993, Flynn & Wesley-Hunt 2005; for novel divergence times and biogeographic hypotheses in the Felidae, see Johnson *et al.* 2006).

Flynn & Wesley-Hunt (2005), Flynn *et al.* (2010) and Spaulding & Flynn (in press) have provided detailed overviews of higher-level phylogeny and taxonomy, temporal distributions and biogeography of modern Carnivora and their extinct relatives. Similarly, the higher-level phylogeny of living Carnivora has been investigated comprehensively by Flynn *et al.* (2005; using primary molecular data), while Bininda-Emonds *et al.* (1999) adopted a 'supertree' approach that derives from phylogenetic tree topologies from earlier studies. Several recent studies have begun expanding taxon or character sampling for living and fossil forms, such as the morphological studies of early fossil Carnivoramorpha (Spaulding *et al.* 2010, Spaulding & Flynn in press) and the molecular analyses of Eizirik *et al.* (2010; 14 nuclear loci for representatives of all extant families), Agnarsson *et al.* (2010; mitochondrial cyt b for about 80% of extant species), Yu *et al.* (2011; 22 new nuclear introns for 16

extant caniforms) and Meredith *et al.* (2011; 164 mammals, 26 loci, >35kb/11k amino acid sequences). Other authors in this volume provide in-depth treatments of current thinking about the phylogeny and evolution of the African Carnivora.

Recent analyses of, and controversies about, the higher-level phylogeny of Carnivora have centred on three hierarchical levels: (1) their closest relatives among the Eutheria (both living and fossil); (2) whether early Cenozoic fossils commonly assigned to the Miacidae and Viverravidae ('Miacoidae') are members of the crown-clade Carnivora or nearest outgroups to the living carnivorans (which together would be considered the Carnivoramorpha); and (3) the composition and positions of various subclades within Carnivora (especially the pinnipeds, Ailuridae, 'Mustelidae' and interrelationships among the modern feliform families).

Some of these problems now appear to have been resolved with significant molecular and palaeontological support, whereas others remain uncertain in spite of intense study and thus are the focus of continuing analysis. Carnivora have been among those living mammal orders that have remained difficult to ally to any others via morphological analyses (see Novacek 1992). These difficulties were often tied to the idea that the orders diversified extremely rapidly following the K/T boundary event (extinction of the dinosaurs). Among extinct forms, anatomical features that might associate Carnivora most closely with creodonts were noted by Wyss & Flynn (1993). Modifying an original conception of Linnaeus (1758), Simpson (1945) classed both as Ferae, a usage of the name accepted by the current author contra the broader definition used in the prior section of this volume. Among living forms, Wyss & Flynn (1993) also noted anatomical features shared by Carnivora and lipotyphlans, while initial molecular studies linked carnivorans to many other distinct lineages, from ungulates to bats, but the most comprehensive molecular samplings to date (e.g. Murphy *et al.* 2001) have suggested a surprising sister-group relationship between Carnivora and Pholidota (pangolins). Morphological support for this would come from an ossified tentorium in the braincase, which is shared by carnivorans, pangolins and creodonts (Wyss & Flynn 1993).

Monophyly of Carnivora is very strongly supported by both molecular and anatomical evidence. Likewise, a major split within the order of Caniformia ('dog-like') and Feliformia ('cat-like') is well supported. Within Caniformia, canids are outgroup to all the remaining forms (Arctoidea). Among arctoids there is sequential branching of ursids, pinnipeds and Musteloidea. Within musteloids there is a tritomy of Mephitidae (now removed from Mustelidae), Ailuridae and the clade of Mustelidae + Procyonidae. *Nandinia* has now been shown to be the outgroup to all other living feliforms. The monophyletic Malagasy Eupleridae is most closely related to Herpestidae, which together form a sister-group to Hyaenidae. Remaining ambiguity centres on the pattern of interrelationships among the Felidae, Viverridae and the HHE (or Hyaenidae–Herpestidae–Eupleridae) clades. In addition, recent documentation of the monophyly of all of Madagascar's Carnivora has resulted in a grouping of anatomically diverse forms that formerly had been placed in at least three separate families: Herpestidae, Viverridae, Felidae (Yoder *et al.* 2003). Furthermore, it has been proposed that prionodontine linsangs, formerly placed in Viverridae, might actually be allied with cats (Gaubert & Véron 2003, Gaubert *et al.*

2005a). These taxonomic upheavals suggest a much more complex pattern of behavioural and morphological transformations within the Feliformia than had previously been indicated.

The pre-Holocene fossil record for modern families is patchy (e.g. none for Eupleridae, extensive for Canidae), which partly reflects dominant habitats, geographic distributions and uneven palaeontological sampling. Entirely extinct clades have provided novel information about carnivoran history and the sabre-toothed nimravids, 'bear-dog' amphicyonids and the early fossil 'miacoids' are well represented. Anatomical data noted a century ago by Matthew (1909) suggested possible placement of the Miacidae and Viverravidae within a crown-clade Carnivora as basal caniforms and feliforms, respectively (Flynn & Galiano 1982). The most recent molecular and palaeontological studies now provide strong evidence for virtually all of these 'miacoids' being stem Carnivoramorpha lying outside the Carnivora (e.g. Wesley-Hunt & Flynn 2005, Spaulding & Flynn *in press*). It now appears that 'miacids' form a paraphyletic array of sequential outgroups to the Carnivora, with a monophyletic grouping of Viverravidae situated at the base of the Carnivoramorpha. This topology of fossil and living forms is highly significant for evolutionary and ecosystem studies because earlier results suggested that the origin of Carnivora and the split between caniforms and feliforms could have been as old as 65–60 mya, whereas the latest results suggest much younger ages for these events (minimum divergence estimate of 43 mya).

The 'order' Creodonta, named more than 125 years ago by Cope (1875), comprised an entirely extinct radiation of early to middle Cenozoic forms that resembled Carnivora in meat-eating specializations and in some locomotor features. In body form, creodonts were generally large-bodied, terrestrial predators or scavengers, with relatively large heads and plantigrade locomotion (Savage 1977). However, their relationship to the Carnivora has long been questioned and creodonts are of debatable monophyly themselves (see Flynn & Wesley-Hunt 2005).

A variety of craniodental and post-cranial features have been used to characterize living Carnivora, including reduction or loss of the clavicle, loss of the stapedial artery in the basicranium, fully ossified auditory bulla (except in *Nandinia*), thin lamina between the head and neck of the malleus, fusion of the scaphoid and lunar bones of the wrist (into a single scapholunar) and the specifically carnivoran P^4/M_1 carnassial pair. However, given that modern carnivorans are reasonably easy to identify, it is noteworthy that it has been difficult to rigorously diagnose the clade based on unique derived characters. There are a variety of potential reasons for this, notably their rapid divergence from other eutherians. Inferences of broader patterns of evolution across the entire Carnivora have been hindered by poor resolution of their higher-level interrelationships. Also, as mentioned above, the classical synapomorphy of Carnivora (P^4/M_1 carnassial shear) now appears to have much deeper roots in evolutionary ancestry, appearing first in early Cenozoic stem-Carnivoramorpha fossils (Palaeocene Viverravidae, ~63 mya) (for these and features cited below, see Wesley-Hunt & Flynn 2005). Similarly, a completely ossified bulla fused to the basicranium is not a synapomorphy of Carnivora, but rather evolved independently several times within the group, while the retractile claws found only in a few living clades

now appear to be a deep synapomorphy, with subsequent loss or reduction independently several times.

Carnivoramorpha are distinguished from all other Mammalia, including creodonts, by dental features such as P^4/M_1 carnassial shear (P^4 with anteriorly situated paracone), and a broad M_1 parastyle that is equal to or larger than the metastyle. Numerous advanced features of the crown-clade Carnivora were acquired sequentially, with Carnivora now uniquely diagnosed by a flange on the basioccipital (attachment for the entotympanic of the bulla), loss of M^3 , fusion of the scaphoid and lunar, and an expanded braincase (Wesley-Hunt & Flynn 2005).

Various features have been used to diagnose major subclades within the Carnivora ever since Turner's (1848) and Flower's (1869a) pioneering use of auditory bulla shape and bony internal partitions (see Ivanoff 2001, Wesley-Hunt & Flynn 2005). Those features that distinguish family and lower-level groups are summarized elsewhere in this volume but it should be remembered that many fossil Carnivora (and the living *Nandinia*) lack a fully ossified auditory bulla. 'The fully ossified entotympanic (wholly or partially fused to the basicranium) evolved independently within the Caniformia and Feliformia, although an increasingly strong attachment and incorporation of the bulla to the basicranium can be inferred along the phylogeny' (Wesley-Hunt & Flynn 2005: 14). Among interesting examples of anatomical specializations in these groups are the marked expansion of the maxilloturbinals in the Caniformia and a long and stylized baculum in Canoidea.

There have been many recent interesting studies of the comparative biology, ecology and evolution of carnivorans, including synthesis of evolutionary patterns through time (Van Valkenburgh 1999); palaeoecology, especially of large carnivorans (Turner 1990, Van Valkenburgh 1996); locomotion (Heinrich & Rose 1997); body size evolution or life history strategies (Gittleman 1993, 1994a, Meiri *et al.* 2004a, b, 2009); brain size (Gittleman 1991, 1994b, Gittleman & Van Valkenburgh 1997); social structure (Creel & Macdonald 1995, Geffen *et al.* 1996); and physiology, energetics or diet (Lee *et al.* 1991, McNab 1995, Carbone *et al.* 1999). Furthermore, the growing resolution and strength of support for the phylogeny of most major groups has brought greater precision to evolutionary analyses, adding genes and fossils to the study of living taxa and this synthesis from different disciplines will surely yield many more exciting results in the near future. Among selected relevant studies are: palaeoecology and ecomorphology (Werdelin 1996a, Van Valkenburgh *et al.* 2003, Werdelin & Lewis 2005, Wesley-Hunt 2005), locomotion (MacLeod & Rose 1993, Wang 1993, MacLeod 2001), body or brain size or correlated life history traits (Lindenfors *et al.* 2003, Webster *et al.* 2004, Finarelli & Flynn 2006, 2009, Flynn *et al.* 2010), biogeography (Hunt & Tedford 1993, Deméré *et al.* 2003) and novel approaches in genetics (Fondon & Garner 2004), modelling and comparative anatomy (Polly 2008) and developmental biology and morphological integration (e.g. relative influences of diet, brain size and phylogeny on cranial anatomy; Goswami 2006). In this thriving discipline are volumes that sample many other approaches and results, notably Gittleman (1989, 1996), Mazin & de Buffrénil (2001), Perrin *et al.* (2002) and Flynn (2003).

Suborder CANIFORMIA – Canids, Mustelids, Pinnipeds

Caniformia Kretzoi, 1943. Földtani Közlöny 73: 194.

Suborder Caniformia is traditionally subdivided into the Cynoidea, containing the family Canidae, and Arctoidea, represented by Ursidae (bears) (the most basal clade), Phocidae (true seals), Odobenidae (Walrus *Odobenus rosmarus*), Otariidae (fur seals and sea lions), Ailuridae (Red Panda *Ailurus fulgens*), Procyonidae (raccoons), Mustelidae (weasels, polecats, otters, ratel and allies) and Mephitidae (skunks). This taxonomic arrangement is consistently well supported both by morphological and molecular data (e.g. Flower 1869a, Flynn & Wesley-Hunt 2005, Eizirik *et al.* 2010, Meredith *et al.* 2011; but see Agnarsson *et al.* [2010] who suggest the possible placement of the Red Panda as sister to canids). In Africa, the suborder is represented by the Canidae (four genera and 12, and probably 13, species), Phocidae (one genus, one species), Otariidae (one genus, one species) and Mustelidae (eight genera and 11 species).

Family CANIDAE
FOXES, WOLVES, JACKALS, DOGS

Canidae Fischer, 1817. Mém. Soc. Imp. Nat. Moscow 5: 372.

| | | |
|---------------------------------------|------------------|-------|
| <i>Canis</i> (4, probably 5, species) | Jackals, Wolves | p. 30 |
| <i>Lycaon</i> (1 species) | African Wild Dog | p. 50 |
| <i>Vulpes</i> (6 species) | Foxes | p. 59 |
| <i>Otocyon</i> (1 species) | Bat-eared Fox | p. 77 |

Canidae – the dog family – is morphologically a relatively homogeneous, polygeneric taxon, distributed widely in all continents with the exception of Antarctica (Macdonald & Sillero-Zubiri 2004). Although much of canid evolution was in open grasslands, their great adaptability has enabled them to flourish in arid habitats, the Arctic, mountains, woodlands and rainforests (and, indeed, cities). Their anatomy is adapted for the cursorial pursuit of prey in relatively open environments, with tall, lithe bodies, a bushy tail, long limbs and digitigrade, four-toed feet. They have triangular heads with long, pointed muzzles, well-developed jaws and prominent, roughly triangular pointed ears (which, in some desert species, are very large).

There are three major groups (subfamilies) in the family Canidae: Hesperocyoninae, Borophaginae and Caninae, the first two represented by fossil forms only. The Hesperocyoninae is the most ancient group of all canids, and its basal member, *Hesperocyon*, gave rise to the two more advanced subfamilies, Borophaginae and Caninae (Wang 1994). Canids originated in North America in the Eocene 56–34 mya and underwent extensive radiations from there before reaching the Old World towards the end of the Miocene (ca. 7 mya) (Wang 1994, Wang *et al.* 1999). The oldest records of canids in Africa are those of a small fox from Chad (de Bonis *et al.* 2007) at 7–6 mya, and Kenya, where remains of the genus *Eucyon* date to 6.1–5.6 mya (Morales *et al.* 2005). Prior to these discoveries, the oldest canid in Africa was known from the very earliest Pliocene of Langebaanweg, South Africa, probably referable to *Eucyon* and dated ca. 5.3–5 mya (Rook 1993, Tedford & Qiu 1996).

The genus *Canis* is first known in Africa from South Turkwel, Kenya at 3.5 mya (Werdelin & Lewis 2000), although material from Laetoli (if demonstrated as belonging to *Canis*) may be older (Werdelin & Dehghani 2011). Until the identification of *Canis ferox* from North America as the oldest member of the genus (Tedford *et al.* 2009), the record from South Turkwel – at the time, more than half a million years older than the oldest record of *Canis* elsewhere – suggested a possible African origin for the genus. Various fossils referred to different species of jackal have been recovered from Plio-Pleistocene deposits, but their relationship to modern jackals is uncertain (Werdelin & Lewis 2005). Interestingly, a primitive member of the racoon-dog lineage (no longer extant in Africa) is known from Laetoli in Tanzania at more than 3.8 mya (Barry 1987, Werdelin & Lewis 2005, Werdelin & Dehghani 2011) and younger members of the genus *Nyctereutes* are known from Morocco (Geraads 1997), South Africa (Ficcarelli *et al.* 1984) and Ethiopia (Geraads *et al.* 2010).

The Canidae can broadly be divided into two distinct lineages, the ‘wolf-like’ and ‘fox-like’ forms (e.g. Tedford *et al.* 1995), which diverged between 9 and 5 mya. Fox-like canids are generally small in size, have a low diploid chromosome number (2n = 36–66) and

African Wild Dog *Lycaon pictus* myology (top) and skeleton (bottom).

Tentative phylogenetic tree for African Canidae (after Lindblad-Toh *et al.* 2005, Wayne & Ostrander 2007).

are typically rodent hunters (Geffen *et al.* 1992d). Wolf-like canids (wolves, coyotes, jackals, dogs) are medium-sized to large and typically have a diploid chromosome number of $2n = 74-78$ (Wayne *et al.* 2004). The family blossomed in the Oligocene (19 genera) and exploded in the Miocene (42 genera), declining to the 13 genera recognized today. Bininda-Emonds *et al.* (1999) present a species-level phylogeny for the family, which indicates that some uncertainty remains, particularly among the monotypic canine genera (e.g. *Cuon*, *Speothos*, *Chrysocyon*).

For the most part, the taxonomy of wild canids is largely uncontroversial, although there is some disagreement regarding, for example, the use of the genus name *Pseudalopex* or *Lycalopex* for the South American genera, the validity of the Red Wolf *Canis rufus* as a distinct species, and the status of the Dingo and Guinean Singing Dog (Wang *et al.* 2004, Wozencraft 2005). Of the 13 extant genera and 35 species of Canidae, four genera and 12 species occur in Africa today: *Canis* (four, and probably five, species); *Lycaon* (one species); *Otocyon* (one species); and *Vulpes* (six species).

The Canidae range in size from the Fennec Fox *Vulpes zerda*, weighing less than 1 kg, to the Grey Wolf *Canis lupus*, which can weigh up to 62 kg (Mech & Boitani 2004). Most fox species weigh 1.5–9.0 kg, most other species 5–27 kg. Sexual dimorphism, when present at all, is minimal, with males slightly larger than females but similar in colour. Pelage is relatively short, with dense underfur mixed with longer guard hairs (colour is generally tawny brown or grey, but black, white and shades of ochre also occur). The underparts are usually paler than the rest of the body. The tail is generally bushy, often with a white tip and a darker, bristly patch covering the dorsal supracaudal scent gland near the root.

The facial region of the typical canid skull is elongated (although relatively shorter in *Canis* than in *Vulpes* and the South American *Pseudalopex*), with wide zygomatic arches and bony orbits that do not form a complete ring (Clutton-Brock *et al.* 1976). The temporal ridges are sometimes united in a sagittal crest. The auditory bullae are relatively large. Powerful jaw-closing muscles are adaptations for seizing, biting and holding prey. A complex cerebral cortex indicates that these carnivores are intelligent. The characteristic dental formula for the family is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/3} = 42$, although the Bat-eared Fox *Otocyon megalotis* departs from this pattern with 46–50 teeth. The shearing carnassial teeth (P^4/M_1) and crushing molars are well developed and the largest teeth in all species, except *Otocyon* (where they are molariform and no larger than the rest). The canine teeth are long and sharply pointed in all species. All canids have excellent senses of smell and hearing, with sight being less acute, although good.

The Canidae are cursorial, running on their toes or the small palmar pad (i.e. digitigrade), with long, slender limbs, compact feet with four functional toes and blunt, non-retractable, claws. A vestigial fifth toe (pollex or dew-claw) on the front feet occurs on all except the African Wild Dog *Lycaon pictus*. Other adaptations to running include fusion of scaphoid and lunar bones in the wrist, and locking of radius and ulna in the front leg to restrict rotation. Caecum always present, coiled into an S-shape.

Male canids have a well-developed grooved penis bone (baculum) and there is a copulatory tie during mating that can last up to an hour or more. This mechanism involves the pair facing away from each other, with the consequence that the blood trapped in the engorged

penis prevents withdrawal. Wild canids usually reach sexual maturity at one year old, and reproduce once annually (gestation lasts approximately nine weeks). However, social suppression of reproduction is common, so reproduction is often delayed and in larger species first reproduction is often after two years. Females have 6–16 nipples and have their young in underground dens. Litter-sizes typically range from 2 to 13; African Wild Dogs, for example, have very large litter-sizes, averaging 10–11, and occasionally as large as 21.

Although canids evolved in relatively open spaces, today they occur in all major African habitats, spanning tropical forests, woodland, savanna, deserts, mountains and afroalpine heathlands. The family is characterized by a great flexibility of diet, opportunistic and adaptable behaviour, and complex social organization with much within- and between-species variation. Most of the smaller species are opportunistic omnivores, eating anything from mammals to birds, reptiles, insects, fruit and carrion. Larger, group-living species may be more strictly carnivorous, preying on medium to large-sized mammals. All canids will feed on some carrion and vegetable matter. Several species – most notably in Africa, jackals and African Wild Dogs (although attitudes to the latter are changing) – are considered pests due to predation on livestock and game species.

Myology showing masticatory muscles and teeth in: African Wild Dog *Lycaon pictus* (wounding bite) (top); Side-striped Jackal *Canis adustus* (firm, puncturing grip) (centre); Bat-eared Fox *Otocyon megalotis* (rapid champing) (bottom).

From solitary to very social, most smaller canids live as territorial pairs (a relatively rare system amongst mammals as a whole) or small family groups, while the larger species are typically, but not invariably, pack hunters (Macdonald & Sillero-Zubiri 2004). Many of the smaller canids are nocturnal, whereas most of the social species are diurnal. Some species hunt in packs, whereas the Ethiopian Wolf *Canis simensis* hunts solitarily but also lives in groups. Benefits of living in groups besides pack hunting include cooperative defence of territories, monopoly of large carcasses and communal care and protection of offspring.

There is a tendency across the family for social system to vary with body size, such that where smaller species form groups these tend to include a dominant pair and female helpers and for dispersal to be male-biased, whereas amongst larger species the tendency is for dispersal to be female-biased and for groups to contain a preponderance of male helpers. In intermediate-sized canids, such as jackals, there is an approximately equal sex ratio of helpers. Scent-marking with both urine and faeces, often aloft visually conspicuous objects (such as tussocks of vegetation) and at trail junctions, is ubiquitous amongst canids – in the case of Ethiopian Wolves territorial border patrols are associated with intensive scent-marking.

Claudio Sillero-Zubiri & David W. Macdonald

GENUS *Canis* Jackals, Wolves

Canis Linnaeus, 1758. Syst. Nat., 10th edn, 1: 38.

Canis is a polytypic genus, comprising six or seven wild species depending on whether the Red Wolf *Canis rufus*, from North America, is considered a valid distinct species or not (Wozencraft 1993, 2005). Coyotes, jackals and wolves are distributed throughout North America, Europe, Asia and Africa, with the dingo (*Canis lupus dingo*) taken to Australasia by man during prehistoric times. Although canids typically favour open biotopes they occur in a wide range of habitats, adapting readily to forests, arid regions, high-altitude mountainous habitats and human-dominated environments.

The genus has generally been considered to include four species in Africa: Golden Jackal *Canis aureus*, Side-striped Jackal *C. adustus*, Black-backed Jackal *C. mesomelas* and Ethiopian Wolf *C. simensis*. The three species of jackals have wide distributions, utilizing most habitat types although absent from dense tropical forests. In contrast, the Ethiopian Wolf is confined to afroalpine grasslands and heathlands in the Ethiopian Highlands. The Grey Wolf is present in the Sinai Desert, Egypt, but has not typically been considered as a species occurring on the African continent. However, several authors have proposed that the taxon *C. aureus lupaster*, present in arid areas of Egypt and Libya (Osborn & Helmy 1980), may actually represent a small Grey Wolf rather than a large jackal (Ferguson 1981; and see Qumsiyeh 1996, Ferguson 2002). Recent genetic data also indicate that *C. a. lupaster* represents an ancient wolf lineage, which most likely colonized Africa prior to the northern hemisphere radiation (Rueness *et al.* 2011). The latter authors detected individuals at two localities in the Ethiopian Highlands, some 2500 km south of

the known distribution, an indication that the taxon may be more widely distributed. An observation in Eritrea may also represent a Grey Wolf (Tiwari & Sillero-Zubiri 2004). The current treatment is cognisant of these recent findings, but as this research became available at the time of going to press, only four species in the genus are profiled here.

Members of the genus *Canis* are medium-sized carnivores (HB varies from 65–140 cm, body mass 8–62 kg), well adapted to a cursorial way of life, with a relatively tall body and long limbs, and feet compact, with four functional toes. Members look alike, their heads being characteristically triangular with a conical muzzle and triangular ears. The pelage of all species is relatively short, with dense underfur mixed with longer guard hairs. The tail is bushy, broadest at its middle, and shorter than half of body length; a darker, bristly patch covers the supracaudal gland, of which the odour is, to the human nose, generally faint and somewhat sweet. They have interdigital glands whose function is unknown, as is that of the well-developed anal sacs, and all use urine and faeces for communication, including in the context of territoriality. Females have 8–10 nipples.

The dental formula is typically canid (although the lower third molar is sometimes absent in the Ethiopian Wolf), with short and heavy canines and upper carnassials highly developed; the upper incisors are predominantly lobed. The skull is heavy set with an elevated frontal region, large frontal sinuses and temporal ridges that are close together, united in a sagittal crest. The facial region of the

skull is relatively shorter than in *Vulpes* and *Pseudalopex*, except in the Ethiopian Wolf (Clutton-Brock *et al.* 1976). The latter had initially been placed in a separate genus or subgenus *Simenia* (Allen 1939), but morphological and genetic analysis places it unambiguously within *Canis* (Clutton-Brock *et al.* 1976, Gottelli *et al.* 1994). Hybridization has been recorded in the wild between Ethiopian Wolves and domestic dogs (Gottelli *et al.* 1994), suggesting a recent common ancestor for this group.

Reproduction in *Canis* is generally monopolized by dominant ♀♀, and non-breeding individuals of both sexes may act as helpers (although evidence that their contribution increases survival of the pups is surprisingly equivocal for the Ethiopian Wolf, although compelling for Black-backed and Golden Jackals). There is evidence of infanticide by dominant ♀♀, of allosuckling and of spontaneous lactation (associated with pseudopregnancy). The sociality in *Canis* species is conspicuously intricate, and variable between species, populations and individuals. The fundamental social unit is the

monogamous pair, but delayed dispersal of young (sometimes indefinitely) leads to the development of groups that, in some cases, become both large and structured. The most ubiquitous element of cooperation in these societies is in care of the young, but cooperative hunting and defence of resources are well documented, as is cooperative territorial defence.

While jackals have a generalist diet of medium and small-size mammals, invertebrates and fruits, Ethiopian Wolves have evolved into afroalpine specialists, existing almost exclusively on a diet of small mammals. The considerable similarity between all *Canis* species may underlie the intensity of intra-guild aggression between them: larger species tend to harass smaller ones throughout the family (and indeed throughout the order Carnivora), with the interesting exception that Black-backed Jackals have been reported as dominating the slightly larger sympatric Side-striped Jackal.

Claudio Sillero-Zubiri & David W. Macdonald

Canis adustus SIDE-STRIPED JACKAL

Fr. Chacal à flancs rayés; Ger. Streifenschakal

Canis adustus Sundevall, 1847. Ofv. K. Svenska Vet.-Akad. Forhandl. Stockholm 1846, 3: 121 [1847].
'Caffraria Interiore'; fixed by Sclater (1900) as 'Magaliesberg' [South Africa].

Side-striped Jackal *Canis adustus*.

Taxonomy Allen (1939) listed seven subspecies from the continent, Coetsee (1977) reduced this to five, while Kingdon (1997) recognizes only three (*C. a. adustus* from southern Africa, *C. a. lateralis* from Equatorial Africa and *C. a. kaffensis* from Ethiopia and Somalia) but without comment. Many authorities have pointed out that, as with Black-backed Jackal *C. mesomelas*, subspecies are hard to distinguish (e.g. Schouteden 1945), and the differences may be a consequence of individual variation (Ansell 1960a, Rosevear 1974, Kingdon 1997). None is recognized here, pending a revision of subspecies classification. Synonyms: *bweha*, *centralis*, *holubi*, *kaffensis*, *lateralis*, *notatus*, *studerii*, *wunderlichi*. Chromosome number: $2n = 78$ (Wayne 1993).

Description Medium-sized canid, grizzled, brown-grey to buff-grey, with white side-stripe half-way up the flanks, and distinctive white tip to tail (sometimes absent). Coat thick, long on back and neck and fluffy on chest, throat and underside. Underfur dark, overlaid by light beige or buff guard hairs. Head grizzled buff-grey; muzzle dark grey with black nose. Ears blackish-grey behind; considerably smaller in proportion to the head than those of other jackals. Back darker in colour (almost black in some animals) than underside and chest, while flanks are marked by white stripes running from elbow to hip with black lower margins. The boldness of markings, particularly flank-stripes, varies between individuals; those of juveniles less well defined than those of adults. Legs are tinged rufous-brown. Tail bushy and may be fluffed out when the animal is threatened or during intra-specific agonistic encounters; it is predominantly black and almost always bears the distinctive white tip (occasionally absent; see Rosevear 1974). Five digits on forefeet; four on hind. First digits on the front feet carry the dew-claw, and is situated far back on the plantar pad, not marking in the spoor. Claws between 15 and 20 mm long and dog-like (Skinner & Chimimba 2005). Two pairs of nipples.

Skull is similar to the Black-backed Jackal, but longer and less robust, with a noticeably narrower and longer rostrum. Elongation of rostrum is evident when the breadth at P^3 is considered relative to the distance from the back of this tooth to the incisors and is compared in the two species: in the Black-backed Jackal the ratio is about 31/42 or 74%, as opposed to about 28/55 or 51% in the Side-striped Jackal (Skinner & Chimimba 2005). Sagittal crest much better defined, and zygomatic arches of lighter build. Interparietal crest only slightly developed, and the bullae are smaller and flatter (Clutton-Brock *et al.* 1976). Canines are longer and more curved, but outer upper incisors not as large or robust as in the Black-

Lateral, palatal and dorsal views of skull of Side-striped Jackal *Canis adustus*.

backed Jackal. As a result of elongation of the rostrum, third upper premolar lies almost in line with the others and not at an angle as in the Black-backed Jackal (Skinner & Chimimba 2005). Permanent dentition starts erupting at 4–5 months. Relative pulp cavity width of the canine can be used to distinguish young adults from mature adults, but is of no value in determining age after one year (Bingham & Purchase 2003).

Geographic Variation Ansell (1960a) and Rosevear (1974) both commented on the great deal of individual variation in pelage colour within the species, and this has contributed to much confusion in apparent geographic variation; the form *centralis* from Cameroon and Central African Republic was apparently noteworthy for its very light ground colour.

Similar Species

Canis mesomelas. Sympatric in parts of eastern and southern Africa; in SW Angola, they appear to have a parapatric distribution (Crawford-Cabral 1993a). Characterized by a prominent dark 'saddle' and black-tipped tail, as well as reddish flanks and limbs; ears reddish-brown behind; lacks white-tipped tail characteristic of the Side-striped Jackal (and see Description above for notes on skull).

C. aureus. Sympatric in parts of East Africa and the Sahelian regions. Golden coat colour, and cream-coloured underparts; ears golden-brown behind; lacks white-tipped tail.

Distribution Endemic to Africa; distributed over much of sub-Saharan Africa, from Gambia and Senegal through the Sahelian regions of West Africa to the Central African Republic, Sudan, Ethiopia and Somalia, southwards into southern Africa, being absent or marginally distributed in the more arid westerly regions of southern Africa (Rosevear 1974, Kingdon 1977, Grubb *et al.* 1998, Skinner & Chimimba 2005). Distribution broadly coincides with broadleaved guinea woodland savannas, especially miombo (*Brachystegia*) woodland of central and southern Africa. In southern part of its range occurs marginally in NE KwaZulu–Natal (South Africa), at an altitude below 100 m, this marking its most southern

Canis adustus

occurrence on the continent (Rowe-Rowe 1992a). Also occurs occasionally in neighbouring lowveld regions of Swaziland, but is more common in the south (Monadjem 1998).

Habitat Found in a wide range of habitats. Distribution tends to coincide with the well-watered woodlands and woodland mosaics of central and West Africa (Coe & Skinner 1993, Skinner & Chimimba 2005). Tends to avoid areas of dry open savanna (areas often favoured by Black-backed Jackals), and is absent from the equatorial forest zone, but may enter in the wake of human cultivation (Kingdon 1997). Other habitats used include areas of abandoned cultivation, marshes and montane habitats up to 2700 m (Kingdon 1977, Estes 1991, Yalden *et al.* 1996). Side-striped Jackals frequently occur near rural dwellings and farm buildings, and penetrate peri-urban and urban areas (Skinner & Chimimba 2005).

Habitat use by the Side-striped Jackal varies considerably between different areas, dependent partly on habitat availability, but often more importantly, on the presence or absence of other jackal species. When allopatric, it occupies a wide range of habitats and appears especially to use grassland (as in Niokolo-Koba N. P., Senegal [C. Sillero-Zubiri pers. comm.], Rwenzori Mountains N. P., Uganda [Kingdon 1977] and NE KwaZulu–Natal [Rowe-Rowe 1992a]), but also savanna woodland on raised plateaux in Niokolo-Koba N. P. (Sillero-Zubiri *et al.* 1997). In Zambia it uses open woodland and grassland, avoiding forest (Ansell 1960a). Similarly, where this species is allopatric in N Zimbabwe, Atkinson (1997) found that grassland was used preferentially over woodland.

However, when it occurs in sympatry with other jackal species habitat is segregated. The Side-striped Jackal uses more thickly vegetated habitats, leaving open grassland and woodland to the other species. In Serengeti N. P., Tanzania it uses dense thicket and riverine habitats (Williams 1967, Wyman 1967, Kingdon 1977, Lamprecht 1978, Moehlman 1983, Estes 1991), with Black-backed Jackals using *Acacia* woodland and Golden Jackals using grassland; a similar

pattern occurred in Laikipia, Kenya (Fuller *et al.* 1989). In southern Africa, when occurring alongside the Black-backed Jackal, the Side-striped Jackal uses the dense vegetation of forest and river valleys and the Black-backed Jackal the open and lightly wooded areas (Pienaar 1969, Loveridge & Macdonald 2002, Skinner & Chimimba 2005). At least in W Zimbabwe, the mechanism for segregation between the two species is aggressive displacement of Side-striped Jackals by Black-backed Jackals (Loveridge & Macdonald 2002).

Abundance Generally common within its range in southern Africa. Rhodes *et al.* (1998) found that the resident population of territory-holding adults was 20–30 per 100 km² expanding to a breeding season peak of 80–120 jackals per 100 km² in N Zimbabwe. In W Zimbabwe (near Hwange N. P.) densities were approximately 54–79 per 100 km² expanding to as much as 97 per 100 km² in the breeding season (Macdonald *et al.* 2004). Ziegler *et al.* (2002) suggest that Side-striped Jackals are ‘rare in West Africa’, an observation that is borne out by the relatively low densities (7 per 100 km²) found in Niokolo-Koba N. P. (Galat *et al.* 1996, Sillero-Zubiri *et al.* 1997). The dietary flexibility of the Side-striped Jackal and its ability to co-exist with humans on the periphery of settlements and towns suggests that populations are only vulnerable in cases of extreme habitat modification, or intense disease epidemics.

Adaptations Like the Black-backed Jackal, this species is relatively unspecialized but well adapted anatomically and behaviourally for opportunism. Kingdon (1997) suggests that, in ecological terms, it is the tropical equivalent of the Red Fox *Vulpes vulpes*. The dentition is well suited to an omnivorous diet (Skinner & Chimimba 2005). The canines are long, curved and sharp-pointed, with a sharp ridge on their posterior surfaces. The upper outer incisors are canine-like, the carnassial shear well adapted for slicing, while the first and second upper molars are broad and developed for crushing. In comparison to the Black-backed Jackal, Side-striped Jackals have similar-shaped carnassials, and hence similar adaptation to carnivory; however, Side-striped Jackals have a larger grinding surface on their premolars and molars and are, therefore, better adapted to an omnivorous life-style (Van Valkenburgh 1991, Van Valkenburgh & Wayne 1994).

The Side-striped Jackal has smaller, more rounded ears than other jackals, which is the case with many forest-dwelling canid species,

such as the Bush Dog *Speothos venaticus* and the Small-eared Dog *Atelocynus microtus* of South America (Stains 1975). This suggests that the Side-striped Jackal is perhaps adapted to more mesic environments and the other jackal species to more arid regions.

The white tail tip of this species is possibly a ‘badge of nocturnal status’ (Kingdon 1977). The Red Fox and the White-tailed Mongoose *Ichneumia albicauda* also have white tail tips and correspondingly nocturnal habits. Macdonald (1987) suggests that a white tail flash may enhance tail signalling in nocturnal species. The white tail flash may also allow members of a foraging group to locate one another in the dark and avoid moving through areas from which food items have already been disturbed and gleaned by other group members (Loveridge 1999).

Foraging and Food Omnivorous, feeding on a wide array of items including small mammals, birds, reptiles, insects, carrion and vegetable matter (Smithers & Wilson 1979, Estes 1991, Atkinson *et al.* 2002a, Loveridge & Macdonald 2003). Their diet is very responsive to both seasonal and local variation in food availability. On commercial farmland in the Zimbabwe highveld, they eat mainly wild fruit (30%) and small (<1 kg) to medium-sized (>1 kg) mammals (27% and 23%, respectively), with the remainder of their diet comprising birds, invertebrates, cattle cake, grass and carrion (Atkinson *et al.* 2002a). In wildlife areas of W Zimbabwe, Side-striped Jackals feed largely on invertebrates during the wet season and small mammals up to the size of springhares *Pedetes* spp. during the dry months of the year.

Side-striped Jackals scavenge extensively from safari camp rubbish dumps and occasionally from large carnivore kills (although they are out-competed for this resource by Black-backed Jackals) (Loveridge & Macdonald 2003). In the Ngorongoro Crater, Estes (1991) recorded the species competing with Black-backed Jackals to catch Grant’s Gazelle *Nanger granti* fawns. Certain fruits (e.g. Mobola plum *Parinari curatelifolia*, wild fig *Ficus capensis* and waterberry *Syzygium guineense*) may be taken almost exclusively when in season (Smithers & Wilson 1979, Atkinson *et al.* 2002a).

As with Black-backed Jackals, this species is primarily nocturnal, with peaks in activity after sunset and before dawn (Loveridge & Macdonald 2003). Occasionally, they are seen active during the late afternoon in areas where they are not persecuted (Kingdon 1977). Side-striped Jackals feed solitarily, although in W Zimbabwe family groups have been observed foraging together on abundant invertebrate food resources (Loveridge 1999), and Estes (1991) mentions that as many as 12 have been counted at kills or scavenging offal outside towns. Similarly, groups have been observed scavenging from both Lion *Panthera leo* and Spotted Hyaena *Crocuta crocuta* kills in Liuwa Plains N. P., Zambia, with as many as 5–10 seen at any one time (G. Purchase pers. comm.).

As with other canids, this species exhibits extreme flexibility in its foraging strategies. Kingdon (1977) observed a captive, free-ranging individual bump vegetation with its body to dislodge invertebrates. A similar pattern of behaviour was observed in Hwange, Zimbabwe, where Side-striped Jackals ‘stamped’ the ground to disturb concealed grasshoppers (Loveridge 1999). Atkinson *et al.* (2002b) found that instead of searching for preferred foods, jackals in farmland tended to use the most seasonally abundant resources, moving through the agricultural landscape using an optimal foraging pathway (with fractal characteristics) for opportunistic use of spatially random

Side-striped Jackal *Canis adustus* facial details.

Side-striped Jackal *Canis adustus* action drawing.

and temporally variable resources. It is likely that this is a common foraging pattern in omnivorous medium-sized canids.

In all studies on the species, there is very little evidence for extensive predation on domestic stock (Shortridge 1934, Roberts 1951, Ansell 1960a, Smithers 1971, Smithers & Wilson 1979, Rowe-Rowe 1992a), or game larger than a baby antelope (Kingdon 1977, Estes 1991).

Social and Reproductive Behaviour Because their tendency to use wooded terrain makes it hard to confirm group sizes, Side-striped Jackals were at one time considered solitary; however, it is now known that they form social groups. As with other jackal species, the basis for the social system is the mated pair, which is known to be stable over several years. They may occasionally occur in family groups, or come together in feeding aggregations (though not as large as in Black-backed Jackals).

In game areas of W Zimbabwe, home-ranges varied from 0.2 km² in the hot dry season to 1.2 km² in the cold dry season, whereas in highveld farmland, they were seasonally stable and in excess of 4.0 km². In highveld farmland, territories are configured to encompass sufficient patches of grassland, where resources are most available, and the structure of the habitat mosaic appears an important factor. Pairs in N Zimbabwe used their home-range with a high degree of concordance, using the same areas with similar intensity and largely at the same times. The central core of each home-range is used exclusively by its occupants, but the peripheral third of the range may overlap widely with four or more neighbouring pairs; home-ranges overlapped by about 20% in highveld farmland and 33% in game areas (Atkinson 1997). In Hwange, Zimbabwe, at least four of five Side-striped Jackal territories included extra-pair members (up to five in one case, two of which were known to be between one and two years of age), and there is evidence for alloparental care in that young adults have been recorded returning to their natal home-ranges during the breeding season (Loveridge & Macdonald 2001).

Side-striped Jackals are not as vocal as other jackal species. The most obvious call is a series of staccato barks (an explosive 'bwaa'), which may be repeated for up to 10 minutes, usually in bouts of 13–17 barks over 30 seconds, with 4–5 seconds between bouts

(Loveridge 1999). These are often used as alarm/mobbing calls in the presence of Leopards *Panthera pardus*, and also during the breeding season where animals from neighbouring territories may answer calls. Side-striped Jackals do not howl, instead they have an 'owl-like hoot' (Kingdon 1977). This call was never heard in Hwange, Zimbabwe (A. Loveridge pers. obs.).

Pups are born in subterranean dens, often abandoned Aardvark *Orycteropus afer* holes or excavated termitaria that the ♀ modifies to her own requirements (Skinner & Chimimba 2005); the breeding chamber often has multiple entrances. Dens are sometimes used by the same pair over consecutive years (Kingdon 1977, A. Loveridge pers. obs.). During the early stages of pup growth, only the ♂ provisions the pups and the ♀, but after weaning both parents assist in rearing the young, returning at intervals of 2–3 hours through the night to feed the pups on food that is probably regurgitated (Moehlman 1979). The pups are aggressive towards each other, as evidenced by the degree of wounding seen.

Reproduction and Population Structure Reproduction can occur in the first year, with most mating occurring in July in Zimbabwe (Bingham & Purchase 2002, 2003). However, the breeding season is variable in different parts of Africa. In Zimbabwe pups are usually born in Sep and Oct, after a 57–60 day gestation period (Bingham & Purchase 2002, Skinner & Chimimba 2005); however, pups are born in Jun and Jul in Uganda, and Sep and Oct in S Kenya (Kingdon 1977) and Sep–Nov in Zambia (Ansell 1960a). Skinner & Chimimba (2005) report mean litter-sizes for Side-striped Jackals of 5.4 pups, and Bingham & Purchase (2002) give (from examination of foetuses and placental scars) a mean pre-birth litter-size of 5.8 (range 3–8). Perinatal litter loss is around 20% (Bingham & Purchase 2002) and Rhodes *et al.* (1998) estimate that only two per litter survive past six months. Lactation lasts about 10 weeks. Juveniles are probably independent before they are one year old and have been recorded dispersing up to 15 km (mean = 4.6 ± 3.51 km) (Loveridge & Macdonald 2001). As with Black-backed Jackals, longevity has been given as 10–13 years (Ginsberg & Macdonald 1990, Weigl 2005), but this is probably more representative of longevity in captivity, and Rhodes *et al.* (1998) suggest that the average life-span in the wild is probably closer to 3–4 years.

Predators, Parasites and Diseases Leopards are the only regular predator of the Side-striped Jackal, although it seems likely that other predators may take pups and young adults as they do with the other jackal species.

In Zimbabwe, seroprevalence of canine distemper virus, canine parvovirus and canine adenovirus (type 1) were 50%, 12.5% and 37.5%, respectively, in 22 free-ranging Side-striped Jackals sampled between 1990 and 1993 (Spencer *et al.* 1999); however, although jackals act as reservoirs for these diseases, susceptibility is not known. Side-striped Jackals, along with other jackal species, are vulnerable to rabies (Bingham & Foggin 1993, Bingham *et al.* 1999a, b), tick fever and sarcoptic mange (Kingdon 1977), for all of which they are known or suspected reservoirs and vectors for domestic dog infection. Computer simulations (Rhodes *et al.* 1998) suggest rabies can only persist in Side-striped Jackal populations where the density is very high – such as around towns – and that most rabies occurrence in Side-striped Jackals is a result of spillover from domestic dogs living on communally owned land. Side-striped Jackals can contract the disease from domestic dogs, conspecifics and other jackal species, although it appears that transmission of rabies cycles does not appear to occur from areas where Black-backed Jackals are the numerically dominant species to areas where Side-striped Jackals are prevalent (Bingham *et al.* 1999a).

Horak *et al.* (1987) collected the following parasites from a single Side-striped Jackal taken in Kruger N. P. in South Africa: *Amblyomma hebraeum*, *Haemaphysalis leachi* and *Rhipicephalus* spp. Ntiamoa-Baidu *et al.* (2005) recorded *Rhipicephalus sulcatus* and *Amblyomma variegatum* from jackals in Ghana.

Conservation IUCN Category: Least Concern. CITES: Not Listed.

Side-striped Jackals are persecuted primarily for their role in rabies transmission and their putative role as stock killers, which although unlikely to affect overall numbers may affect local abundance. In areas of high human population density, snaring may be the commonest cause of death in adults, and may account for as much as a third of adult deaths in such areas (Atkinson 1997, Atkinson & Loveridge 2004). Ziegler *et*

al. (2002) did not observe any Side-striped Jackals during a mammal survey in Upper Niger N. P., Guinea (where they have previously been recorded), perhaps because the level of illegal hunting is high. In towns and suburbs they may be run over by vehicles (Kingdon 1977). High reproductive productivity ensures this species is capable of rapid recovery following population crashes (Bingham & Purchase 2002). There may be some limited trade in jackal parts, because of their role in traditional practices and beliefs in parts of East Africa (Kingdon 1977), but this is not thought to be extensive. This species occurs in a number of well-managed protected areas throughout its range, including Niokolo-Koba N. P. (Senegal), Comoé N. P. (Côte d'Ivoire), Queen Elizabeth N. P. (Uganda), Serengeti N. P. (Tanzania), Hwange N. P. (Zimbabwe) and Kruger N. P. (South Africa), and seems well able to exploit semi-urban and urban habitats (Atkinson & Loveridge 2004).

Measurements

Canis adustus

TL (♂ ♂): 1082 (960–1165) mm, n = 50

TL (♀ ♀): 1075 (1000–1170) mm, n = 50

T (♂ ♂): 361 (305–390) mm, n = 50

T (♀ ♀): 354 (310–410) mm, n = 50

HF c.u. (♂ ♂): 172 (160–190) mm, n = 50

HF c.u. (♀ ♀): 168 (153–178) mm, n = 50

E (♂ ♂): 88 (80–97) mm, n = 50

E (♀ ♀): 86 (80–95) mm, n = 50

WT (♂ ♂): 9.4 (7.3–12.0) kg, n = 50

WT (♀ ♀): 8.3 (7.3–10.0) kg, n = 50

Zimbabwe (Smithers 1983)

Canis aureus GOLDEN JACKAL (ASIATIC JACKAL, COMMON JACKAL)

Fr. Le Chacal commun; Ger. Goldschakal

Canis aureus Linnaeus, 1758. Syst. Nat., 10th edn, 1: 40 'oriente';
restricted by Thomas (1911) to 'Benna Mountains, Laristan, Southern Persia' [Iran].

Golden Jackal *Canis aureus*
(in defensive posture).

Taxonomy Some 12 subspecies have been distinguished across the range (Allen 1939, Ellerman & Morrison-Scott 1951), and Coetzee (1977) listed seven for Africa, including the East African population, *C. aureus bea*, which is almost discrete (and see Heller 1914, Swynnerton & Hayman 1950). Ferguson (1981) has suggested that the taxon *C. aureus lupaster*, present in arid areas of Egypt and Libya (Osborn & Helmy 1980) may actually represent a small Grey Wolf *Canis lupus* rather than a large jackal. It is retained here as a form of the Golden Jackal following Wozencraft (2005) (see also Qumsiyeh 1996, Ferguson 2002). However, recent genetic data suggest that *C. a. lupaster* represents an ancient wolf lineage, which most likely colonized Africa prior to the northern hemisphere radiation (Rueness *et al.* 2011). The latter authors detected individuals at two localities in the Ethiopian Highlands, some 2500 km south of the known distribution, an indication that the taxon

may be more widely distributed than thought. Synonyms: *algirensis*, *anthus*, *bea*, *doederleini*, *grayi*, *hagenbacki*, *lamperti*, *lupaster*, *maroccanus*, *mengesi*, *nubianus*, *riparius*, *sacer*, *senegalensis*, *somalicus*, *soudanicus*, *studer*, *thooides*, *tripolitanus*, *variegatus*. Chromosome number: $2n = 78$ (Wurster & Benirschke 1968).

Description Considered to be the most typical representative of the genus *Canis*, without any outstanding features or specialization (Clutton-Brock *et al.* 1976), the Golden Jackal is medium-sized, with ears upright, legs relatively long and feet slender with small pads. Basic coat colour is golden but varies from pale creamy-yellow to a dark tawny hue on a seasonal basis. Pelage on the back is often a mixture of black, brown and white hairs, such that they can appear to have a dark saddle similar to the Black-backed Jackal *C. mesomelas*. Belly and underparts are a lighter pale ginger to cream. Unique lighter markings on throat and chest (Macdonald 1979a) and facial and body scars (Moehlman 1983) make it possible to differentiate individuals in a population. Tail is bushy with tan to black tip. Approximately 12% difference in body weight between sexes, with mean female body mass of 5.8 kg and mean male body mass 6.6 kg (Moehlman & Hofer 1997). Females have four pairs of nipples.

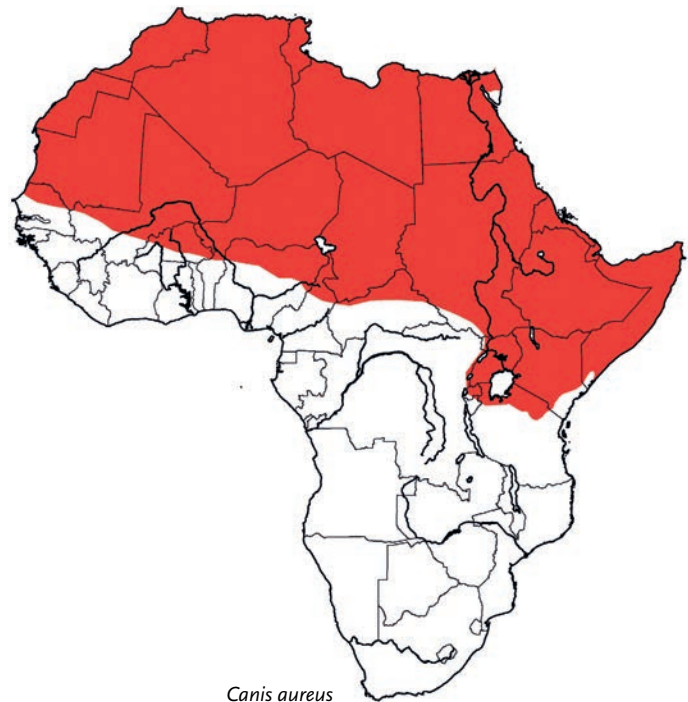

Lateral and palatal views of skull of Golden Jackal *Canis aureus*.

Skull has: well-developed, high-crowned teeth; interparietal crest present; facial region somewhat short; and often a well-marked cingulum on labial side of upper first molar. In these respects, skull is more similar to that of the Coyote *C. latrans* or a small Grey Wolf than that of the Black-backed Jackal, Side-striped Jackal *C. adustus*, or Ethiopian Wolf *C. simensis* (Clutton-Brock *et al.* 1976).

Geographic Variation Jackals inhabiting rocky, mountainous terrain may have a greyer coat shade (Sheldon 1992), and melanistic and piebald forms are sometimes reported (Muller-Using 1975, Jerdon 1984, P. Moehlman pers. obs.).

Similar Species

Canis mesomelas. Sympatric in East Africa. Distinguished by the smaller size and shape of its skull and, usually, a prominent dark saddle (the latter sometimes apparent in the Golden Jackal though usually not as prominent), and a distinct rufous tinge to flanks and legs.

Canis aureus

- C. adustus*. Sympatric in parts of East Africa and the Sahelian regions. Relatively shorter ears, a pale side stripe and a white-tipped tail; interparietal crest poorly developed; cheekteeth less high-crowned.
- C. simensis*. Ethiopian Highlands only. Larger, with longer legs; distinctive reddish coat, white underparts, throat, chest and tail markings.

Distribution Occurs across much of north-east and North Africa, from Senegal (though there is no confirmed record from Gambia; see Grubb *et al.* 1998), Mauritania, Morocco (including Western Sahara), and Algeria in the west through Libya, Niger, N Nigeria and Chad, to Egypt, the Horn of Africa (including Ethiopia, Djibouti, Eritrea and Somalia) and south to Kenya and N Tanzania. A record from Guinea-Bissau (Frade & Silva 1980) is the result of confusion with the Side-striped Jackal (Crawford-Cabral & Esteves 1989).

Extralimital to Africa, ranges from the Arabian Peninsula into western Europe to Austria and Bulgaria, and then continues eastwards into Turkey, Syria, Iraq, Iran, central Asia, the entire Indian sub-continent, then east and south to Sri Lanka, Myanmar, Thailand and parts of Indo-China (Jhala & Moehlman 2004).

Habitat Due to tolerance of dry habitats and omnivorous diet, the Golden Jackal can inhabit a wide variety of habitats, from the Sahara Desert (except the most hyper-arid parts) and Sahel to the evergreen forests of Myanmar and Thailand. In Africa, typically prefers semi-desert, short to medium grasslands and savannas, and has been recorded at 3800 m altitude in the Bale Mts of Ethiopia (Sillero-Zubiri 1996, Yalden *et al.* 1996).

Abundance Fairly common throughout its range. High densities are observed in areas with abundant food and cover. In Serengeti N. P. densities can be as high as two adults per km² (Moehlman 1983, 1986, 1989).

Adaptations The medium body size is energetically flexible and allows Golden Jackals to live off small prey items such as invertebrates, rodents, reptiles and even wild berries. They can trot for long distances in search of food, and are reported to have the ability to forego water, obtaining much of their moisture requirements from their food (Kingdon 1977); Golden Jackals have been observed on Pirotan I., in the Gulf of Kutch, India, where there is no fresh water (Y. Jhala pers. comm.).

Foraging and Food Golden Jackals are omnivorous and opportunistic foragers, and their diet varies according to season and habitat (Wyman 1967). In Serengeti N. P., although they consume invertebrates and fruit, over 60% of their diet is vertebrates and they will kill rodents (particularly gerbils; see Senzota 1990), lizards, snakes, birds (from quail to flamingos), hares, Thomson's Gazelle *Eudorcas thomsonii* and Grant's Gazelle *Nanger granti* (Wyman 1967, Moehlman 1983, 1986, 1989). They also scavenge the carcasses of larger herbivores, such as Common Wildebeest *Connochaetes taurinus*, Plains Zebra *Equus quagga* and African Buffalo *Syncerus caffer*. In C Niger, an analysis of scat samples ($n = 143$) showed that vegetable matter (including various species of grasses, *Acacia* seeds and *Cordia sinensis* and *Ziziphus mauritania* fruit) and invertebrates (ants, dung beetles, grasshoppers and scorpions) constituted the main identifiable items in the diet. Several rodent species, including gerbils, spiny mice and the Striped Ground Squirrel *Xerus erythropus*, were recorded, as were the remains of hares. Bird remains were recorded in 23.7% of scats, and in one sample, eggshell fragments were recovered. The remains of an unidentified snake were also found in one scat (McShane & Grettenberger 1984). Jackals have been recorded feeding on desert snails (*Eremica desertorum*) in Egypt, and digging freshwater snails (*Pila wernerei*) out of cracks in a mud pan in NE Sudan (Osborn & Helmy 1980 and references therein).

Single individuals typically hunt smaller prey such as rodents and birds, using their hearing to locate rodents in the grass and then pouncing on them by leaping through the air, or digging out gerbils from their burrows. However, individual animals will also hunt Thomson's Gazelle fawns. Golden Jackals have been observed to hunt young, old and infirm ungulates that are sometimes 4–5 times their own body weight (Van Lawick & Van Lawick-Goodall 1970, Eisenberg & Lockhart 1972). Admasu *et al.* (2004a) suggest that Golden Jackals in Bale may be more solitary than elsewhere in the range, with animals having been observed foraging alone on 87% of occasions. This is likely because food resources were widely dispersed and rarely concentrated enough for jackals to forage in groups (Admasu *et al.* 2004a). In Serengeti N. P., mated pairs will hunt cooperatively and regularly kill Thomson Gazelle fawns and occasionally adults; pairs have a higher kill rate than individuals (Wyman 1967, Kruuk 1972, Rosevear 1974). Indeed, cooperative hunting permits them to harvest much larger prey in areas where available. In some areas, particularly where food resources are clumped, aggregations of jackals may occur. Van Lawick & Van Lawick-Goodall (1970) reported 14 jackals on a carcass in Ngorongoro, and aggregations of between five and 18 jackals have been sighted scavenging on carcasses of large ungulates in India (Y. Jhala pers. obs.). Golden Jackals will cache excess food.

Golden Jackals are known to predate on domestic livestock. In C Niger, 17 of 37 herders reported losses of livestock to jackals, with an average of 1.7 goats and 0.24 sheep reported lost each year. Most

Golden Jackal *Canis aureus* facial detail.

predation was reported to occur during the day, when animals were unattended and away from camp, though some also occurred at night (McShane & Grettenberger 1984). In Egypt, jackals living near the Nile Valley and Delta are reputed to feed on various cultivated crops and fruit, as well as to prey upon domestic animals (Osborn & Helmy 1980).

Social and Reproductive Behaviour Social organization is extremely flexible depending on demography and food resources (Macdonald 1979a, Moehlman 1983, 1986, 1989, Fuller *et al.* 1989, Moehlman & Hofer 1997, Admasu *et al.* 2004a). The basic social unit is the breeding pair. Some offspring from the previous year's litter may remain with the parents and help to raise the current litter of pups (Moehlman 1983, 1986, 1989). In Tanzania, Golden Jackals usually form long-term pair bonds, both members of which mark and defend their territories, hunt together, share food and cooperatively rear the young (Moehlman 1983, 1986, 1989). Moehlman & Hofer (1997) give average group size as 2.5 (Serengeti N. P., Tanzania), similar to average group size (3; $n = 7$) in Velavadar N. P., India (Y. Jhala pers. obs.).

In Serengeti N. P., Golden Jackals (Moehlman 1983) maintain year-round exclusive territories of 0.5–7.0 km² in size (Moehlman 1983) and 2–5 km² in Ngorongoro (Van Lawick & Van Lawick-Goodall 1970), but will make excursions beyond these territorial boundaries to gain access to fresh carcasses. In Algeria, Khidas (1990) recorded seasonal territories as small as 0.39 km². Home-range size may depend on the age of individuals, demography and the distribution of food resources. For example, home-range size for an adult pair in *Acacia* woodland in Kenya was 2.4 km² and for two juvenile ♀♀, 5.6 and 21.7 km² (Fuller *et al.* 1989), while range size over a 16-month period in the Bale Mountains of Ethiopia varied from 7.9 to 48.2 km² for adults and from 24.2 to 64.8 km² for subadults (Admasu *et al.* 2004a). Home-ranges of individuals within a social group tend to overlap, as reported by Van Lawick & Van Lawick-Goodall (1970), Khidas (1990) and Admasu *et al.* (2004a).

In Serengeti N. P. only the territorial pair does raised-leg urinations. These urination scent-marks are done in tandem on the same spot as the pair forage in their territory. Such scent-marks are considered to play an important role in territorial defence (Rosevear 1974). Affiliative behaviours like greeting ceremonies, grooming and group vocalizations are common in jackal social interactions (Van Lawick & Van Lawick-Goodall 1970, Golani & Keller 1975). Vocalization consists of a complex howl repertoire beginning with 2–3 simple low-pitch howls and culminating in a high-pitched staccato of calls. In Serengeti N. P. individuals give reciprocal howls

to locate their mates and family members. Families also occasionally group howl in response to neighbouring family howls.

In the Serengeti mating typically occurs from Oct to Dec (Moehlman 1983, 1986), and involves a copulatory tie that lasts for several minutes (Golani & Mendelssohn 1971, Golani & Keller 1975). Young are born in dens, which can take the form of existing earthen burrows of Aardvark *Oryzomys afer* or warthogs *Phacochoerus* spp., or rivulets, gullies, road embankments, drainage pipes and other man-made structures. Earthen dens may have 1–3 openings and are typically about 2–3 m long and 0.5–1 m deep. Young pups could be moved from 2–4 dens during their first 14 weeks of life (Jhala & Moehlman 2004).

In the Serengeti both parents and ‘helpers’ – offspring from previous litters – provision and guard the new pups. The ♂ also feeds his mate during her pregnancy and both the ♂ and the ‘helpers’ provision the ♀ during the period of lactation (Moehlman 1983, 1986, 1989, Moehlman & Hofer 1997). The ‘helpers’ are the offspring of the same ‘behavioural’ parents and thus may be full siblings to the young pups that they are provisioning and guarding. However, the paternity of the pups has not been checked genetically. The presence of helpers correlates with a higher pup survival (Moehlman 1986).

Reproduction and Population Structure In the Serengeti, pups may be born in most months of the year, but usually from Dec to Mar, coinciding with the wet season and the arrival of the migrating herds of Common Wildebeest, Plains Zebra and Thomson’s Gazelle (Moehlman 1983, 1986, 1989). In Egypt, wild-born litters have been recorded in Mar, Apr and May (Flower 1932). Females are typically monoestrous, but there is evidence in Tanzania of multiple litters (P. Moehlman pers. obs.). Gestation lasts about 63 days (Sheldon 1992). Litter-size ranges from 1 to 9, and Moehlman & Hofer (1997) give mean litter-size as 5.7. In Tanzania, Wyman (1967) reported an average of two pups emerging from the den at three weeks of age. Pups are born blind and their eyes open at approximately nine days and their teeth erupt at 11 days after birth (Moehlman & Hofer 1997). Lactation usually lasts for 8–10 weeks. Maximum longevity recorded in Serengeti N. P. is about 14 years (Moehlman & Hofer 1997).

Predators, Parasites and Diseases In East Africa, Spotted Hyaenas *Crocuta crocuta* have been observed to kill and feed on Golden Jackals (Kruuk 1972, Kingdon 1977). In Serengeti N. P., Golden Jackals will give a ‘warning yowl’ when Spotted Hyaenas approach their dens. The adult jackals will then chase the hyaenas and bite them on the rump/genitals.

The co-existence of three sympatric species of jackals (Golden, Black-backed and Side-striped) in East Africa is possibly due to resource partitioning in terms of foraging ecology and spatial and temporal habitat utilization and the high relative diversity of prey and predators in Africa (Fuller *et al.* 1989, Wayne *et al.* 1989b). Jackals often scavenge off the kills of larger predators like Lions *Panthera leo*, Leopards *P. pardus*, and Spotted Hyaenas (Van Lawick & Van Lawick-Goodall 1970, Kruuk 1972, Moehlman 1986).

In Serengeti N. P. blood serology of three animals had positive titres to canine parvovirus ($n = 1$), canine adenovirus ($n = 2$), canine coronavirus ($n = 3$) and canine herpesvirus ($n = 2$). All three individuals had negative titres to rabies virus, canine distemper, canine brucellosis, leptospirosis, rinderpest, African horse sickness

and Rift Valley fever (W. B. Karesh pers. comm.). During the 1994–95 distemper outbreak in the Serengeti, a single jackal tested positive for canine distemper (Roelke-Parker *et al.* 1996).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although the Golden Jackal is present in a number of protected areas across its wide range, including the Serengeti–Masai Mara–Ngorongoro complex, there is evidence that some populations are undergoing declines, as traditional land use practices (such as livestock rearing and dry farming) that were conducive to the survival of jackals and other wildlife, are being steadily replaced by industrialization and intensive agriculture (Jhala & Moehlman 2004). As with other jackal species, they are sometimes killed in indiscriminate predator control programmes.

Measurements

Canis aureus

HB: 872 (822–893) mm, $n = 9$

T: 312 (290–347) mm, $n = 9$

‘Vorgebirge der guten Hofnung’ [‘Cape of Good Hope’, South Africa].

Black-backed Jackal *Canis mesomelas*.

Taxonomy As many as six (Allen 1939) and five (Coetzee 1977) subspecies have been recognized. Meester *et al.* (1986) assigned all southern African material to the nominate subspecies. Considering the regional variation in the species, recognition of only two, geographically isolated, subspecies is followed here (and see Kingdon 1997, Walton & Joly 2003). Synonyms: *achrotes*, *arenarum*, *elgonae*, *mcmillani*, *schmidtii*, *variegatoides*. Chromosome number: $2n = 78$, with all but two chromosomes acrocentric (Wallace 1977).

Description Fox-like in appearance, weighing between 6 and 13 kg (see Measurements). Diagnostic features are dark saddle, black, bushy tail and reddish head, flanks and limbs. Muzzle pointed with black nose. In common with other arid-adapted carnivores, ears are relatively large and constantly mobile. Flanks, legs, ears and head tawny to rufous-brown, belly and front of neck pale brown to beige. A black stripe mid-way up each flank slopes up obliquely from behind shoulder to top of rump; dark saddle is broadest at shoulders and tapers to narrow point at base of the tail. Anterior to this stripe, behind the shoulder, is a small vertical stripe, diffuse in some individuals. Above side markings, the back is interspersed with black and white hairs giving an overall silver appearance in mature animals (hence the alternative name Silver-backed Jackal). Juveniles and subadults have similar markings but are drabber and only gain mature pelage at around two years of age. Tail dark brown to black with distinctive black subcaudal marking; tip of tail black. Markings, especially side- and shoulder-stripes, are unique to each individual and can be used as features for individual identification. In the drier west and Namib coast in southern Africa winter coat is deep reddish-brown (particularly so in ♂♂). Distinctive side markings are likely to be signals to conspecifics, flanks being a focus for behaviours such as side-slammings (a common behaviour between dominant and subordinate

canids). Albinism may occur. Five digits on front feet; the first carries the dew-claw and is set well back from the remainder, not marking in the spoor; the hindfoot has four digits. The claws are relatively short, measuring about 150 mm over the curve. Black-backed Jackals have 6–8 nipples (Smithers 1971). Little obvious sexual dimorphism when seen in the field (Moehlman 1983, A. J. Loveridge pers. obs.) although ♂ is in fact slightly larger and heavier than ♀ (Smithers 1971, Rowe-Rowe 1978a, Stuart 1981; and see Measurements).

Skull elongated, braincase pear-shaped, rostrum narrow, supraoccipital crest well developed, bullae rounded and paroccipital processes fused to back of bullae; zygomatic arches broad and well developed; postorbital bars incomplete represented by blunt processes on the zygoma and frontals. Overall, skull and dentition more robust than in Side-striped Jackal *C. adustus* and Golden Jackal *C. aureus*, with outer upper incisors larger, and more pointed and caniniform.

Geographic Variation*C. m. mesomelas*: southern Africa.*C. m. schmidtii*: East Africa and Horn of Africa.

In southern Africa, slight variation in body size and weight has been recorded, with jackals from the former Cape Province, for example, slightly larger than those collected from Zimbabwe (see Measurements). In addition, Rautenbach (1982) found evidence of a clinal increase southwards in mean greatest skull length and suggested this could apply throughout the range of the species in southern Africa. The data of Stuart (1981) from the former Cape Province lend support to this finding. According to Van Valkenburgh & Wayne (1994), skulls of jackals from East Africa are shorter in total length and wider than skulls from southern Africa, and, likewise, animals in East Africa have longer and narrower carnassials and smaller upper and lower molar grinding areas than do animals in southern Africa. Sexual dimorphism also appears less evident, at least in male : female skull length ratio. Van Valkenburgh & Wayne (1994) suggested this was evidence of significant character displacement in East Africa where the species' range overlaps with that of both the Golden and Side-striped Jackal, and that this species is less sexually dimorphic when sympatric with other jackal species than when allopatric (and see Loveridge 1999).

Similar Species

Canis adustus. Lacks dark saddle and rich reddish colour of the flanks and limbs; tail not uniformly black, and with a white tip; white stripe along side, from shoulder to top of rump. Sympatric in parts of East Africa (see also Yalden *et al.* 1980), NE Namibia, N Botswana, C and S Zimbabwe, Mozambique, NE Limpopo Province and E Mpumalanga (South Africa), Swaziland and NE KwaZulu-Natal (South Africa); apparently parapatric in SW Angola (Crawford-Cabral 1993a).

C. aureus. Slightly larger and taller; saddle not so prominent; body colour golden sand to fawn, not russet-red. Sympatric in parts of East Africa.

Distribution Endemic to Africa; occurs in two separate populations, one in north-east and East Africa, the other in southern Africa. Entirely absent from Zambia and through much of central and Equatorial Africa (Ansell 1978). The disjunct distribution of this species is similar to that of the Aardwolf *Proteles cristatus* and Bat-eared Fox *Otocyon megalotis*. The two populations are separated by as much as 1000 km and their discontinuous distribution suggests that regions of dry *Acacia* bush and savanna, the preferred habitat of this species, once connected south-west Africa with the Horn of Africa (Coe & Skinner 1993).

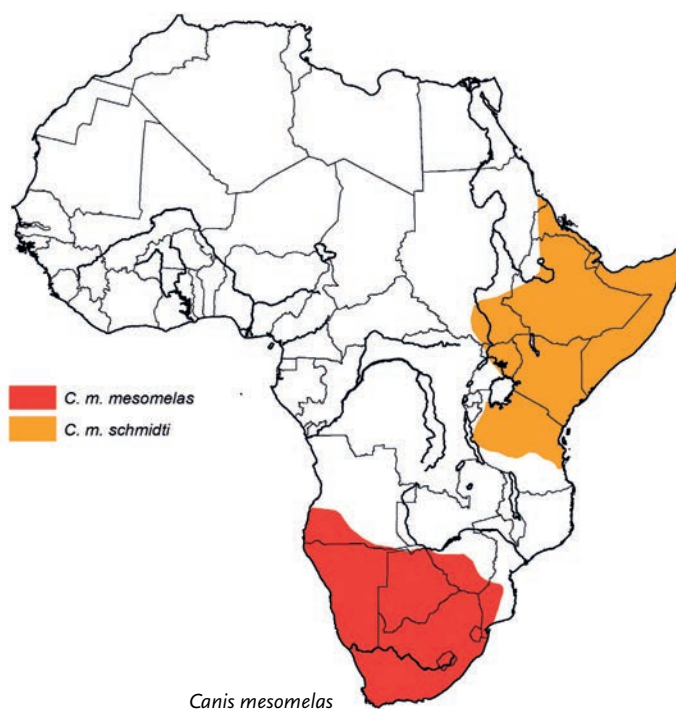

Historical Distribution Black-backed Jackal fossils are found in deposits in South Africa dating to at least 2 mya (Ewer 1956, Hendey 1974a), and there have been numerous palaeontological records in southern Africa over the past 30,000 years (Plug & Badenhorst 2001). Fossil remains have never been found north of Ethiopia, suggesting that they have always been restricted to sub-Saharan Africa. Commenting on remains of bones found in Bir Tarfawi and Bir Sahara, in the extreme south of Egypt, Gautier (1980) remarks 'The material should be certainly ascribed to Golden Jackal *Canis aureus*, although the presence of the small jackal *Canis mesomelas*, a species today found toward the south in the Sudan, cannot be ruled out *a priori*.'

Current Distribution In north-east and East Africa from Sudan through Eritrea, Djibouti and Ethiopia, south to Kenya, E Uganda and N Tanzania. Southern range extends from SW Angola and Namibia through Botswana and S Zimbabwe to S Mozambique, Swaziland, Lesotho and South Africa, where they are mostly widespread (Crawford-Cabral 1993a, Lynch 1994, Monadjem 1998, Skinner & Chimimba 2005).

Habitat Occurs in a wide variety of habitats, from the arid coastal desert of Namibia and W South Africa (Dreyer & Nel 1990) to areas receiving more than 2000 mm of rainfall (Rowe-Rowe 1982). Occurs in montane grassland in the South African Drakensberg and Lesotho Maluti's (above 3000 m) (Rowe-Rowe 1982, 1984, 1992a, Lynch 1994, N. Avenant pers. comm.) and in the alpine zone of Mt Kenya (3660 m; Young & Evans 1993), open savanna in Serengeti N. P., parts of Kenya, South Africa and Botswana (Kingdon 1977, Moehlman 1983, Fuller *et al.* 1989, Skinner & Chimimba 2005), woodland savanna mosaics in Zimbabwe and Mozambique (Smithers 1971, Loveridge & Macdonald 2002) and farmland. In most cases shows a preference for open habitats, tending to avoid dense vegetation. However, in Mokolodi G. R., Botswana, three radio-tracked Black-backed Jackals used bush savanna, mixed bushveld and agricultural land in preference to open grassland (Kaunda 2001).

Where more than one jackal species occurs in sympatry, the habitat is partitioned. Black-backed Jackals preferentially use either the grassland (when sympatric with the Side-striped Jackal, e.g. Hwange N. P., Zimbabwe), or *Acacia/Commiphora* woodland and long grassland (when sympatric with Golden and Side-striped Jackals, e.g. Laikipia and Serengeti; Kingdon 1977, Lamprecht 1978, Moehlman 1983, Estes 1991). In W Zimbabwe habitat partitioning is realized by aggressive encounters in which Black-backed Jackals displace Side-striped Jackals from grassland habitats into the less desirable woodland habitat (Loveridge & Macdonald 2002).

Abundance Generally common, especially in protected areas where suitable habitat occurs. In a wildlife area adjacent to Hwange N.

P. they occurred at densities of 53.9–79.1 per 100 km², expanding to 68.3–97.1 per 100 km² during the breeding season (A. Loveridge pers. obs.). Rowe-Rowe (1984, 1992a) recorded densities of 40/100 km² in Giants Castle G. R., KwaZulu–Natal, and 10–20/100 km² in other areas of the province (Rowe-Rowe 1982, 1992a). In dry river beds in the SW Kalahari strip counts yield densities that vary from 0.09 to 1.3/km² (mean = 0.62), extrapolated to 62/100 km² (mean = 9–130) (J. A. J. Nel unpubl.). In Serengeti N. P., East Africa, Waser (1980) found densities of 0.5/km². Densities of 22/km² have been reported at Cape Cross Seal Reserve, Namibia, perhaps because of superabundant resources there (Hiscocks & Perrin 1988). This density estimate for the Cape Cross population would only apply to the area in the immediate vicinity of the colony where the jackals aggregate at the seal colony to feed. In the surrounding West Coast Recreation Area where the jackals reside they are more dispersed (N. Jenner pers. comm.). Despite strenuous control measures (such as dog hunting, shooting, trapping and poisoning) in many farming areas of southern Africa this species has never been completely exterminated.

Adaptations Black-backed Jackals are relatively unspecialized canids and are well suited for an opportunistic life-style in a wide variety of habitats. They have a well-developed carnassial shear, with a longer premolar cutting blade than other jackal species, which suggests a greater tendency towards carnivory than other jackal species (Van Valkenburgh 1991, Van Valkenburgh & Koepfli 1993). Examination of kidney structure suggests that this species is well adapted to water deprivation (Loveridge 1999), which may explain its presence in the drier parts of the African continent. They apparently have a narrow thermoneutral zone (22.5–27.5 °C) above which thermal conductance – controlled by fur thickness, posture and piloerection – increases (Downs *et al.* 1991).

They show a high propensity for social learning (Nel 1999) and learn to avoid coyote getters (Brand & Nel 1997). Kingdon (1997) suggests that the Black-backed Jackal's brighter, more contrasting

Lateral view of skull of Black-backed Jackal *Canis mesomelas*.

colouration is indicative of its less cryptic behaviour. In addition, Black-backed Jackals are reputed to be more aggressive than other species of jackal (Kingdon 1977, Estes 1991, Skinner & Chimimba 2005). Wyman (1967) found that this species was much more common than Golden Jackals at large carnivore kills in the Ngorongoro Crater, Tanzania, despite being less numerous in the area. Estes (1991) notes that Black-backed Jackals are more likely to attempt to feed on Lion *Panthera leo* and Spotted Hyaena *Crocuta crocuta* kills than other jackal species and that pups of this species become 'quarrelsome and unsociable' and are more likely to emigrate than Golden Jackal pups. Greater tendency towards aggressive behaviour is an adaptation that allows this species to oust the Side-striped Jackal from favourable habitat (Loveridge & Macdonald 2002).

Foraging and Food Opportunistic, generalist feeders. Kok & Nel (2004) found Black-backed Jackals to be more opportunistic and less specialized than sympatric felids (Wildcat *Felis silvestris* and Caracal *Caracal caracal*), reflecting phylogenetic adaptations to prey acquisition, and less specialized than the sympatric Cape Fox *Vulpes chama*. Diet varies according to food availability (Loveridge & Macdonald 2003, Skinner & Chimimba 2005). Numerous studies of dietary preferences have been undertaken, with dietary items generally including small to medium-sized mammals (e.g. murids, springhares *Pedestes* spp., young ungulates), reptiles, birds and birds' eggs, carrion and human refuse, as well as invertebrates (e.g. termites, grasshoppers) and plant matter (Roberts 1922, Bothma 1966a, 1971a, Smithers 1971, Stuart 1976, 1981, 1987, Kingdon 1977, Lamprecht 1978, Rowe-Rowe 1978a, 1983, Ferguson 1980, Dreyer & Nel 1990, Kok 1996, Kaunda & Skinner 2003, Klare *et al.* 2009). They also will feed on beached marine mammals, seals, fish, sea birds (e.g. Cape Cormorant *Phalacrocorax capensis* and Kelp Gull *Larus dominicanus*) and mussels on coasts (Nel & Loutit 1986, Avery *et al.* 1987, Nel *et al.* 1997, Oosthuizen *et al.* 1997, Kolar 2005).

The main feature of this species' foraging behaviour is flexibility and opportunism. Black-backed Jackals are largely nocturnal, but activity periods are extended well into the daylight hours in areas where they are free from persecution. In Hwange N. P. (Zimbabwe), Mokolodi G. R. (Botswana) and the Kalahari of South Africa, Black-backed Jackals exhibited peaks of activity in the evening and early morning (Ferguson *et al.* 1988, Kaunda 2000, Loveridge & Macdonald 2003). The large, mobile ears are used to locate quails, invertebrates and small mammalian prey in long grass. A leap, followed by an accurate pounce is employed to capture prey, guided by the sound, after the manner of a Red Fox *Vulpes vulpes* (Kingdon 1977, A.J. Loveridge & J.A.J. Nel pers. obs.).

Rowe-Rowe (1983) showed that, in the Drakensberg (South Africa), occurrence of carrion, rodent and ungulate prey in the diet closely corresponded to availability within the environment. In Hwange N. P., the diet changed from seasonally abundant invertebrates in the wet season to mammalian prey and carrion in

the dry season. Seasonally, temporally or locally abundant patches of food are exploited wherever possible. Ferguson *et al.* (1988) found that their activity closely approximates the activity cycles of local rodent prey. Black-backed Jackals on the Namib Desert coast of southern Africa scavenge extensively in the seal colonies, where marine refuse provides a rich resource base (Dreyer & Nel 1990) and where they have been seen to kill and eat neonate seal pups (e.g. Kolar 2005). Jackals especially favour the rich afterbirth. Outside the seal birthing period, jackals actively kill yearling and adult seals (N. Jenner pers. comm.). In Serengeti N. P. Black-backed Jackals exploited temporally abundant African Arvicanthis *Arvicanthis nilotica* (Moehlman 1983). On game ranches in the Northern Cape, South Africa, medium-sized ungulates, particularly Springbok *Antidorcas marsupialis*, make up a large proportion (up to 78% of biomass ingested) of Black-backed Jackal diet, and jackals may have significant impact on Springbok numbers in this area (Klare *et al.* 2009).

Black-backed Jackals are quick to respond to prey distress calls and often investigate the activities of large carnivores such as Lions and Spotted Hyaenas (A. Loveridge pers. obs.). They are recorded hunting cooperatively with Cheetahs *Acinonyx jubatus* (Eaton 1969), and, in the Namib, frequently occur in association with Brown Hyaenas *Hyaena brunnea* and may benefit by occasionally scavenging food items from the larger carnivore. Weak or unwary prey items are quickly capitalized upon; for instance, a pair of Black-backed Jackals in Hwange N. P. was, on two occasions, observed snatching young Chacma Baboons *Papio ursinus* that had strayed too far from the protection of the troop (A. Loveridge pers. obs.).

Commonly, pairs and small family groups are seen foraging together; for example, in the Ukhahlamba Drakensberg Park, KwaZulu-Natal, 78% of sightings (n = 872) were of single animals, 19% of pairs and only 3% of groups of three or four (Rowe-Rowe 1984). Less often large aggregations have been observed at particularly rich food resources. Groups of between 8 and 12 aggregate at large carcasses of herbivores, and more than 80 have been recorded at seal colonies on the Namib Desert coast (Oosthuizen *et al.* 1997), with jackals commuting up to 20 km from their denning or resting sites to access this resource (Jenner *et al.* 2011). Such aggregations are accompanied by aggressive behaviour between territorial individuals. However, in the SW Kalahari, where antelope carcasses are uncommon, pairs or groups of up to 30 individuals congregated at Common Eland *Tragelaphus oryx* or Gemsbok *Oryx gazella* carcasses and fed in succession, without much overt aggression (J. A. J. Nel pers. obs.). Mated Black-backed Jackal pairs will often cooperate in the capture of prey resulting in a higher success rate (Lamprecht 1978, Macdonald *et al.* 2004.). In Botswana, McKenzie (1990) found that, on occasion, they form 'packs' in order to hunt adult Impala *Aepyceros melampus*, and other authors have recorded several jackals taking adult antelope (Pienaar 1969, Van Lawick & Van Lawick-Goodall 1970, Sleicher 1973, Lamprecht 1978, Krofel 2008). Kamler *et al.* (2010) report an observation of a single Black-backed Jackal chasing and killing, by means of a throat bite, an apparently healthy adult Impala.

Caching of food is common (Lamprecht 1978), while on the Namib Desert coast accumulations of prey remains result in 'middens' as a result of animals carrying prey to feeding sites (Avery *et al.* 1987, Dreyer & Nel 1990).

This species will prey on livestock (especially juvenile goats and sheep) and is thus considered vermin in many livestock-producing

regions (Van der Merwe 1953). In some sheep-farming areas of KwaZulu–Natal, Black-backed Jackal predation may account for 3% of newborn lambs (Lawson 1989), equating to 2% of the total flock per year (Rowe-Rowe 1975a). In the Graaff Reinet and Nuwe Roggeveld areas losses amount to 3.9% (De Villiers 1979) and 2.4% (Vorster 1988), respectively, and on some individual farms, as high as 15–18% (Brand 1993). In N Botswana, 77% of domestic livestock losses to wild carnivores were due to Black-backed Jackal predation (Gusset *et al.* 2009). By contrast, in S Namibia, where controlled herding is practised, losses due to predation amount to only 0.3–0.5% (Brown 1988). Likewise, in villages bordering Serengeti N. P., where households lose 4.5% of their livestock annually to predators, Black-backed Jackals accounted for < 1% of incidents (Holmern *et al.* 2007).

Social and Reproductive Behaviour The monogamous mated pair is the basis for social structure. The pair bond appears to be life-long in most cases, and if one member of a pair dies the other will often lose its territory (Moehlman 1978, 1986, Estes 1991). However, on one occasion an immigrant ♀ was observed to displace the established ♀ in a territory, subsequently mating with the original territorial ♂ and giving birth to a litter of pups (A. Loveridge pers. obs.). Black-backed Jackals are territorial, using faeces and urine to demarcate their territorial boundaries (Kingdon 1977, Ferguson *et al.* 1983). A mated pair will often scent-mark in tandem, and Moehlman (1983) reports that one foraging pair tandem marked on 76% of observed marking incidents. Tandem marking advertises the presence of both members of the pair, and the pair will aggressively expel intruders. Vocalization by the territorial pair advertises occupancy of the territory and thereby reduces the number of aggressive encounters. Territories are spatially and temporally stable, but may fluctuate in size with season (Loveridge & Macdonald 2001) or where resource levels are widely variable between years (Moehlman 1983). In Hwange N. P., a mated pair of Black-backed Jackals is known to have held the same territory for at least four years (A. J. Loveridge pers. obs.). In Cape Cross Seal Reserve, jackals actively defend a territory during the breeding season. One mated pair has been recorded in the same breeding territory for at least four years (N. Jenner pers. comm.).

Home-ranges differ between localities: in the Rift Valley in Kenya, home-ranges varied from 0.7 to 3.5 km², with a mean of 1.8 km² (Fuller *et al.* 1989). In Zimbabwe home-ranges were larger in the cold dry season (1.05–1.3 km²) and smaller in the hot dry season (0.32–0.62 km²) (Loveridge & Macdonald 2001). In South Africa, home-range size averaged 18.2 km² (n = 14) in Giants Castle G. R. in the Drakensberg (Rowe-Rowe 1982), and 17.8 km² in the Northern Cape Province (Kamler *et al.* 2012). In Gauteng and North West Province, home-range size was 3.4–21.5 km² (mean 10.6 km²; n = 8) (Ferguson *et al.* 1983). Ranges of subadults varied considerably, from 1.9 to 575 km² (mean 85.2 km², n = 11), with the largest ranges likely attained by dispersing individuals. In the more arid SW Kalahari, ranges were smaller, with adult ranges varying from 2.56 to 5.2 km² (mean 4.32 km²; n = 4) and subadult ranges from 4.04 to 8.8 km² (mean 6.32 km²; n = 4) (Ferguson *et al.* 1983). At Cape Cross Seal Reserve, average home-range size was 7.1 km² (range 3.2–13.2) or 24.9 km² (range 17.6–34) as calculated by the minimum area or modified minimum area methods (n = 4 in both cases). Here Black-backed Jackals did not defend their ranges, with home-ranges

Black-backed Jackal *Canis mesomelas* action drawing.

overlapping, and thus were not territorial (Hiscocks & Perrin 1988). At Cape Cross Seal Reserve home-range overlap is extensive around the seal colony. However, during the breeding season jackals actively defend and mark a territory (N. Jenner pers. comm.). In all other cases ranges were defended and mutually exclusive for pairs. Ferguson *et al.* (1983) reported that adults moved an average daily distance of 12 km.

In southern Africa the Black-backed Jackal is a very vocal species. A high-pitched, whining howl is used to communicate with group members and is often used to call the group together in the early evening. This may also function in territorial advertisement. Howling often stimulates the same behaviour in adjacent territories. A three- to five-syllable alarm call, consisting of an explosive yelp followed by a series of shorter high-pitched yelps, is used when disturbed and may be frantic and prolonged when mobbing a Leopard *Panthera pardus*. A low-pitched, gruff bark is used to warn pups of intruders near the den, and whines are used to call to pups. Kingdon (1997) notes the use of a 'clattering distress call' and a loud yelp when alarmed. Interestingly, Black-backed Jackals are much less vocal where they occur alongside the Golden Jackal in Serengeti N. P. in that they do not howl, and instead vocalize with yaps interspersed with howls. This is in contrast to their southern range where, in the absence of Golden Jackals, they howl in much the same way as Golden Jackals (Kingdon 1977, 1997, H. Kruuk pers. comm.). Elimination of the howl from the vocal repertoire of this species may serve to reduce the ambiguity of the signal, thereby limiting competition between these two species, and perhaps reducing instances of inter-specific territorial conflict.

Mating in this species is accompanied by increased vocalization and territoriality in both sexes (Skead 1973, Bernard & Stuart 1992, Loveridge & Macdonald 2001). The dominant individuals within the territory prevent same sex subordinates (usually offspring) from

mating by constant harassment. As with other canids, there is a copulatory tie after mating.

Pups are born in modified termitaria, disused burrows of Aardvark *Orycteropus afer* or other convenient burrows (less frequently caves or other crevices), often with multiple entrances. Jackals sometimes dig their own dens. At Cape Cross Seal Reserve jackals dig their own dens in salt-pans, dry river beds and under large boulders, but will also den in disused Brown Hyaena dens (N. Jenner pers. comm.). Jackals with pups will move dens several times during the first 4–5 months; the most likely explanation for this behaviour on the Namib coast is to reduce parasites (N. Jenner pers. comm.). The same den sites may be used from year to year. For the first three weeks the mother spends up to 90% of her time in the den with the pups; the ♂ and any helpers provision her during this time (Moehlman 1983). Parents and alloparents feed pups by regurgitation. Alloparental care is most fully documented for Black-backed Jackals in Serengeti N. P. (Moehlman 1978, 1983; but see also Ferguson *et al.* 1983). Alloparents guard the pups when the parents are foraging. One helper may increase the average number of pups surviving per mated pair from 1 to 3.3, and two helpers further increases survival to 4 pups (Moehlman 1979, 1983). Estes (1991) suggests that guarding of pups is more important in this species because they tend to den in thicker cover, allowing predators to approach the den more closely without detection. On the Namib coast, guarding helps protect pups from Brown Hyaena predation. Alloparents contribute to boundary defence and will actively protect young from intruding jackals (N. Jenner pers. comm.). Predators such as Spotted Hyaenas, approaching the den, are driven off by determined harassment, in some instances a pair of defending Black-backed Jackals will cooperate in this defence by alternately dashing in to nip the hindquarters of the intruder, before making a hasty escape (Moehlman 1983).

Juveniles disperse at one year of age, although some (24% in Serengeti; Moehlman 1983) may remain within their natal territory to act as helpers. In Hwange N. P., dispersal of five young Black-backed Jackals was documented (two ♀♀, three ♂♂). They dispersed over an average of 2.8 ± 2.05 km, the maximum distance being 20 km. Two (one ♀, one ♂) dispersed to neighbouring territories where a vacancy existed, two (one ♀, one ♂) dispersed to nearby territories using only the periphery of the territory until they were later integrated into the group, and one floated between the natal territory and adjacent territories (A. Loveridge pers. obs.). Elsewhere dispersal distances of more than 100 km have been recorded, in one instance a ♂ dispersing 126 km over a 15-month period (Bothma 1971b, Ferguson *et al.* 1983).

Reproduction and Population Structure Mating generally occurs from late May to Aug and, following a gestation period of about 60 days, births occur from around Jul (sometimes Jun) to Oct (Wyman 1967, Fairall 1968, Kingdon 1977, Stuart 1981, Moehlman 1983, Bernard & Stuart 1992, Bingham & Purchase 2002, N. Jenner pers. comm.); later births were recorded in the Rift Valley in Kenya (Sep–Jan; Fuller *et al.* 1989). In the KwaZulu–Natal Drakensberg, Rowe-Rowe (1978a) recorded a peak in births in Jul. Bernard & Stuart (1992) suggested that summer births are timed to coincide with the reproductive season of important prey like the Southern African Vlei Rat *Otomys irroratus* and Mesic Four-striped Grass Rat *Rhabdomys dilectus*, and winter births with an increase in the availability of ungulate carcasses at the end of the winter dry season.

Litter-size ranges between one and nine (Wyman 1967, Rowe-Rowe 1978a, Bingham & Purchase 2002, N. Jenner pers. comm.); Bingham & Purchase (2002) found mean prenatal litter-size to be 4.6 (range 1–8) pups based on examination of foetuses and placental scars. Pups are born blind, open their eyes at days 8–10, first emerge from the den at three weeks, are weaned at 8–9 weeks, and are completely independent of the den at 14 weeks (Moehlman 1978, A. Loveridge pers. obs.). Permanent teeth start erupting at around 14–16 weeks of age, and are usually fully erupted at one year (Lombaard 1971, Bingham & Purchase 2003). Pups are able to hunt on their own at six months of age, but parents continue to occasionally groom and feed them (Moehlman 1983). They reach sexual maturity at about 11 months (Ferguson *et al.* 1983), but they seldom reproduce in their first year (Ferguson *et al.* 1983, Bingham & Purchase 2002).

Most pup mortality occurs in pups younger than 14 weeks (Moehlman 1987). On the Namib coast, where jackals have few predators, risk of mortality may be greatest during dispersal (post six months) (N. Jenner pers. comm.). It is unlikely that Black-backed Jackals live much beyond about seven years of age in the wild (Rowe-Rowe 1986, 1992a), though captives have lived more than 14 years (Nowak 1999, Weigl 2005).

Predators, Parasites and Diseases Main predator of adults is the Leopard (Turnbull-Kemp 1967). Four of 11 radio-collared Black-backed Jackals were killed and eaten by Leopards in a study in Hwange N. P. (A. Loveridge pers. obs.) and Estes (1967) observed 11 jackals taken by a single Leopard over the course of three weeks, and they may be a favourite Leopard prey item in some areas (Kingdon 1977). Other large predators, such as Spotted Hyaenas and Brown Hyaenas, may prey on unprotected pups (Van Lawick & Van Lawick-Goodall 1970, N. Jenner pers. comm.), as will the Ratel *Mellivora capensis* (Begg *et al.* 2003a), and Kamler *et al.* (2007) document several instances of predation on Black-backed Jackals by African Wild Dogs *Lycaon pictus*. There is also a record of them being preyed upon by Caracals *Caracal caracal* (Melville *et al.* 2004). Other predators include birds of prey; Van Lawick & Van Lawick-Goodall (1970) observed a Martial Eagle *Polemaetus bellicosus* fly away carrying a subadult Black-backed Jackal.

In Zimbabwe, seroprevalence of canine distemper virus, canine parvovirus and canine adenovirus (type 1) were 63.6%, 18.5% and 9.1%, respectively, in 22 Black-backed Jackals sampled (Spencer *et al.* 1999). Although jackals act as reservoirs for these diseases, susceptibility is not known. However, in Serengeti N. P. distemper is believed to have been the cause of several epidemics affecting Black-backed Jackals (Moehlman 1983). Black-backed Jackals are extremely susceptible to rabies, succumbing to the disease after an incubation period of between 15 and 17 days (Foggin 1988, Bingham *et al.* 1995). They are significant vectors of rabies in C southern Africa and are responsible for transmission of the disease to domestic stock (Foggin 1988, Bingham & Foggin 1993, Swanepoel *et al.* 1993, Bingham *et al.* 1999a). Seasonal peaks in rabies cases correspond closely to the mating season and dispersal periods when social disturbance is high (Loveridge & Macdonald 2001). The loss of livestock and the expense of vaccination make rabies economically significant in southern Africa. In some areas rabies control is undertaken by culling of wildlife, especially jackals, and is thus a major cause of mortality. However, rabies spread may be more restricted in stable populations

than in those disturbed by culling regimes. Rabies is rare in national parks, which may be due to the absence of domestic dogs (Cumming 1982) or to intact ecological processes and low disturbance (Foggin 1988, McKenzie 1993). Rabies in jackals is probably better controlled by oral vaccination techniques (e.g. Bingham *et al.* 1995, 1999a) and immunization of domestic dogs (Rhodes *et al.* 1998, Bingham *et al.* 1999a) than by culling (Loveridge & Macdonald 2001). If, as in other sympatric canids, behavioural avoidance and spatial segregation between species occurs, the contact rate (and hence the opportunity for transmission) may be low and reduced overall when jackals occur in sympatry (Loveridge 1999).

Black-backed Jackals have been recorded infected with internal parasites, including the trematode *Athesmia* (Hammond 1972), various cestodes (see list in Walton & Joly 2003) and protozoan parasites such as *Babesia canis* (Van Heerden 1980), *Ehrlichia canis* (Price & Karstad 1980) and *Sarcocystis* spp. (Wesemeier *et al.* 1995). Black-backed Jackals have also succumbed to sarcoptic mange (Keep 1970, Van Heerden 1980), particularly on the Namib coast (N. Jenner pers. comm.). Ectoparasites recorded on Black-backed Jackals include numerous ixodid ticks: *Amblyomma hebraeum*, *A. marmoreum*, *A. variegatum*, *Boophilus decoloratus*, *Haemaphysalis leachi*, *H. silacea*, *H. spinulosa*, *Ixodes pilosus*, *I. rubicundus*, *Rhipicephalus appendiculatus*, *R. evertsi*, *R. nuttalli*, *R. simus* and *R. zambeziensis* (Hall-Martin & Botha 1980, Horak *et al.* 1987, 2000).

Conservation IUCN Category: Least Concern. CITES: Not Listed.

Black-backed Jackals are persecuted for their role as livestock killers and as rabies vectors. Such efforts at population control appear largely ineffective (Rowe-Rowe 1986) and probably only succeed in producing a temporary reduction in local numbers. Bingham & Purchase (2003) note that productivity in this species is sufficiently high for rapid recovery following population crashes or extermination campaigns. There is now no significant trade in jackal products, although hunting and trapping for skins occurs in some areas, and body parts are used in traditional African medicine and clothing (N. Avenant pers. comm.). Populations of the species occur in numerous well-managed protected areas across their range, including Masai Mara (Kenya), Serengeti N. P. and Selous G. R. (Tanzania), Skeleton Coast N. P., Cape Cross Seal Reserve and Etosha N. P. (Namibia), Kgalagadi Transfrontier Park (Botswana, South Africa), Hwange N. P. (Zimbabwe) and Ukhahlamba-Drakensberg Park and Kruger N. P. (South Africa) (Loveridge & Nel 2004). Black-backed Jackals have been maintained in captivity for use in experiments testing rabies vaccine (Bingham *et al.* 1995), but are usually not a common zoo species.

Measurements

Canis mesomelas

HB (♂ ♂): 721 (680–755) mm, n = 39
 HB (♀ ♀): 673 (640–725) mm, n = 52
 T (♂ ♂): 329 (280–365) mm, n = 39
 T (♀ ♀): 314 (250–370) mm, n = 52
 HF c.u. (♂ ♂): 161 (150–179) mm, n = 39
 HF c.u. (♀ ♀): 160 (140–180) mm, n = 52
 E (♂ ♂): 109 (90–115) mm, n = 39
 E (♀ ♀): 99 (80–115) mm, n = 52
 WT (♂ ♂): 7.9 (6.8–9.5) kg, n = 39

WT (♀ ♀): 6.6 (5.5–10.0) kg, n = 52
 Zimbabwe (Smithers 1983)

HB (♂ ♂): 785 (690–900) mm, n = 65
 HB (♀ ♀): 745 (650–850) mm, n = 42
 T (♂ ♂): 326 (270–395) mm, n = 70
 T (♀ ♀): 316 (260–381) mm, n = 45
 HF c.u. (♂ ♂): 160 (130–185) mm, n = 66
 HF c.u. (♀ ♀): 156 (140–180) mm, n = 43
 E (♂ ♂): 109 (90–132) mm, n = 68
 E (♀ ♀): 104 (80–120) mm, n = 41
 WT (♂ ♂): 8.2 (5.9–12.0) kg, n = 59
 WT (♀ ♀): 7.4 (6.2–9.9) kg, n = 42

Northern Cape, Western Cape and Eastern Cape, South Africa (Stuart 1981)

Other mean measurements recorded include: 8.4 kg for ♂ ♂ (range 6.4–11.4; n = 123) and 7.7 kg for ♀ ♀ (range 5.9–10.0; n = 84) in Ukhahlamba-Drakensberg Park, KwaZulu-Natal (Rowe-Rowe 1978a); and 8.2 kg for ♂ ♂ (range 5.0–9.3; n = 26) and 7.6 kg for ♀ ♀ (range 6.3–8.5; n = 19) in the former Transvaal (Rautenbach 1982). At Cape Cross Seal Reserve, jackals are slightly larger than in other parts of southern Africa and ♂ ♂ weigh 10.3 (7.5–13.3) kg, n = 28, and ♀ ♀ weigh on average 8.7 (7.0–10.7) kg, n = 29 (N. Jenner pers. comm.); Stutterheim (in litt.) recorded weights for ♂ ♂ of 9.7 (8.4–10.5) kg, n = 7, and for ♀ ♀ 8.7 (6.9–10) kg, n = 12. In East Africa, average weight of ♂ ♂ and ♀ ♀ is around 8.5 kg (7–13.5 kg) (Kingdon 1977).

Black-backed Jackal
Canis mesomelas.

Canis simensis ETHIOPIAN WOLF (SIMIEN FOX)

Fr. Loup d'Abyssinie; Ger. Aethiopienfuchs

Canis simensis Rüppell, 1835. Neue Wirbelt. Fauna Abyssin. Gehörig. Säugeth.
1: 39, pl. 14. 'in der Bergen von Simen' [Simen Mountains, Ethiopia, ca. 13° 15' N, 38° 00' E].

Ethiopian Wolf *Canis simensis*.

Taxonomy The most distinct species in the genus *Canis*. Clutton-Brock *et al.* (1976) suggested close affinity with Side-striped Jackal *Canis adustus* and *Dusicyon* spp., and the species was placed in a separate genus *Simenia* by Gray (1868). Although it has been called the Simien or Simenian Fox, the Ethiopian Wolf is not closely linked to the *Vulpes* group (Clutton-Brock *et al.* 1976). Rook & Azzaroli Puccetti (1997) suggested a close relationship with jackals. Phylogenetic analysis using mitochondrial DNA sequencing suggested that *Canis simensis* is more closely related to the Grey Wolf *C. lupus* and the Coyote *C. latrans* than to any African canid (Gottelli *et al.* 1994). It may be an evolutionary relict of a grey wolf-like ancestor crossing to northern Africa from Eurasia (Gottelli *et al.* 1994), where fossils of wolf-like canids are known from the late Pleistocene (Kurtén 1968). Microsatellite and mitochondrial DNA variability is small relative to other canid species, suggesting small population sizes may have characterized its recent evolution (Gottelli *et al.* 2004). There is no fossil record of *C. simensis*. Two subspecies have been recognized (Coetzee 1977). Synonyms: *citernii*, *sinus*, *walgie*. Chromosome number: not known.

Description Medium-sized canid with reddish coat with distinctive white markings, long legs and elongate muzzle, resembling a large German Shepherd dog in conformation and size (Sillero-Zubiri & Gottelli 1994). Overall colour tawny-rufous (ochre to rusty-red), with dense whitish to pale ginger underfur. Throat, chest and underparts white. Distinctive white band around ventral part of neck; inner aspect of limbs white. Face, upper part of slender muzzle and dorsal surface of ears red. Ears broad and pointed, and directed forward; thickly fringed with long white hairs growing inward from the edge, whereas inside of pinnae is almost naked. Tail furry; anterior part white underneath. Rufous colour of coat continues in a short strip down back of tail, becoming a black strip connecting to

a thick black brush of guard hairs, which have black tips. No evident seasonal variation in coat colour, but contrast of white markings against the red coat increases with age and social rank in both sexes. Very long and slender legs. Forefoot has five toes; hindfoot has four toes. Limb posture is digitigrade. Male Ethiopian Wolves are larger than ♀♀ (20% larger in body mass). Female's coat generally paler than male's; during breeding and pregnancy coat turns pale yellow and becomes woolly, and tail turns brownish and loses much of its hair. There are eight nipples, but often only six are functional.

Skull elongated with a slender elongate nose. Facial length 58% of total skull length. Skull very flat in profile, with only a shallow angle between frontals and nasals. Neurocranium low and narrow, thick and almost cylindrical. Interparietal crest slightly developed. Teeth, especially premolars, small and widely spaced. Sharply pointed canines average 19 mm long (14–22 mm) and carnassials are relatively small (Sillero-Zubiri & Gottelli 1994). Lower third molar occasionally absent.

Geographic Variation

C. s. simensis: north-west of the Rift Valley. Nasal bones consistently shorter than those from the southern race.

C. s. citernii: south-east of the Rift Valley.

Dalton (2001) identified differences in the craniomorphology of wolves on both sides of the Rift Valley, but mtDNA analysis from a larger sample of individuals does not lend any support to subspecies recognition of northern and southern clades (Gottelli *et al.* 2004).

Similar Species

Canis aureus. Smaller, with relatively shorter legs; lacks distinctive reddish coat, white underparts, throat, chest, and tail markings of the Ethiopian Wolf. Other jackals (*C. mesomelas*, *C. adustus*) share same differences, but are not sympatric with Ethiopian Wolves.

Distribution Endemic to Africa; confined entirely to the Ethiopian Highlands, where species is restricted to a few mountain ranges of afroalpine grasslands and heathlands, between 6°N and 14°N.

Historical Distribution There are no recent records of the species at altitudes below 3000 m, although specimens were collected at 2500 m from Gojjam (where the species is now extinct – Marino 2003a) and north-western Shoa at the beginning of the century (Yalden *et al.* 1980). Its range restricted altitudinally by increasing agricultural pressure and small populations in Gosh Meda and Mt Guna recently became extinct (Marino 2003a, Marino *et al.* 2011). Reports from Chercher and North Sidamo are either erroneous or suggest further recent extinctions. There is no evidence that Ethiopian Wolves ever occurred in Eritrea.

Current Distribution Confined to seven mountain ranges of the Ethiopian Highlands, at altitudes of 3000–4500 m (Gottelli & Sillero-Zubiri 1992, Marino 2003a). Wolf populations occur both sides of the Rift Valley: the Simen Mts, North and South Wollo highlands and Menz to the north; and Arsi Mts, Bale Mts and West Bale to the south.

Habitat A very localized endemic species, confined to isolated pockets of afroalpine grasslands and heathlands where they prey on afroalpine rodents. Suitable habitats extend from above the treeline at about 3200 m, up to 4500 m, with some montane grasslands at 3000 m. However, subsistence agriculture extends up to 3500–3800 m in many areas, restricting wolves to higher ranges (Marino 2003b). Rainfall at high altitude varies between 1000 and 2000 mm/year, with one pronounced dry period from Dec to Feb/Mar.

Ethiopian Wolves utilize all afroalpine habitats, but prefer open areas with short herbaceous and grassland communities where rodents are most abundant, along flat or gently sloping areas with deep soils and poor drainage in parts. Prime habitats in the Bale Mts are characterized by short herbs (*Alchemilla* spp.) and grasses and low vegetation cover, a community maintained in continuous succession as a result of Giant Root-rat *Tachyoryctes macrocephalus* burrowing activity. Other good habitats include tussock grasslands (*Festuca* spp., *Agrostis* spp.), high-altitude scrubs dominated by *Helichrysum* spp. and short grasslands in shallow soils. In northern parts of the range, plant communities characterized by a matrix of 'guassa' tussock grasses (*Festuca* spp.), 'cherenfi' bushes (*Euryops pinifolius*) and giant lobelias (*Lobelia rhynchopetalum*) sustain high rodent abundance and are preferred by Ethiopian Wolves. Ericaceous moorlands (*Erica* and *Phyllipia* spp.) at 3200–3600 m are of marginal value, with open moorlands with patches of herbs and grasses being relatively good habitat.

Abundance With only 400–450 individuals surviving (Gottelli & Sillero-Zubiri 1992, Marino 2003a, Marino *et al.* 2011), this distinctive carnivore is considered the rarest canid in the world (Sillero-Zubiri &

Lateral, palatal and dorsal views of skull of Ethiopian Wolf *Canis simensis*.

Marino 2004). More than half of the species' population (220–300) live in Bale Mts N. P., where density is positively correlated with density of rodent prey and negatively with vegetation height (Sillero-Zubiri & Gottelli 1995a, Marino 2003b). Not more than 110–150 Ethiopian Wolves persist north of the Rift Valley with less than 75 in Simien (Marino *et al.* 2011).

Highest densities are found in short afroalpine herbaceous communities (1.0–1.2 adults/km²); lower densities are found in *Helichrysum* dwarf-scrub (0.2/km²), and in ericaceous heathlands and barren peaks (0.1/km²). Ethiopian Wolves also are present at low density (0.1–0.2/km²) in montane grasslands at lower altitudes. Elsewhere, overall wolf density is relatively lower. In Menz, wolf density was estimated at 0.2 animals per km² (Tefera Ashenafi *et al.* 2005). Census data indicate higher abundance in North Wollo (0.20 ± 0.20 sightings per km), intermediate in Arsi and Guna (0.10 ± 0.11 and 0.10 ± 0.14, respectively), and lower in South Wollo and Simien (0.08 ± 0.13 and 0.06 ± 0.11, respectively) (Marino 2003b).

Adaptations The legs are strikingly long and slender, seemingly suitable for coursing in open country. The muzzle is long, and the small, well-spaced teeth suggest morphological adaptation to feeding on rodents. They have an unusually good sense of smell, and bolt more readily at scent than sight of man. The guard hairs are short and the underfur is thick, providing protection at temperatures as low as –15 °C. Ethiopian Wolves do not use dens to rest at night, and during the breeding season only pups and nursing ♀♀ use the den. Wolves sleep in the open, alone or in groups, curled up, with the nose beneath the tail. Several animals may sleep close together. During the cold nights in the dry season, a 'bed' is carefully prepared from a pile of vegetation debris, the product of Giant Root-rat activity. During the day they take frequent naps, usually resting on their sides. Occasionally, they seek shelter from the rain under overhanging rocks and behind boulders (Sillero-Zubiri 1994).

Foraging and Food Pack members forage and feed alone on small prey, contradicting the general trend in carnivores for grouping and

cooperative hunting. In the Bale Mts they are most active during the day feeding chiefly upon diurnal small mammals of the high-altitude afroalpine grassland community, such as the endemic Giant Root-rat (300–930 g), grass rats (*Arvicanthis blicki*, *Lophuromys melanonyx*, *L. flavopunctatus*, *Otomys typus*) and Starck's Hare *Lepus starcki*. Murid rodents accounted for 96% of all prey occurrences in faeces in Bale (Sillero-Zubiri & Gottelli 1995a). Elsewhere, Giant Root-rats are absent and the smaller African Root-rat *Tachyoryctes splendens* becomes an important component of the wolf diet (Malcolm 1997, Marino 2003b). Occasionally, Ethiopian Wolves were observed feeding on goslings and eggs, Rock Hyraxes *Procavia capensis*, and young of the Common Duiker *Sylvicapra grimmia*, Bohor Reedbuck *Redunca redunca* and Mountain Nyala *Tragelaphus buxtoni* (Sillero-Zubiri & Gottelli 1995a, Malcolm 1997, C. Sillero-Zubiri pers. obs.). Leaves of sedge (*Carex monostachya*) are occasionally ingested, probably to assist digestion or control parasites.

Ethiopian Wolves will take carrion or feed on carcasses; in fact a sheep carcass is the most successful bait for trapping. The local name 'Jeedala fardaa' – the horse's jackal – refers to the habit of following mares and cows about to deliver and eating the afterbirth. In areas of grazing in Bale Ethiopian Wolves were often seen foraging among herds of cattle, a tactic that may aid in ambushing rodents out of their holes, by using the herd as a mobile hide (Sillero-Zubiri 1994).

Ethiopian Wolves are mostly diurnal. Peaks of foraging activity in Bale suggest that they synchronize their activity with that of rodents above the ground (Sillero-Zubiri *et al.* 1995a, b). There is little nocturnal activity, with wolves seldom moving far from their evening resting site. They are more crepuscular and nocturnal where human interference is severe.

Digging out prey is common, mostly to catch Giant Root-rats, with the effort expended varying from a few scratches at a rat hole to the total destruction of a set of burrows. Sometimes digging serves to reach a nest of grass-rats. Kills often are cached and later retrieved. Rich food patches are carefully explored by wolves walking slowly, pausing frequently to investigate holes or to locate the rodents by hearing. Once a prey is located, the wolf moves stealthily towards it, taking short steps, and freezing, sometimes with its belly pressed flat to the ground. The quarry is grabbed with the mouth after a short dash. A stalk can last from seconds to up to one hour, in the case of a Giant Root-rat. Occasionally, wolves run in zig-zags across rat colonies picking up the rodents in passing.

Until recently, Ethiopian Wolves in Bale were unmolested by humans and did not appear to be regarded as a threat to sheep and goats, which are sometimes left unattended during the day (Gottelli & Sillero-Zubiri 1992). Only two instances of predation upon lambs were recorded during 1800 hours of foraging observation (Sillero-Zubiri & Gottelli 1994). Losses to wolves in the southern highlands were dismissed by herders as unimportant when compared with damage by Golden Jackals *Canis aureus* and Spotted Hyenas *Crocuta crocuta*. In N Ethiopia, Ethiopian Wolves have been persecuted in the past due to their reputation as predators of sheep and goats; livestock predation is reported as important in the heavily populated areas of Wollo and Simien (Marino 2003b).

Social and Reproductive Behaviour Ethiopian Wolves live in packs, a discrete and cohesive social unit that communally shares and defends an exclusive territory. Packs of 3–18 adults (mean 6)

congregate for social greetings and border patrols at dawn, noon and evenings, and to rest together at night, but break up to forage individually in the morning and early afternoon. Peaks of foraging activity suggest that wolves synchronize their activity with that of rodents above the ground. There is little nocturnal activity, with wolves seldom moving far from their evening resting site.

Annual home-ranges of eight packs monitored for four years averaged 6.0 km², with some overlap in home-ranges. Home-ranges in an area of lower prey biomass averaged 13.4 km² (n = 4) (Sillero-Zubiri & Gottelli 1995b). Overlap and aggressive encounters between packs were highest during the mating season. Dispersal movements are tightly constrained by the scarcity of suitable habitat. Males do not disperse and are recruited into multi-male philopatric packs; some ♀♀ disperse at two years of age and become 'floaters', occupying narrow ranges between pack territories until a breeding vacancy becomes available (Sillero-Zubiri *et al.* 2004b). Dead breeding ♀♀ typically are replaced by a resident daughter.

Adult Ethiopian Wolves hunt alone but travel in packs when patrolling to advertise and maintain their territories. All pack members, independent of social rank, regularly scent-mark territory boundaries, via urine posts, scratching and deposition of faeces on conspicuous sites (mounds, rocks, bushes) (Sillero-Zubiri & Macdonald 1998). More often only adults of both sexes take part, led by one of the dominant pair, usually the ♀. Vocalizations also play a role in territory defence. Aggressive interactions with neighbouring packs are common, highly vocal and always end with the smaller group fleeing from the larger (Sillero-Zubiri *et al.* 2004b).

Calls can be grouped into two categories: alarm calls, given at the scent or sight of man, dogs, or unfamiliar wolves, start with a 'huff' (rapid expulsion of air through mouth and nose), followed by a quick succession of high-pitched 'yelps' (a series of 4–5 'yeahp-yeahp-yeahp-yeahp') and 'barks'. 'Yelps' and 'barks' can be also given as contact calls, and often attract nearby pack mates. Greeting calls include a 'growl' of threat, a high-frequency 'whine' of submission, and intense 'group yip-howls', given at the reunion of pack members and advertise pack size, composition and position. A lone howl and a group howl are long-distance calls used to contact separate pack members and can be heard up to 5 km away. Howling by one pack of wolves may stimulate howling in adjacent packs. Communal calls mustered pack members before a border patrol (Sillero-Zubiri & Macdonald 1998).

Many postures and habits of the Ethiopian Wolf are typical of other social canids. It grooms itself by licking and nibbling and by reciprocating attention of others. It laps water with its tongue. Wolves often wade streams and swim across narrow rivers when necessary. Ethiopian Wolves remain playful throughout their lives, particularly male siblings.

Precopulatory behaviour by the dominant ♀ includes an increase in the scent-marking rate, play soliciting, food-begging towards the dominant ♂ and agonistic behaviour towards subordinate ♀♀. The receptive period is synchronized in sympatric ♀♀ to less than two weeks (Sillero-Zubiri *et al.* 1998). Courtship may take place between adult members of a pack or with members of neighbouring packs. After a short courtship, which primarily involves the dominant ♂ permanently accompanying the ♀, the pair copulate over a period of 3 to 5 days. Copulation involves a tie lasting up to 15 min. Other ♂♂ may stand by a tied pair with no signs of aggression. Mate

Ethiopian Wolf *Canis simensis* dominance display.

preference is shown, with the ♀ discouraging attempts from all but the pack's dominant ♂, by either defensive snarls or moving away; she is receptive to any visiting ♂ from neighbouring packs. Up to 70% of matings ($n = 30$) involved ♂♂ from outside the pack (Sillero-Zubiri *et al.* 1996a, 2004b).

During the breeding season social gatherings are more common and take place next to the den. Intense, energetic and noisy greetings that occur primarily when groups form or before tandem-marking patrols seem to be an important component in keeping cohesion and friendly relations within the pack. Other common interactions are food-sharing, allogrooming, nibbling and playing, which involves chasing, ambushing and mock fighting. Strong affiliative ties are developed between siblings during the first months of their life. Vicious play-fighting during the first weeks outside the den may determine the establishment of rank between siblings. Hierarchies among pack members are well established with frequent displays of dominance and subordination; a dominance rank develops among adults of each gender; shifts in rank may occasionally take place in ♂♂ but not among ♀♀ (Sillero-Zubiri *et al.* 2004b).

Reproduction and Population Structure The dominant ♀ of each pack gives birth once a year between Oct and Jan (Sillero-Zubiri *et al.* 1998, 2004b). Gestation, based on the time from last day of mating to parturition, lasts 60–62 days. Pups are born with their eyes closed and without teeth, in a den dug by the ♀ in open ground, under a boulder or inside a rocky crevice. Five and six placental scars were counted in the uteri of two ♀♀. A seven-week-old unborn litter comprised three female and two male foetuses, averaging 122 g. A ten-day-old female pup had a mass of 650 g. The natal coat is charcoal grey with a buff patch in chest and inguinal regions. Two to seven pups emerge from the den after three weeks. At this time, the dark natal coat begins to be replaced by the pelage typical of the species. Pups are regularly shifted between dens, up to 1300 m apart. In eight out of 18 natal dens watched, a subordinate ♀ assisted the mother in suckling the pups (Sillero-Zubiri *et al.* 2004b). At least 50% of extra nursing ♀♀ showed signs of pregnancy and may have lost or deserted their own offspring before joining the den of dominant ♀.

Development of the young is divisible into three stages: (1) early nesting (Week 1 to Week 4), when the young are entirely dependent on milk; (2) mixed nutritional dependency (Week 5 to Week 10), when milk is supplemented by solid foods regurgitated by all pack members until pups are completely weaned; and (3) postweaning dependency (Week 10 to Month 6), when the pups subsist almost entirely on solid foods supplied by helpers. Adults have been observed providing food to juveniles up to one year old. Juveniles will join adults in patrols as early as six months of age, but will not urinate with raised leg until 11 months if male or 18 months if female. Yearlings have 80–90% of adult body mass. Full adult appearance is attained at two years. Both sexes become sexually mature during their second year. Only about 60% of ♀♀ breed successfully each year (Sillero-Zubiri *et al.* 1996a). A ♂ in Bale lived to 15 years, but 8–10 is the norm (C. Sillero-Zubiri pers. obs.).

Adult sex ratio in packs is biased toward ♂♂ 1.8 : 1 ($n = 59$), with small family groups closer to 1 : 1 (Sillero-Zubiri & Gottelli 1995b).

Predators, Parasites and Diseases No known predators, but unattended young may be taken by Spotted Hyaenas or Verreaux's Eagles *Aquila verreauxi*. Attacks of the Tawny Eagle *Aquila rapax* directed at small pups result in swift defence by guarding adults. The high densities and diversity of raptors (12 recorded species in Bale), many of which have been observed to feed on small mammals, are likely to pose the greatest competitive threat to Ethiopian Wolves. In addition, free-ranging domestic dogs, Golden Jackals and Servals *Leptailurus serval* may also feed upon the same prey species, and, therefore, will compete when food resources are limited. There is interference competition with domestic dogs, which will actively chase away Ethiopian Wolves from large carcasses. The Ratel *Mellivora capensis* is also a possible competitor for food and burrows (Sillero-Zubiri 1996).

The most widespread disease to affect Ethiopian Wolves is rabies, and is the main cause of mortality, killing whole wolf packs and accounting for a major population decline in Bale Mts with losses of up to 77% in 1991–92 (Sillero-Zubiri *et al.* 1996b, Haydon *et al.* 2002, Randall *et al.* 2006). In 2003–2004 and 2008–2009, rabies epizootics had a similar impact; the outbreaks were contained through parental vaccination (Randall *et al.* 2004, 2006, Johnson *et al.* 2010). Elsewhere, rabies has been reported in domestic dogs, livestock, people and wolves (Marino 2003b). The level of rabies awareness amongst people in the highlands, and the frequency of the reports, suggests high incidence across the highlands. In Bale, dogs travel regularly with their owners in and out of wolf range, and are in contact with many other dogs that are attracted to garbage and carrion in villages, and they may provide the vehicle for pathogens such as rabies or distemper to reach their wild relatives (Haydon *et al.* 2002). The risk of transmission, however, will depend on the probability of contact between wolves and dogs, which varies with grazing regimes in high-altitude pastures, dog husbandry and the spatial distribution of wolf habitat in relationship to settlements. High-density populations of Ethiopian Wolves are particularly vulnerable to decline due to rabies (Marino *et al.* 2006). A population viability model indicates that disease-induced population fluctuations and extinction risks can be markedly reduced with the vaccination against rabies of a relatively small

proportion of wolves (Haydon *et al.* 2002). Randall *et al.* (2006) present an integrated management strategy for rabies in Ethiopian Wolves combining long-term population monitoring, disease surveillance, conventional and emergency vaccination programmes, and advanced modelling techniques.

Other causes of mortality in Ethiopian Wolves include starvation of juveniles between weaning and one year of age, road kills and shooting. At least four animals have been killed by vehicles in Bale since 1988. Two others have been shot from the road and another two were left with permanent limps from collisions with vehicles.

Ethiopian Wolves are free of ectoparasites, perhaps because of the cold mountain climate; none were found on any of over 300 animals handled (C. Sillero-Zubiri pers. obs.). Nematodes and trematodes were present in faeces and carcasses, including *Taenia pisiformis* (M. Anwar pers. comm.).

Conservation IUCN Category: Endangered B1ab(iii,v); C1+2a(i), D. CITES: Not listed.

The Ethiopian Wolf is less common and less widely distributed now than in the past (Yalden *et al.* 1980, Marino 2003a). The main causes of this decline are loss of habitat to agriculture and grazing, disease, hybridization with domestic dogs and human persecution.

The highlands of Ethiopia are among the most densely populated agricultural areas within Africa. Habitat destruction and soil degradation have steadily reduced the afroalpine ecosystems, which increasingly resemble islands. Sixty per cent of all land above 3200 m has been converted into farmland, and all populations below 3700 m are particularly vulnerable to further habitat loss, especially if the areas are small and of relatively flat relief (Marino 2003b). Extensive overgrazing by livestock probably depresses rodent populations significantly, and in some areas habitat is threatened by proposed development of commercial sheep farms.

Human persecution is currently less severe than in the past and associated with conflicts over livestock losses (Marino 2003a). Some Ethiopian Wolf populations have been exterminated due to their reputation as predators of sheep and goats. Local people in Simien regard them as a menace to sheep, and report that they would come near the pens at night. In many regions, people living close to wolves believe numbers are recovering through successive years of good breeding and less persecution. Still, the degree of conflict due to predation determines the negative attitudes to wolves in some regions and resulting persecution (Marino 2003a). In the past, sport hunters occasionally killed Ethiopian Wolves, but no hunting is currently permitted and the species is protected by national law. Most of the range of the two largest populations, i.e. Bale and Simien, is protected within National Parks. There are no reports of exploitation for fur or other purposes, although parts of wolf skins were seen used as saddle pads (C. Sillero-Zubiri pers. obs.). There are no animals in captivity.

In western areas of Bale some Ethiopian Wolves had pale-coloured coats, heavily built bodies and kinky tails (Gottelli *et al.* 1994). One melanistic ♀ was heavier than any other ♀ captured, did not belong to any pack, and gave birth outside the breeding season; she twice lost her offspring after birth. Mitochondrial DNA restriction fragments and microsatellite alleles concluded that hybridization

occurred in areas with sympatric dogs, and was due only to crosses between female Ethiopian Wolves and male domestic dogs (Gottelli *et al.* 1994). Although hybrids are confined to parts of Bale, they may threaten the genetic integrity of the wolf population. Following hybridization, a population may be affected by outbreeding depression, or reduction in fitness, although to date this does not seem to have taken place in Bale.

Ethiopian Wolves have been monitored since 1983. The IUCN SSC Canid Specialist Group produced an action plan for the Ethiopian Wolf (Sillero-Zubiri & Macdonald 1997), providing a detailed strategy for the conservation and management of remaining wolf populations. This plan advocated immediate action on three fronts – education, wolf population monitoring and rabies control in domestic dogs – to conserve the afroalpine ecosystem and its top predator. As a result, the Ethiopian Wolf Conservation Programme (EWCP) was established in 1995 by the University of Oxford with support from the Born Free Foundation, UK. Its overall aim is to protect the afroalpine ecosystem and many of its rare highland endemic plants and animals through better management in Bale and the establishment of other conservation areas in Arsi, Menz and Wollo. The EWCP has taken a number of important steps, including: (1) a dog vaccination campaign in Bale and north Ethiopia; (2) sterilization programme for domestic dogs and hybrids in Bale; (3) community and school education programme; (4) strengthening the capacity of protected areas – funding patrolling and infrastructure; (5) surveys to determine the persistence and status of all populations of wolves; (6) monitoring of all wolf populations; (7) wolf vaccination interventions to mitigate rabies epizootics in the Bale Mts; and (8) setting up the Ethiopian Wolf Conservation Committee within Ethiopia as a national steering committee for dealing with conservation issues (see Sillero-Zubiri & Marino 2004). A conservation strategy and National Action Plan for the conservation of Ethiopian Wolves is now in place (IUCN SSC Canid Specialist Group 2011).

Measurements

Canis simensis

HB (♂ ♂): 963 (928–1012) mm, n = 18

HB (♀ ♀): 919 (841–960) mm, n = 8

T (♂ ♂): 311 (290–396) mm, n = 18

T (♀ ♀): 287 (270–297) mm, n = 8

HF c.u. (♂ ♂): 199 (193–209) mm, n = 18

HF c.u. (♀ ♀): 187 (170–197) mm, n = 8

E (♂ ♂): 108 (100–119) mm, n = 18

E (♀ ♀): 104 (95–110) mm, n = 8

WT (♂ ♂): 16.2 (14.2–19.3) kg, n = 18

WT (♀ ♀): 12.8 (11.2–14.2) kg, n = 8

Bale Mts, Ethiopia (Sillero-Zubiri & Gottelli 1994)

GENUS *Lycaon* African Wild Dog

Lycaon Brookes, 1827. In: Griffith *et al.* Anim. Kingd. 5: 151.

The genus *Lycaon* was first identified by Brookes in 1827 after revising an earlier description by Temminck (1820) who identified a specimen as *Hyaena picta*. Extant *Lycaon* are known only from sub-Saharan Africa with fossil evidence of early forms of *Lycaon* identified in Africa from 3 to 2 mya. However, fossil evidence of *Lycaon* from the late middle Pleistocene also exists from localities outside of sub-Saharan Africa and includes a *Lycaon* specimen from Israel (Stiner *et al.* 2001) and possibly *Lycaon*-like fossils in Europe (Kurtén 1968; but see Stiner *et al.* 2001).

Studies by Matthew (1924, 1930) and Simpson (1945) placed *Lycaon* within the subfamily Simocyoninae. This was largely based on a modification of the carnassial tooth or blade-like lower molar with a unicuspid talonid (trenchant heel) possessed only by three extant canid genera (all monospecific); *Lycaon* (the African Wild Dog), *Cuon* (the Asian Dhole) and *Speothos* (the South American Bush

Dog). These hypercarnivorous canids have teeth specifically adapted for processing meat unlike other canid genera that are adapted more for omnivory (Van Valkenburgh 1989). More recent analyses of morphological and molecular genetic data reject the monophyly of the Simocyoninae. These data strongly support *Lycaon* as a distinct genus associated with the wolf-like canids, which include species in the genus *Canis* (wolves, coyotes, jackals, domestic dog) and *Cuon* (Clutton-Brock *et al.* 1976, Van Gelder 1978, Wayne & O'Brien 1987, Girman *et al.* 1993, Tedford *et al.* 1995, Wayne *et al.* 1997). The combination of molecular evidence (Wayne *et al.* 1997) and a review of palaeontological evidence (Rook 1994) suggests that *Lycaon* may be the sister taxon to the wolf-like canids and one of its most basal lineages.

Derek J. Girman

Pelage pattern formation in African Wild Dog *Lycaon pictus*. (a) Generalized, semi-cryptic formation in genus *Canis*, as expressed in various jackals and wolves. (b) Similar pattern becoming more conspicuous through enhanced tonal contrast. (c) *Lycaon* pelage in which *Canis*-like format has been dislocated but elements are still perceptible. (d) *Lycaon* pelage in which dislocation has generated typical 'marbling' (individual from Longido, N Tanzania).

Geographic Variation African Wild Dogs in East Africa are smaller than those in southern Africa and were originally believed to represent distinct subspecific populations. African Wild Dogs in north-east Africa also tend to be predominantly black with small white and yellow patches, while dogs in southern Africa are more brightly coloured with a mix of brown, black and white. However, on the basis of genetic analysis, no subspecies are currently recognized (Girman & Wayne 1997, Girman *et al.* 2001).

Similar Species Spotted Hyenas *Crocuta crocuta*, Striped Hyenas *Hyaena hyaena* and even jackals (*Canis* spp.) and feral domestic dogs are occasionally misidentified as African Wild Dogs, but all are only distantly related and morphologically distinct.

Distribution Endemic to Africa; formerly distributed throughout sub-Saharan Africa, from desert (Lhotse 1946) to mountain summits (Thesiger 1970). In North Africa occurred as disjunct populations in S and SW Algeria; there are no confirmed records from Libya, but they persisted (as vagrants) in Egypt until the late 1800s (Osborn & Osbornová 1998). Probably absent only from lowland rainforest and the most arid deserts (Schaller 1972).

Current Distribution African Wild Dogs have disappeared from much of their former range (Fanshawe *et al.* 1997, Woodroffe *et al.* 2004, IUCN SSC 2008, 2009). In North Africa, they may still survive in S Algeria, but there is no recent information; they were last recorded in the Tassili N. P. in 1996 (K. de Smet pers. comm.). The species is virtually eradicated from West Africa, where populations survive in Niokolo-Koba N. P. in Senegal and in the protected areas complex between Niger, Benin and Burkina Faso (Lamarque 2004, P. Chardonnet pers. comm.). African Wild Dogs are similarly greatly reduced in central Africa, where the only surviving populations are known in N Central African Republic and Chad. In north-east Africa they survive in good numbers only in parts of Ethiopia and S Sudan. The largest populations remain in southern Africa (especially N Botswana/W Zimbabwe/E Namibia) and parts of East Africa (particularly S Tanzania and N Mozambique). Important but relatively isolated populations, persist in C Zambia (Kafue N. P.), C Kenya (Laikipia and Samburu) and E South Africa (Kruger N. P.) (IUCN SSC 2008, 2009).

African Wild Dogs are known, or presumed, to be extinct, or near-extinct, in Burundi, Cameroon, Congo, Côte d'Ivoire, DR Congo, Eritrea, Gabon, Gambia, Ghana, Guinea, Guinea-Bissau, Mali, Nigeria, Rwanda, Sierra Leone, Swaziland, Togo and Uganda (updated from Fanshawe *et al.* 1997, Woodroffe *et al.* 2004).

Abundance Historical records indicate that African Wild Dog populations have always existed at relatively low densities, with very occasional historical reports of large aggregations (e.g. Cumming 1850). Today they are rarely seen even in the few protected areas where they are relatively common. Density estimates vary widely for the few populations comparatively unconstrained by fences or human population expansion. These range from a low of 0.5 adults/100 km² in some areas associated with the dry Kalahari Desert in C Botswana and NE Namibia, to a high of 3.5–4.6 adults/100 km² in NW Botswana and the Selous G. R. in Tanzania (Woodroffe *et al.* 2004). Relatively small and somewhat more fragmented populations persist in several additional parts of their former range with densities that vary between these extremes. The cur-

Lycaon pictus

rent population of free-ranging African Wild Dogs remaining in Africa has been estimated at less than 8000 individuals, in ~750 packs, with the largest populations in N Botswana/E Namibia/W Zimbabwe/S Angola (~2500) and in S Tanzania/N Mozambique (1300). These estimates are based primarily on density estimates from studied populations, on knowledge of presence elsewhere and on habitat characteristics.

Habitat African Wild Dogs occupy a range of habitats, including short-grass plains, semi-desert, bushy savannas, woodlands and upland forest. While early studies in Serengeti N. P., Tanzania, led to the belief that they were primarily an open plains species, more recent data indicate that they reach their highest densities in thick bush and woodland habitats (e.g. Selous G. R., Tanzania; Mana Pools N. P., Zimbabwe; and N Botswana). African Wild Dogs have been recorded in desert (Lhotse 1946), montane (Thesiger 1970) and coastal scrub and woodland habitats (Temminck 1820). Several relict populations occupy dense upland forest (e.g. Harenna Forest, Ethiopia; Ngare Ndare Forest, Kenya), and they are also the only mammal species, other than humans, known to have reached the summit of Kilimanjaro at 5895 m (Thesiger 1970, Grimshaw *et al.* 1995) and are recorded from 4250 m on Mt Kenya (Young & Evans 1993) and 4050 m on the Sanetti Plateau in Ethiopia (Dutson & Sillero-Zubiri 2005). It appears that their current distribution is limited primarily by human activities (which they avoid; Woodroffe 2011a), the availability of prey, and disease, rather than by the loss of a specific habitat type.

Adaptations The teeth are adapted to holding and slicing and show a much lesser function of grinding than in some other canids. The outer upper incisors are larger than the central ones, heavily built and recurved; they wear to sharp edges to assist the short, sharp-pointed canines in holding prey. The outer incisors in the lower jaw are less well developed. The back portion of the lower first molar is sectorial, adding to the slicing ability of the carnassial mechanism. The crushing function is performed by the second upper molar and

Lateral, palatal and dorsal views of skull of African Wild Dog *Lycaon pictus*.

the lower second and third molars that are less developed than the remainder of the teeth (Skinner & Chimimba 2005).

One of the most striking peculiarities of African Wild Dogs is their extraordinary tri-coloured mottle pattern, which is never the same in any two individuals and is almost without precedent in a wild mammal, although it does resemble the artificially selected polymorphisms of several domestic animal species. The conspicuous white tail-tip resembles a flag, and playing pups try to bite the white tip while chasing one another (Kuhme 1965a). Bold patterns have also been interpreted as helping scattered pack members to keep in visual contact and maintain group cohesion (Schaller 1972). Other authors have suggested that the main function of individual variation in colour is to aid recognition within the pack (Ewer 1973). Although it appears conspicuous to the human eye this type of patterning has been interpreted as camouflage by some observers because it breaks up the body's contours. Its adaptive value has also been linked to the social disciplines that maintain pack cohesion (Kingdon 1977).

African Wild Dogs can run at speeds of up to 60 km/h, and are specially adapted to deal with the heat stress that this involves (Taylor *et al.* 1971).

Foraging and Food African Wild Dogs are cursorial predators that opportunistically hunt medium-sized antelope. Many of the common prey species are more than twice their size, the average weighing around 50 kg, and may be as large as 200 kg (Creel & Creel 2002). In most areas where African Wild Dogs persist in relatively large numbers, their principal prey are Impala *Aepyceros melampus*, comprising, for example, around 54% of their prey in Selous G. R. (Creel & Creel 2002), more than 80% of their diet in Moremi G. R. in

N Botswana (McNutt 1996a) and as much as 94% of their diet in Kruger N. P. (Pienaar 1969, Reich 1981, Mills & Biggs 1993, Mills & Gorman 1997). In some habitats (and sometimes even in areas where Impala populations are not necessarily low), several other species take over as primary prey. These vary with habitat type and region but include in particular Greater Kudu *Tragelaphus strepsiceros* and Springbok *Antidorcas marsupialis* in southern Africa, and Thomson's Gazelle *Eudorcas thomsonii* and Common Wildebeest *Connochaetes taurinus* in East Africa (Estes & Goddard 1967, Schaller 1972, Fanshawe & FitzGibbon 1993, Creel & Creel 1995); for example, in Aitong, Kenya, Thomson's Gazelle made up 67% of prey compared with only 17% Impala (Fuller & Kat 1990). Similarly, in Kafue Valley, Zambia, Impala made up only 2% of kills whereas Common Duiker *Sylvicapra grimmia* and Common Reedbuck *Redunca arundinum* made up half their prey in about equal parts, with Lichtenstein's Hartebeest *Alcelaphus buselaphus lichtensteini* accounting for about 15% (Mitchell *et al.* 1965).

African Wild Dogs will chase, but rarely kill, larger species, such as Eland *Tragelaphus oryx*, Roan *Hippotragus equinus* and African Buffalo *Syncerus caffer*. More typically, calves of these species are targeted when encountered. Small antelopes, especially Common Duiker, dikdik *Madoqua* spp. and Steenbok *Raphicerus campestris*, are important in some areas. Warthogs *Phacochoerus* spp. are taken in some populations. In Samburu and Laikipia Districts, Kenya, dikdik made up 70% of the biomass consumed by African Wild Dogs, with Impala comprising 11% (Woodroffe *et al.* 2007b). African Wild dogs also opportunistically capture relatively smaller prey such as small carnivores like Bat-eared Foxes *Otocyon megalotis* (Rasmussen 1996), Black-backed Jackals *Canis mesomelas* (Kamler *et al.* 2007) or Banded Mongooses *Mungos mungo* (Creel & Creel 2002), hares, springhares *Pedetes* spp., francolins, lizards and even eggs, but these constitute a small proportion of their diet.

African Wild Dogs travel and hunt in packs. Hunts typically take place around the first and last hour of daylight and are preceded by a 'social rally' or 'greet' believed to alert and collect the pack in anticipation of departure (Kuhme 1964b, 1965a, Kingdon 1977). Occasionally, hunts can begin before dawn or extend after dusk. They commonly also hunt on moonlit nights. Typical capture is as follows: one dog bites and holds the quarry, usually at the flank, and other pack members help pull it to ground and quickly kill it by disembowelling. In some hunts, usually involving large prey, one pack member may effectively immobilize the prey by biting and holding its nose while others make the kill. Hunts can appear to be highly coordinated events, but in many areas, particularly typical woodland habitats with dense brush understorey, packs tend to split during hunts with individual dogs opportunistically chasing and often bringing down prey alone. In the Selous, successful chase distances varied from 50 m to as much as 4.6 km (n = 304, Creel & Creel 2002).

Although hunting is not necessarily cooperative, feeding at kills, in contrast, is highly coordinated and cooperative. In general, prey is consumed rapidly – Van Lawick & Van Lawick-Goodall (1970) recorded the consumption of a Thomson's Gazelle in 15 minutes – and quietly by the entire pack with several individuals pulling against others to facilitate the rending of the carcass. When pups are travelling with the pack a system of priority of access is given to the youngest first and reinforced by the dominant pair. Otherwise, all members of the pack eat together rapidly and leave a carcass after eating. If they have left pups somewhere, they return to the pups and regurgitate meat to them. Caching of food has also been recorded (Malcolm 1980).

Hunting success is relatively high in comparison with some other large carnivore species. In Serengeti N. P. 44% of hunts ($n = 666$) were successful (see Creel & Creel 2002, based on pooled data from studies of Schaller 1972, Malcolm & Van Lawick 1975, Fuller & Kat 1990, Fanshawe & FitzGibbon 1993), which is the same as hunting success of animals in Selous G. R. (Creel & Creel 2002). Hunting success also varies with prey; in their study in the Selous, Creel & Creel (2002) noted that Impala were not only hunted most often (40% of hunts) and killed most often (54%), but also yielded the highest hunting success (64%). Zebra, on the other hand, provided the most mass per kill, but were rarely killed, with a probability of killing (7%) far lower than other species (presumably because zebra are dangerous to hunt).

As a result of social hunting, each pack member has a higher foraging success (measured as kg killed per km chased) than it would if it hunted alone: hunting success increased from 42% in packs of three adults to 67% in packs of 20 adults while the mass of prey killed increased from 16 kg to 40 kg and the distance chased decreased from 1.1 km to 0.5 km, accordingly (Creel & Creel 1995). Small packs are more selective in their hunting decisions, likely because they are not as effective as larger packs in hunting larger prey (Creel & Creel 2002). Larger packs are able to utilize larger, more profitable prey species (e.g. Common Wildebeest; Creel & Creel 2002), and are better able to defend their kills against scavenging hyaenas (Fanshawe & FitzGibbon 1993; though see Carbone *et al.* 1997). African Wild Dogs themselves very rarely scavenge (Mills & Biggs 1993), although they have been observed appropriating kills of Leopards *Panthera pardus*, Lions *P. leo* and Spotted Hyaenas (Kruuk 1972, Creel & Creel 1995).

Consumption rates in the wild vary from 1.2 to 5.9 kg/dog/day. In East Africa, a pack of 17–43 African Wild Dogs killed an average of at least three animals per day (independent of size or composition of the pack), consuming 1.7 kg/dog/day (Fuller & Kat 1990), which compares favourably with the findings of Creel & Creel (2002) in the Selous (where food consumption averaged between 2.0 and 2.5 kg/dog/day). Observations in the Selous suggest an animal can consume 8–9 kg in one sitting (Creel & Creel 2002).

Social and Reproductive Behaviour African Wild Dogs are intensely social animals, spending virtually their entire lives in close association with other dogs (e.g. Kuhme 1965a, McCreery 2000). They are obligate social breeders that live in a close kin-related pack. A pack, then, rather than a pair of individuals, should be considered the basic reproductive unit within the population. A pack, defined by its potential for reproduction, is rarely static in membership for extended periods. Rather, pack membership typically changes throughout the year due to relatively high rates of mortality, dispersal and high variance in reproductive success. By definition a pack may be as small as a pair, but packs with fewer than four adults often dissolve or extinguish following unsuccessful attempts to rear pups through to one year. In Botswana, of 11 packs comprising fewer than four adults, only one (a pair) successfully raised pups to one year. Three had pups but lost them all to other predators before they were four months old. No pack of the 10 small packs that failed survived to attempt a second litter (J. W. McNutt pers. obs.). In contrast, in Kenya three packs of 3–4 adults all successfully raised pups and grew in size, although their reproductive success was lower than that of larger packs (Woodroffe 2011b). The low success of small packs provides empirical evidence of an Allee effect for African Wild Dogs that should

be incorporated into population viability estimates for all populations (Courchamp *et al.* 2000, 2002, Courchamp & Macdonald 2001; but see Buettner *et al.* 2007). Pack size varies between populations and also within populations over time (average range 5.9–13.2 from six studied populations), but the cumulative average pack falls roughly on the median: 9–10 adults, including yearlings ($n = 221$ pack-years) (Woodroffe *et al.* 2004). Packs greater than 30 adults and yearlings have been recorded in the comparatively large remaining populations in Botswana (max. = 36) and Tanzania (max. = 44). In the past, much larger, but very rare aggregations have been reported. In the nineteenth century packs of several hundred dogs were recorded in South Africa (Cumming 1850). In the 1920s an aggregation travelling across Masailand in S Kenya was estimated in the region of 500 dogs as described by Blixen (1937).

Both ♂♂ and ♀♀ emigrate from their natal packs in groups, with ♀♀ typically dispersing a year earlier than ♂♂. As with most mammals, ♂♂ disperse further than ♀♀, which often establish reproductive territories that incorporate part of their natal area (McNutt 1996a). Packs are formed when small same-sex subgroups (usually full siblings and litter-mates) leave their natal group and join subgroups of the opposite sex from other packs (McNutt 1996a, McCreery & Robbins 2001). In a new pack, therefore, the ♀♀ (mean = 2) are typically closely related to one another, but not to the ♂♂, and the ♂♂ (mean = 3–4) are closely related to one another, but not to the ♀♀. Offspring produced by the dominant pair are, therefore, typically related to all adults in the pack. In this sense most African Wild Dog packs represent an extended kin group, within which all dogs are closely related to others in the pack. However, it is not uncommon (25% of observed packs in Botswana) for packs to have an adult unrelated to any of the others as a consequence of stochastic events affecting subgroup membership among packs in transition, especially adoption of unrelated pups (McNutt 1996b, McNutt *et al.* 2008). As a result, inferences cannot be made safely about the kin relationships within any pack without a thorough knowledge of the history of the pack members. Occasionally, new packs form by fission of large packs, with some of the original founders of both sexes emigrating together in a secondary dispersal event. In such situations pups might remain with the natal pack or join the secondary dispersal group, irrespective of the whereabouts of their parents. The priority of access to meat in favour of the youngest animals (and reinforced by the dominant pair, as mentioned earlier) has implications for social structure. Older ♂♂ that had been designated as dominant have been recorded being replaced, after serious fighting, by young ♂♂ (Creel & Creel 2002). The susceptibility of adults to coercion (notably to regurgitate meat) by very young animals and a tendency for adult ♂♂ from the youngest cohorts to achieve dominant status has been called the 'youth first protocol' (Burrows 2004).

African Wild Dogs have large home-ranges for their body size and the mean is 606 km² ($n = 50$ packs) across habitats. However, these ranges vary widely between habitats (probably with prey density and availability) from 150 km² in the lowveld savanna woodlands of Kruger N. P. ($n = 20$ packs; Fuller *et al.* 1992a) to more than 2000 km² in the arid habitats of southern Africa, such as the Kahalari (J. W. McNutt pers. obs.), where prey populations live at comparatively low densities and are widely dispersed, and in Serengeti N. P. where migratory prey is only seasonally abundant. During the 3–4 months while feeding young pups at a den, packs are

confined to relatively small areas (50–200 km²), but the rest of the year a pack ranges widely within their much larger territory.

Although neighbouring African Wild Dog packs overlap along boundaries, African Wild Dogs should be considered territorial. They rarely enter other packs' core areas and they defend their ranges infrequently but aggressively, occasionally with fatal consequences, against intruders and unrelated neighbours. The large territories of packs translate into very low population densities typical for the species. Even packs that inhabit protected areas may travel extensively outside reserve borders, where they encounter conflict with human activities and threats such as roads, snares and livestock and game farmers likely to persecute them. African Wild Dogs of both sexes emigrating from their natal packs may range over extremely wide areas compared with territory sizes. Dispersing African Wild Dogs have been tracked over hundreds of kilometres (Fuller *et al.* 1992b), a characteristic that could account for the occasional reports of single animals, or single-sex groups from countries such as Uganda, DR Congo and Swaziland, where there have been no resident populations for several decades. It can also account for the occasional re-colonization of formerly occupied habitats such as the Serengeti ecosystem, Laikipia and Savé Valley in Zimbabwe.

African Wild Dogs have a complex communication system, including a number of unique vocalizations (Robbins 2000), as well as olfactory communication both within and between packs (Van Heerden 1981, M. Parker pers. comm.). Territory boundaries appear to be predominantly communicated through scent-marking with faecal and urine marks by the dominant pair. Semio-chemical communication is also important in maintaining pack cohesion during hunting in bush habitats. Most vocalizations are for intra-pack communication and are generally high frequency, and relatively low in volume and broadcast quality. Food-begging calls are typically twittering. Whines combine with body postures to suggest an appeasing function and yelps denote the anticipation of food. Broadcast inter-pack vocalizations such as the howls typical of other canids (e.g. wolves, coyotes, jackals) are rare in African Wild Dogs and only occur in the specific context of direct interactions between residents and intruders. This rare vocalization is a howl-like duet projected at the ground by the resident pack's dominant pair immediately following inter-pack encounters (J. W. McNutt pers. obs.). Even the commonly described intra-pack contact call, or 'hoo call' used to regroup a dispersed pack or a lost individual is only used conservatively, perhaps to minimize chances of alerting other large predators such as Lions and Spotted Hyaenas to their location (Webster *et al.* 2010).

In a pack larger than two adults the reproductive pair consists of the dominant ♂ and the dominant ♀ (Frame *et al.* 1979, Malcolm & Marten 1982). In most African Wild Dog packs, the dominant ♀ is the mother of all the pups, although two or even three ♀♀ may breed on some occasions. Similarly, the dominant ♂ fathers most of the pups but multiple paternity has been reported (Girman *et al.* 1997). All pack members are involved in caring for the pups and dominant ♂♂ are usually no more assiduous in caring for pups than are other ♂♂ in the pack (Malcolm & Marten 1982). There is some evidence to suggest that pup survival is higher in large packs where there are more helpers to assist with their care (Creel *et al.* 1997).

The advantages in terms of survival and reproduction associated with larger packs, including increased hunting success, appears to predispose African Wild Dogs to an unusual willingness to adopt pups irrespective of their relatedness. Adoption (provisioning and protection) of pups

African Wild Dogs *Lycaon pictus* action drawings. Note the solicitation-like postures during 'social rallies' (right foreground).

by free-ranging animals carries few costs to an average pack preying on medium-sized prey, and the predisposition has provided important management options for isolated populations and for African Wild Dogs living in conflict with domestic livestock (McNutt 1996b).

Pups are born in an underground den that they use for the first three months of life. Such dens are usually those of Aardvark *Oryzomys azer*, and are often enlarged and modified by Cape Porcupines *Hystrix africaeaustralis* or Spotted Hyaenas. Dens may also take the form of small caves or other suitable structures in rocky formations. The mother is confined to the den during early lactation, and is reliant on other pack members to provision her during this time. Pack members feed the mother, and, starting from about four weeks of age, the pups by regurgitating solid pieces of meat. Some pack members also 'baby-sit' the pups, and chase predators off while the remainder of the pack is away hunting. These adults sometimes join the pups in begging for food when the provisioners return.

Reproduction and Population Structure Births occur roughly annually. In southern Africa, pups are born between Apr and Sep, with a peak during the dry season in late May and early Jun. Following a gestation period of approximately 71–73 days (J. W. McNutt pers. obs.), ♀♀ whelp large litters for their body size, averaging 8–11 and occasionally as many as 21 pups (Fuller *et al.* 1992b). Birth-weight is approximately 300–350 g and pups are born blind. Pups are generally fully weaned by eight weeks but continue to use a den for refuge until 12–16 weeks of age. African Wild Dogs reach sexual maturity in their second year of life, and it is common for ♀♀ to first reproduce at this age though ♂♂ commonly delay another year (McNutt 1996a). However, reproductive suppression of subordinates of both sexes means that disproportionately few of those that live to reproductive age ever reproduce directly (Creel *et al.* 1997).

African Wild Dog populations have been widely reported to have male-biased sex ratios both at birth and among adult populations. Although some populations occasionally show deviations in favour of female pups (Fuller *et al.* 1992a), long-term observations (McNutt & Silk 2008) statistically support the male-biases first reported in Serengeti N. P. by Frame *et al.* (1979).

In Kruger N. P. and N Botswana, no African Wild Dog has survived more than 11 years, and most dogs studied in Selous lived six years or less (Creel & Creel 2002). In captivity, record longevity is 15 years (Weigl 2005). Annual age-specific adult mortality is generally quite high for African Wild Dogs compared with other large carnivore species (range 20–57%), but it varies with other demographic characteristics such as fecundity, litter-size and pup survival among populations. Pup mortality during the first year of life is relatively high, and averages around 50% in most populations. However, mean litter-size and variance in pup survivorship vary widely among populations. Juvenile survival has been shown to be an important variable in a population's long-term growth and stability (Creel *et al.* 2004), although adult mortality is also important. Buettner *et al.* (2007) investigated the influence of rainfall and pack size on juvenile survival from den emergence to 12 months of age in Kruger N. P. (based on data on 30 packs monitored over a period of 15 years), and found that past rainfall significantly influenced pup survival up to nine months of age, such that pups benefited from preceding dry periods. The positive effects of pack size on juvenile survival only became evident for pups older than nine months. Consequently, survival of juveniles as well as adults has been flagged as a focal point for assessing population status and conservation action.

Predators, Parasites and Diseases Competition with larger predators has a major impact on African Wild Dog behaviour and population biology (Creel & Creel 1996, 2002, Mills & Gorman 1997). There is a large degree of dietary overlap between African Wild Dogs and Spotted Hyaenas and Lions (see Creel & Creel 2002), and the latter two species will steal kills from African Wild Dogs, particularly in open areas, such as the Serengeti and Ngorongoro Crater, where such kills are easily located (Kruuk 1972, Fanshawe & FitzGibbon 1993). Loss of kills to other predators is much less common in well-wooded ecosystems (such as Kruger and the Selous). For example, Fanshawe & FitzGibbon (1993) found that Spotted Hyaenas were present at over 85% of all kills of Common Wildebeest and Thomson's Gazelle in Serengeti N. P. (24.5% of which were appropriated by hyaenas); on the other hand, Creel & Creel (1996), in the more densely vegetated Selous, reported their occurrence at only 18% of kills (of which only 2% were appropriated by hyaenas).

The high metabolic rate of African Wild Dogs means that prey loss to competitors has the potential to seriously impact their energy balance: a model based on data from Kruger suggested that dogs must spend about 3.5 hours/day hunting in order to meet their energy requirements but would need to increase this to some 12 hours if they lost 25% of their food (Gorman *et al.* 1998). Despite earlier suggestions (Fanshawe & FitzGibbon 1993), the benefits of increased group size for the purpose of defending the carcass against kleptoparasites such as Spotted Hyaenas might be countered by increasing intra-specific competition for food as pack size increases. Small groups would probably be particularly vulnerable to kleptoparasitism, because they would not be able to consume enough food before the hyaenas

appropriated the kill, and medium-sized groups may, therefore, be most effective to meet energy and nutritional demands (Carbone *et al.* 1997). As such African Wild Dogs seem to fare well where interference competition is minimal. However, where Spotted Hyaena density is high and visibility good, hyaenas can accumulate at kills in sufficient numbers to negatively impact foraging success (Creel & Creel 2002).

The degree of competition between African Wild Dogs and Lions is less clear, but predation by Lions (outside the context of kills) is a principal cause of natural mortality in African Wild Dogs. Lion predation accounted for 9% of 45 known-cause deaths in Selous (Creel & Creel 1996, 2002), 33% of 57 deaths in Kruger (Van Heerden *et al.* 1995), and 50% of 14 deaths in Moremi (McNutt 1995). An attempt to reintroduce African Wild Dogs to Etosha N. P. in Namibia failed because they were hunted out by a pride of Lions over a period of weeks (Scheepers & Venzke 1995). Away from kills, Spotted Hyaenas also occasionally kill dogs of all ages (Ginsberg *et al.* 1995, Creel & Creel 2002, J. W. McNutt & R. Woodroffe pers. obs.), and Leopards and African Rock Pythons *Python sebae* have also been recorded killing animals.

Competition with larger carnivores could help explain the ranging behaviour of African Wild Dogs. While larger predators tend to occur at higher densities where prey species are relatively abundant, African Wild Dogs (like Cheetahs *Acinonyx jubatus*) tend to avoid these areas. Because they range in areas of comparatively low prey densities, they tend to occupy ranges effectively requiring greater travel distances during hunting. Naturally wide-ranging behaviour, and a preference for areas with reduced large predator densities, can explain in part why African Wild Dogs are often found in habitats outside of protected areas. As a result of changes in Lion and Spotted Hyaena populations, some habitats with suitable prey populations can become marginal or completely unsuitable for African Wild Dogs.

In addition to inter-specific competition, adults and pups have been killed in inter-pack clashes. Intra-specific competition caused 69% of known-cause deaths in Selous through conflict within and between packs (Creel & Creel 1998).

Infectious disease can also play an important role in the dynamics of some African Wild Dog populations. Pups appear to be particularly susceptible, with 26% of pup deaths attributed to disease in some populations (Woodroffe *et al.* 2007a). Many of the pathogens infecting African Wild Dogs are common canine pathogens that also infect domestic dogs and other wild canids, such as jackals and foxes. Some, such as canine coronavirus, adenovirus and herpesvirus, probably have little effect on populations: a high proportion of healthy adults show evidence of past exposure to these infections (Woodroffe & Ginsberg 1997, Alexander *et al.* 2010). At the opposite extreme, rabies virus can have major population impacts, especially in small populations. Rabies has been implicated in the 'disappearance' (see Marsden *et al.* 2012) of the African Wild Dog population in the Serengeti ecosystem on the Kenya–Tanzania border in 1990–91 (Gascoyne *et al.* 1993, Burrows 1995, Kat *et al.* 1995) and has hindered the re-establishment of packs in Madikwe G. R., South Africa (Hofmeyr *et al.* 2000, 2004) as well as killing animals reintroduced to Etosha N. P. in Namibia (Scheepers & Venzke 1995). Evidence suggests that rabies similarly caused the deaths of several packs in N Botswana in 1995 and 1996 (J. W. McNutt pers. obs.) and in N Kenya in 2005 (R. Woodroffe pers. obs.).

African Wild Dog populations cannot maintain rabies infection: rates of contact between packs are so low that all pack members would

be expected to die before coming into contact with other packs to which infection could be transmitted (Woodroffe & Donnelly 2011). Instead, infection appears to spill over from other, more abundant, host species. Domestic dogs are likely to be an important reservoir of rabies infection (Woodroffe & Donnelly 2011, Woodroffe *et al.* 2012), but jackals (Hofmeyr *et al.* 2000), foxes and hyaenas may also be involved. Large African Wild Dog populations occupying extensive wildlife areas appear able to persist in the face of occasional rabies outbreaks that extirpate a few packs (Woodroffe 2011b), but small, isolated populations may be driven to extinction in a single outbreak. Vial *et al.* (2006) and Prager *et al.* (2011) developed population viability models, which predict that vaccination campaigns, using vaccines that provide two years of immunity, and targeting 30–40% of individuals within a population every 1–2 years would be successful in ensuring persistence of small populations.

The impact of some other diseases on African Wild Dog populations appears more variable. For example, canine distemper virus can be highly pathogenic for captive animals (van de Bildt *et al.* 2002) and has caused episodes of high mortality among free-ranging dogs in Botswana (Alexander *et al.* 1996) and Tanzania (Goller *et al.* 2010). However, some populations show high levels of exposure to this virus, without any observed ill-effects (Woodroffe & Ginsberg 1997, Alexander *et al.* 2010, K. C. Prager pers. comm.). Likewise, while Creel *et al.* (1995b) showed that adults can recover from anthrax infection, and the Kruger N. P. population increased during anthrax outbreaks in the early 1990s (M. G. L. Mills pers. comm.), the population in the Luangwa Valley, Zambia, declined dramatically in association with an anthrax epidemic (Turnbull *et al.* 1991). The reason for this variation is unknown, though it is not restricted to African Wild Dogs. For example, canine distemper has been shown to occasionally cause high mortality in Lions, but no detectable ill effects at other times (Packer *et al.* 1999), with mortality apparently reflecting exposure to concomitant infection with other pathogens (Munson *et al.* 2008). There is no evidence that canine parvovirus causes mortality in adult African Wild Dogs, although it may be a factor in some pup deaths.

African Wild Dogs are known to carry infections of *Hepatozoon* spp. (K. C. Prager pers. comm.), and there is some evidence that *Toxoplasma gondii* can have an important effect on pup survival; in Kruger N. P. an entire litter of 20 pups disappeared, and four of the pups were confirmed to have succumbed to *Toxoplasma* and/or *Neospora* (a related protozoan) (Van Heerden *et al.* 1995). In Selous, dogs were commonly infected with cestodes and trematodes (Creel & Creel 2002), and in Kruger *Taenia* and *Ancylostoma* hookworms were found in faecal samples (Van Heerden *et al.* 1995). Penzhorn *et al.* (1998a) recovered *Sarcocystis* oocysts from a free-ranging animal. In Kruger, Van Heerden *et al.* (1995) recorded a number of ticks, including *Haemaphysalis leachi*, *Amblyomma hebraeum*, *A. marmoreum*, *Boophilus decoloratus*, and a number of species of *Rhipicephalus* (and see Horak *et al.* 2000).

Conservation IUCN Category: Endangered C2a(i). CITES: Not listed. CMS: Appendix II.

Historically, African Wild Dogs have been perceived to have a negative impact on 'game' populations (e.g. Bere 1955), and they are still commonly reviled especially by game farmers who consider them a serious problem because they prey on valuable game species (Lindsey *et al.* 2005b). An average pack preying on medium-size antelope kills on average two prey every three days, or approximately

220 individuals of medium-sized prey per year (J. W. McNutt pers. obs.). Therefore, the health of a Wild Dog population is dependent on the size and health of those prey populations (see McNutt & Gusset 2012). In large intact ecosystems such as that found in N Botswana, the impact of the African Wild Dog population on Impala, their primary prey, is estimated to be approximately 10–20% of annual rate of reproduction (J. W. McNutt pers. obs.).

African Wild Dogs are a threat to livestock in some areas, but stock depredation is infrequent compared with the frequency of range overlap with domestic grazers. In and around Masai Mara National Reserve, Kenya, African Wild Dogs ignored livestock, and data from Samburu and Maasai areas of N Kenya indicate that they rarely caused problems unless wild prey was severely depleted (Woodroffe *et al.* 2005). A two-year study of African Wild Dog depredation of commercial livestock in Zimbabwe found that African Wild Dogs actually killed approximately half the number of cattle believed by farmers to have been lost (representing an actual annual loss of 0.4% of the regional herd; Rasmussen 1999). African Wild Dogs hunting in livestock areas outside Selous G. R., Tanzania, were never observed to kill livestock in six years of observation (Creel & Creel 2002). Nevertheless, African Wild Dogs can become a severe problem for small domestic stock (including calves), especially in areas where native prey species populations have been reduced by hunting (Woodroffe *et al.* 2005). Multiple kills of small stock have been reported from a single attack by packs of African Wild Dogs in Kenya, Botswana and Namibia.

While pups die almost exclusively from 'natural' causes (see Reproduction and Population Structure), a substantial proportion of known mortality recorded among adults in studied populations is caused directly by human activity such as road kills and snares, even in some of the largest and best-protected areas (summarized in Woodroffe *et al.* 2007a). In addition, African Wild Dogs originating in protected areas often range outside the boundaries where they encounter high-speed vehicles, guns, snares and poisons.

The occurrence of African Wild Dogs in protected areas is described in detail elsewhere (IUCN SSC 2008, 2009). The largest populations inside protected areas occur in Selous G. R. and Ruaha N. P. (Tanzania), Moremi G. R. and Chobe N. P. (Botswana), Kaudom N. P. (Namibia), Kruger N. P. (South Africa), Hwange N. P. (Zimbabwe) and Kafue N. P. (Zambia). Their presence outside protected areas especially where they overlap with commercial game and livestock interests is often viewed as undesirable by the people involved in these developments, although research in N Kenya suggests that coexistence with people and livestock is possible where wild prey remain and where traditional livestock husbandry methods are still practised (Woodroffe *et al.* 2007b).

The important role played by human-induced mortality has two long-term implications. First, it makes it likely that, outside protected areas, African Wild Dogs may well be unable to co-exist with increasing human populations unless better protection and local education programmes are implemented. Second, African Wild Dog ranging behaviour leads to a very substantial 'edge effect', even in large reserves. Simple geometry dictates that a reserve of 5000 km² contains no point more than 40 km from its borders – a distance well within the range of distances travelled by a pack of wild dogs in their usual ranging behaviour. Thus, a reserve of this size (fairly large by most standards) could be, from an African Wild Dog's perspective, all edge. As human populations increase around reserve borders, the risks to African Wild Dogs venturing outside are also likely to increase.

Under these conditions, only the very largest reserves, if they remain unfenced, will be able to provide adequate protection for African Wild Dogs. In South Africa, fencing around quite small reserves has proved moderately effective in keeping dogs confined to the reserve, although, of course, genetic interchange between sub-populations must then be managed artificially, contributing to the high cost of such intensive management (Lindsey *et al.* 2005a).

Even in large, well-protected reserves, or in stable populations persisting largely independent of protected areas (as in N Botswana/NE Namibia), African Wild Dogs live at low population densities. Predation by Lions, and, perhaps, competition with Spotted Hyenas, contribute to keeping African Wild Dog numbers below the level that their prey base could support. Such low population density brings its own problems. The largest areas contain only relatively small populations; for example, the Selous, with an area of 43,000 km² (about the size of Switzerland), is estimated to contain about 800 African Wild Dogs. Most reserves, and probably most African Wild Dog populations, are smaller: for example, the population in Niokolo-Koba N. P. and buffer zones (about 25,000 km², larger than the state of Israel) is likely to be not more than 50–100 dogs. ‘Catastrophic’ events such as outbreaks of epidemic disease may drive small populations to extinction when larger populations have a greater probability of recovery – such an event seems to have led to the extinction of the small population in the Serengeti. Problems of small population size will be exacerbated if, as seems likely, small populations occur in small reserves or habitat patches. As discussed above, animals inhabiting such areas suffer a strong ‘edge effect’. Thus, small populations might be expected to suffer disproportionately high mortality as a result of their contact with humans and human activity (Alexander & McNutt 2010).

African Wild Dogs are legally protected across much of their known former range. However, legal protection is rarely enforced where they still remain and they may have been exterminated in several countries despite stringent legal protection. Outside reserves, legal protection may have questionable value when it concerns a species that comes into conflict with people, often in remote areas with poor infrastructure. Under such circumstances, legal protection may serve only to alienate people from conservation activities.

Virtually no conservation measures have been implemented specifically for African Wild Dogs. The establishment of very large protected areas (e.g. Selous, Kruger) has ensured their persistence in parts of eastern and southern Africa, and maintenance of large wildlife areas remains the highest priority for their conservation. Conservation priorities include: (i) to maintain and expand connectivity of habitat available to African Wild Dogs, particularly in numerous transboundary areas in N Botswana/E Namibia/W Zimbabwe, South Africa/W Mozambique/SE Zimbabwe, N South Africa/SE Botswana/SW Zimbabwe and S Tanzania/N Mozambique; (ii) to work with local people to reduce deliberate killing of African Wild Dogs in and around these areas, and also in smaller populations elsewhere; (iii) to establish effective techniques for protecting small populations from serious infections such as rabies and distemper; (iv) to carry out surveys to establish the status of other potentially important populations, particularly in Algeria, Angola, Central African Republic, Ethiopia, Mozambique and Sudan; and (v) to continue long-term monitoring of ‘sentinel’ populations to identify emerging threats. Re-establishment of extirpated populations through reintroduction currently has a low

priority in most areas, although natural recolonizations should be encouraged (Woodroffe *et al.* 2004).

GENUS *Vulpes*

Foxes

Vulpes Frisch, 1775. das Natur-System der Vierfüßigen Thiere, p. 15.

The genus *Vulpes* is present in North America, Europe, Africa and Asia, and was introduced to Australasia in the nineteenth century. It is represented by 11 species (Sillero-Zubiri *et al.* 2004a; although see Wozencraft 2005 who included the Arctic Fox *Alopex lagopus*), of which six occur in Africa: Cape Fox *Vulpes chama*, Rüppell's Fox *V. rueppellii*, Fennec Fox *V. zerda*, Pale Fox *V. pallida*, Blanford's Fox *V. cana* and Red Fox *V. vulpes*.

Each species occurs within communities that sometimes comprise several species of fox, and other canids, between which there is probably size-related competition. Cape Foxes are associated with open country and lightly wooded areas in southern Africa (where they may occur alongside the Black-backed Jackal *Canis mesomelas*, Bat-eared Fox *Otocyon megalotis* and African Wild Dog *Lycaon pictus*), particularly in the dry Karoo regions, the Kalahari and the fringes of the Namib Desert. Desert-dwelling foxes are widespread and present throughout their range in North Africa, but in most parts locally rare. The Pale Fox is one of the least-known canid species, typically inhabiting very dry sandy and stony sub-Saharan desert and semi-desert areas, but extending to some extent southwards into moister Guinean savannas where they may occur near human habitation. Well-developed molars suggest Pale Foxes are insectivorous and vegetarian, eating mainly arthropods, berries and wild fruit such as melons. The Rüppell's Fox is widespread in arid biotopes of desert and semi-desert regions of North Africa, the northern limit of which is the northern fringes of the Sahara Desert (and indeed into the Middle East), and are in many respects a scaled-down model of the Red Fox. They may occur alongside Red, Blanford's and Fennec Foxes, and jackals and wolves, and can survive without drinking water; they also live in coastal areas.

The Fennec Fox is the smallest canid (0.8–1.9 kg), although some Pale Fox and Blanford's Fox individuals are equally small. Fennecs have extremely large ears, the greatest ear to body ratio in the Canidae. They subsist in arid desert environments, preferring stable sand dunes. Blanford's Fox is a small fox with an exceptionally long and very bushy tail and, unlike the Fennec, naked foot pads for traction on steep terrain. Confined in Africa to the eastern fringes of the north-east (Peters & Rödel 1994) it is adapted to cliffs and steep, rocky slopes and canyons. Blanford's Fox is sufficiently elusive (and, like the other desert foxes, easily confused with other desert foxes) that its distribution is poorly known, so it may extend further south, into Sudan and Eritrea. It is primarily insectivorous and frugivorous and, in Israel (the only place where it has been studied in depth), eats mainly beetles and the fruits of caper bushes.

Although the most widespread extant canid, and very widely studied in the northern hemisphere, little is known of Red Foxes in North Africa. However, in the Middle East, where they have been studied, they are opportunistic foragers for small mammals, birds,

reptiles and invertebrates together with fruit. Although desert-dwelling Red Foxes are significantly smaller than their Palaearctic conspecifics, they are the largest members of the vulpine guild and hostile to their smaller congeners.

Vulpine foxes are characterized by a rather long, low body, relatively short legs, a long pointed muzzle, large triangular ears and bushy tails that are at least half as long as the head and body. The tail tip is often a different colour from the rest of the coat (e.g. black or white) but the presence of a white tail tag is not, as sometimes supposed, an indicator of the individual's sex; vulpine foxes have black, triangular face marks between eyes and nose. The pupils generally appear elliptical in strong light, and the vulpine skull is flattened in comparison with *Canis* species. Foxes have a pungent odour, characteristic particularly of their urine, while the odour of the Red Fox's supracaudal gland is sometimes characterized as reminiscent of violets. The odour of their anal sacs, in contrast, is strongly acrid, and these glands are evacuated when the animal is frightened, and their secretions probably also routinely coat faeces. Females usually have 6–8 nipples. Although once considered solitary, in some habitats vulpine foxes have territorial family groups of one ♂ and several related ♀♀, some of which may act as non-breeding helpers at the den. However, such groups are probably rare in the low carrying capacity of African arid habitats, although the poorly known Fennec Fox is thought sometimes to occur in larger social groups.

Vulpes has, in the past, been considered a subgenus of *Canis* (Van Gelder 1978), but is now widely regarded as generically distinct. Fennec Foxes have been placed in the genus *Fennecus* by some authors (Ellerman & Morrison-Scott 1951, Stains 1975, Coetzee 1977), but *Fennecus* is now generally included in the genus *Vulpes* (Clutton-Brock *et al.* 1976, Geffen *et al.* 1992d, Wozencraft 1993, 2005).

Thomas (1918) associated *Vulpes pallida* with Rüppell's Fox and the Fennec Fox. Clutton-Brock *et al.* (1976) support this grouping and suggest that these desert foxes are also closely related to the Indian Fox *V. bengalensis* and the Cape Fox. Blanford's Fox and Fennec Fox are an old radiation (3–4 million years) and are sister taxa, forming a monophyletic clade distinct from the other fox-like canids (Geffen *et al.* 1992d). This divergence of the Blanford's and Fennec from other vulpine foxes is thought to have coincided with the appearance of desert regions in the Middle East and North Africa (Wickens 1984). There is a second cluster of vulpine foxes – those that are Red Fox-like; the latter includes many of the Old World species as well as the Kit *V. macrotis*, Swift *V. velox* and Arctic Foxes (only recently evolved in the mid-Pleistocene; 0.5 mya).

Claudio Sillero-Zubiri & David W. Macdonald

Vulpes cana BLANFORD'S FOX (ROYAL FOX, HOARY FOX)

Fr. Renard royale; Ger. Afghanfuchs

Vulpes cana Blanford, 1877. J. Asiat. Soc. Bengal 46 (2): 321. Gwadar, Baluchistan, Pakistan.Blanford's Fox *Vulpes cana*.

The specific epithet *cana* (grey) refers to the colour of the species' pelage.

Taxonomy Monotypic. Genetic analysis has revealed that Blanford's Fox and the co-existing desert species, the Fennec Fox *Vulpes zerda*, are sister taxa forming a monophyletic clade distinct from the other fox-like canids (Geffen *et al.* 1992d). There is a single published record of this species' occurrence in Africa from Egypt (Peters & Rödel 1994), but its wider distribution on the continent is likely (Geffen *et al.* 1993, Peters & Rödel 1994). Accordingly, most data in this species account are based on studies of animals from its non-African populations, mainly from Israel. Synonyms: *nigricans*. Chromosome number: not known.

Description Small beige fox with slender face and pointed muzzle, and bushy and relatively long tail that almost equals its body length. Head orange-buff, especially in the winter coat, with black lacrimal stripe from the internal angle of the eye to the anteromedial part of the upper lip, extending over the muzzle to the chin. Iris almost as dark as the pupil. Ears pale brown on both sides, or grey on the back, with long white hairs along the anteromedial border. Pelage of body and tail brownish-grey, fading to pale yellow on belly, with dark mid-dorsal band on back and tail and distinctive dorsal black spot at base of tail, which usually has a black tip (in some individuals it is white). The fore- and hindfeet are dorsally pale yellowish-white, while posteriorly they are dark grey. Feet have blackish-naked pads, and claws are curved, sharp and semi-retractile. Winter coat is soft and woolly with dense, black underwool, dorsally sprinkled with white-tipped hair. Summer coat is less dense, fur is paler coloured and white-tipped hairs are less apparent. Juveniles have similar markings as adults, but coat is darker and more greyish. Slight sexual dimorphism in size, and some body measurements, but otherwise sexes are alike (Harrison & Bates 1991, Geffen 1994, Peters & Rödel 1994). Females have three pairs of nipples.

Skull is typically vulpine with noticeably slender rostrum and long and thin nasal bones. Postorbital processes well developed. Braincase is relatively narrow and weakly ridged; zygomatic width averages

*Vulpes cana*

about 50 mm. Tympanic bullae are relatively smaller than those of Rüppell's Fox *V. rueppellii*.

Geographic Variation The scarcity and scattered nature of records of Blanford's Fox from the species' large distribution range are insufficient for a sensible evaluation of possible causes of variation seen in some characters (size, pelage colour and markings) and their significance. Pelage colour of foxes from Iran and further eastward is predominantly grey, whereas in animals from the Arabian Peninsula, Israel and the one from Egypt the ground colour is beige. Animals from SW Arabia frequently have a white tail tip. Genetic data are necessary to clarify the situation.

Similar Species

Vulpes zerda. Smaller, with relatively shorter tail and larger ears. Sandy deserts and semi-deserts of North Africa from Morocco and Mauritania to Egypt and the Sudan.

V. rueppellii. Slightly larger, with relatively shorter tail and larger ears; long hair totally concealing the naked footpads. Widespread in desert and semi-desert regions of North Africa (north of 17° N) from Morocco and Mauritania to Egypt and Somalia.

V. vulpes. Larger, with relatively shorter tail and smaller ears. Coastal belt of North Africa from the hills of Morocco to Egypt and south along the Nile R. to N Sudan.

Distribution The only record of the species from Africa hitherto documented is an adult ♂ from Wadi Qiseib (29° 24' N, 32° 29' E), Governate Suez, Egypt (Peters & Rödel 1994), collected in 1988.

The closest records are from the S Sinai Peninsula (Jabal Umm Shawmar: 28° 22' N, 33° 55' E, Geffen *et al.* 1993; Jabal Sirbal: 28° 39' N, 33° 37' E, T. Wachter pers. comm.). A wider distribution than presently documented, along the western shore of the Red Sea, is likely (Geffen *et al.* 1993, Geffen 1994, Peters & Rödel 1994).

Main range is in arid mountainous regions from the Middle East eastward to Afghanistan and Pakistan and then north-eastward to Turkmenistan and Tajikistan (Geffen 1994, Peters & Rödel 1994, Geffen *et al.* 2004).

Habitat Mountainous desert ranges with steep, rocky slopes, canyons and cliffs but also occurs on various rock or gravel formations, irrespective of altitude (−400–3000 m). For example, in the United Arab Emirates (UAE) the southern Hajar, the Shimaliyya and the Rus Al Jibbal Mountains are the typical habitat of Blanford's Foxes.

Abundance Fairly common in SE Israel, the only region where the species has been studied in detail (Geffen 1994). An ongoing study in the UAE indicates that the species is fairly common in the eastern parts (Smith *et al.* 2003, C. Drew pers. comm). Abundance in other parts of the species' range is unknown. In Israel, 0.5–2 individuals/km² was recorded for the Judean and S Negev Deserts (Geffen 1994).

Adaptations Mendelssohn *et al.* (1987) described the jumping ability of Blanford's Fox as astonishing; captive individuals bounced from one wall to another or jumped to the highest ledges (2–3 m) in their cage with remarkable ease and as part of their normal movements. In the field, these foxes were observed climbing vertical, crumbling cliffs by a series of jumps up the vertical sections. Blanford's Fox has a relatively long, bushy tail, which is probably an important counter-balance during jumps and may function like a parachute (Geffen *et al.* 1992c). The small feet, naked pads and curved claws provide sure footing even on the narrow ledges of a vertical wall.

Blanford's Foxes in Israel are strictly nocturnal. Onset of activity is governed largely by light conditions, and closely follows sunset. Animals were active ca. 8–9 h/night, independent of duration of darkness (Geffen 1994).

Daily energy expenditure of free-ranging Blanford's Foxes near the Dead Sea was 0.63–0.65 kJ/g/day, with no significant seasonal difference (Geffen *et al.* 1992a). Mean rate of water intake is significantly higher in summer (0.11 mg/l/day) than in winter (0.08 mg/l/day). These foxes maintain water and energy balance on their diet of invertebrates and fruits, and forage more for water than for energy needs. In Israel these foxes consume more fruit during the hot summer, which compensates for deficiencies in body water (Geffen *et al.* 1992a, b).

Dens used by Blanford's Foxes in Israel usually were natural cavities under a large rock or boulder pile on a mountain slope, and the animals never dug burrows. Dens were used both for rearing young during spring and for day-time resting throughout the year. Frequent changes in location of den from day to day were more common in summer and autumn (Geffen & Macdonald 1992).

Foraging and Food Primarily insectivorous (mainly beetles, grasshoppers, ants, termites) and frugivorous (Ilani 1979, Geffen *et*

Lateral view of skull of Blanford's Fox *Vulpes cana*.

al. 1992b). Plant food in Israel consists mainly of the fruit of two caperbush species, *Capparis cartilaginea* and *Capparis spinosa*; fruits and plant material of *Phoenix dactylifera*, *Ochradenus baccatus*, *Fagonia mollis* and various species of Gramineae also were eaten. Remains of vertebrates were present in ca. 10% of faecal samples analysed. Diet differed significantly between two sites examined in Israel, but seasonal and individual differences were not detected (Geffen *et al.* 1992b).

Almost always forages solitarily (92% of 463 observations; Geffen *et al.* 1992b), only occasionally in pairs. Animals forage by searching between rocks in a small area, sniffing and looking under large stones and occasionally digging a shallow scrape; standing near a bush for a few seconds, alert with ears erect, prior to circling the bush or pouncing upon prey within it; or short, fast sprints after small terrestrial or low-flying prey. Average distance (\pm S.D.) travelled per night in Israel was 9.3 ± 2.7 km, and size of nightly home-range averages 1.1 ± 0.7 km² (Geffen & Macdonald 1992); there were no significant seasonal or sexual differences in duration of nightly distance travelled, or nightly home-range. Food caching is rare or absent, contrary to other fox species (Geffen *et al.* 1992b).

Social and Reproductive Behaviour Based on studies of Blanford's Foxes in Israel, the species lives in monogamous pairs in territories of ca. 1.6 km² with minimal overlap. During winter and spring, both members of a pair frequently occupy the same den, or adjacent dens at the same site, while during summer and autumn they often den in separate locations. Locations and configurations of home-ranges remained stable during a two-year study period. Shifts in the location of the home-range were observed only once following the death of a pair member. Three of five territories contained one, non-breeding yearling ♀ during the mating season, but there was no evidence of polygyny.

There are no specific data on details of social and reproductive behaviour and behaviour of young. Adult Blanford's Foxes have never been observed to carry food to the young and only one den was found with remains of prey at the entrance. Observations suggest that food is not regurgitated to the young, as in other small canids. There is no indication that the ♂ provides food either to the ♀ or to the cubs. Therefore, it appears that the direct contribution to survival of the young by any individual (other than the mother) probably is minimal. Young start to forage at about two months, accompanied by one of the parents, and at three months start to forage alone. Offspring often remain on their natal home-range until autumn (Oct–Nov) (Geffen & Macdonald 1992).

Two types of vocalizations have been recorded in adults: a high-pitched bark against intruders like Leopards *Panthera pardus* and humans and a greeting scream between pair members.

Blanford's Fox *Vulpes cana* action drawing of 'tail fluff'.

Reproduction and Population Structure Females are monoestrous and, in Israel, come into heat during Jan–Feb. Gestation period is ca. 50–60 days, and litter-size is one to three pups. Neonates are born with soft, black fur and weigh about 29 g at birth. Females have two to six active teats, and young are entirely dependent upon mother's milk until they begin to forage for themselves. Lactation period is 30–45 days. Based on repeated weighing of three young born in captivity, body mass of subadult (700–900 g) is reached in ca. 3–4 months. Sexual maturity is reached at 10–12 months of age (Mendelssohn *et al.* 1987, Geffen 1994).

Although they may live to four to five years in the wild, average longevity is 1.9 years; captives have lived to six years of age (Geffen 1994). Mortality rate, as likelihood of survival to the next month at two study sites in Israel, was 0.972 and 0.944.

Predators, Parasites and Diseases Primary causes of natural mortality are old age and rabies. Only a single known case of mortality

from predation was recorded, where the predator was suspected to be a Red Fox (Geffen 1994). Other likely predators include larger carnivores, such as Leopards. No other diseases have been documented (Geffen 1994). Individuals in poor body condition often have ticks.

Conservation IUCN Category: Least Concern. CITES: Appendix II.

In Africa, the known distribution range is not within any protected area and the species has no legal status. It is not trapped in Egypt, and no information is available on mortality causes or the status of this population. Elsewhere, the species is threatened by habitat loss.

Vulpes chama CAPE FOX (SILVER FOX)

Fr. Le Renard du Cap; Ger. Kapfuchs

Vulpes chama (A. Smith, 1833). S. Afr. Quart. J. ser. 2, 2: 89. 'Namaqualand and the country on both sides of the Orange river', determined by Shortridge (1942: 41) as 'Port Nolloth, Little Namaqualand' [South Africa, ca. 29°15' N, 16°52' E].

Cape Fox
Vulpes chama.

Taxonomy Monotypic (Meester *et al.* 1986). Synonyms: *hodgsoni*, *variegatoides*. Chromosome number: not known.

Description The smallest canid and only true fox occurring in southern Africa. Slender build with bushy, black-tipped tail. Upper parts grizzled silver-grey, with lower limbs, face and back of ears reddish-brown to pale tawny-brown; upper chest fawny-red, with underparts off-white to pale fawn, often with a reddish-brown tinge. Head, and back of the long ears, reddish-fawn with some freckling of white hairs on face; front of ears also fringed with white hairs. Upper region of front legs reddish-yellow, paler towards paws, with a dark brown patch on backs of thighs of hindlegs. Overall, body pelage soft, with dense underfur of wavy hairs about 25 mm long. Hairs grey at base, buffy above. Underfur overlaid by thick guard coat, with individual hairs averaging 45 mm in length, predominantly black but with light-

coloured bases and banded silver. Slightly longer black tactile hairs scattered through the body coat. During the moulting period, from Oct to Dec, much of the guard coat is lost, giving the animals a rather dull and 'naked' appearance. Tail very bushy with individual hairs 55 mm long, with buffy-white bases and broadly black or dark brown towards the tips. Upper surfaces of paws pale fawn to reddish, with sharp curved claws, ca. 15 mm long on the curve, on the front feet. Pronounced hair growth between the foot-pads. Males slightly larger than ♀♀. Females have one pair inguinal and two pairs abdominal nipples.

Skull narrow and elongated (about 115 mm in length), with narrow rostrum and weak zygomatic arch. Mandible narrow and lightly built; bullae large relative to size of skull. Canines long, slender and strongly curved and the two upper molars are broad as an adaptation to crushing.

Geographic Variation None recorded.

Similar Species

Otocyon megalotis. Broadly sympatric in southern Africa. Similar in size, but more bushy silvery-grey to beige pelage; very large dark-backed ears; legs black; bushy tail black above and at tip.

Distribution Endemic to Africa, and largely restricted to southern Africa, being extralimital only in extreme SW Angola, to about 15° N (Crawford-Cabral 1989a). Widespread in arid and semi-arid C and W Namibia, Botswana and South Africa, but also occurs in areas with denser vegetation and receiving higher rainfall, such as fynbos biome of the Western Cape (Skinner & Chimimba 2005).

Current Distribution Has expanded its range over recent decades to the south-west, where it reaches the Atlantic and Indian Ocean coastlines (Stuart 1981). Expansion through the Eastern Cape of South Africa has been documented (Coetzee 1979). Status of the species in Swaziland is uncertain, but there are sight records from Nhlanguano and Mhlambanyatsi (Monadjem 1998); it occurs in adjacent regions of NW KwaZulu–Natal in South Africa (Rowe-Rowe 1992a). Not yet recorded from Lesotho, but may occur (Lynch 1994). Previous records of its occurrence in W Zimbabwe (Roberts 1951, Coetzee 1977) and Mozambique (Travassos Dias 1968) remain unsubstantiated, and it is unlikely that these records are valid.

Habitat Mainly open country, including grassland, grassland with scattered thickets, arid scrub and lightly wooded areas in a precipitation range of between 100 and 500 mm per annum, although in KwaZulu–Natal they have been recorded between 1000 and 1500 m above sea level, where annual rainfall is roughly 720–760 mm (Rowe-Rowe 1992a). Prefer open scrub country and grassland, and are particularly associated with dry pans in arid Karoo, Kalahari and fringes of the Namib Desert. Also penetrates moderately dense scrub of Lowland Fynbos in SW South Africa, as well as agricultural lands (Stuart 1981), lying up in pockets of natural vegetation by day. Along the eastern flank of the Namib Desert and C South Africa they occupy rock outcroppings, inselbergs and kopjes, ranging out onto the plains at night (Stuart 1975, O. B. Kok & J. A. J. Nel unpubl.). In Botswana, they have been recorded from *Acacia*-scrubland, short grassland and especially on the fringes of shallow seasonal pans, as well as cleared and overgrazed areas (Smithers 1971).

Vulpes chama

Abundance Common to fairly abundant across most of its range, although problem animal control activities have resulted in population reductions in some areas. In the Free State, South Africa, an average density of 0.3 foxes/km² was estimated (total population of 31,000) (Bester 1982). Annual offtake from problem animal control operations averaged 16% up to 1985, with no obvious declines in overall populations (Bester 1982). Range and numbers have increased in SW and E South Africa (Stuart 1981).

Adaptations Large ears, bullae and auditory meatus suggest enhanced detection of prey and predators. Long rostrum and long,

Lateral, palatal and dorsal views of skull of Cape Fox *Vulpes chama*.

thin canines would aid capture of small prey, such as rodents. Molar teeth high cusped, facilitating crushing of insects. Thick coat aids thermoregulation in exposed habitats at low ambient temperatures during winter nocturnal foraging. Nocturnal activity could serve to reduce predation, especially by larger diurnal raptors, and coincides with the activity period of small rodents, an important prey. Changing dens could avoid accumulation of parasites and confuse predators (Bester 1982). The bushy tail serves as a counterbalance to the body when a fox makes sudden sharp turns during a hunt or when trying to evade predators. This accounts for the colloquial Afrikaans name *draaijakkals* (= 'jackal that makes turns').

Foraging and Food Omnivorous. Prey includes small rodents (murids), hares, reptiles, birds and invertebrates (e.g. arachnids, beetles and termites); Cape Foxes also eat some wild fruits (Bothma 1966b, 1971c, Lynch 1975, Stuart 1981, Bester 1982, Kok 1996, Kok & Nel 2004, Skinner & Chimimba 2005). In most studies, rodents are the most important mammal prey, with beetle larvae and adults, and grasshoppers predominating among the invertebrates. The largest wild prey species recorded include hares (*Lepus* spp.) and the Southern African Springhare *Pedetes capensis* (Lynch 1975) and Steenbok *Raphicerus campestris* (Kok & Nel 2004). Birds and reptiles are occasionally eaten. Where Cape Foxes coexist with possible competitors, such as Black-backed Jackals *Canis mesomelas*, some separation in prey use occurs (Bothma *et al.* 1984, Kok 1996, Kok & Nel 2004). Prey use seems to reflect prey availability, and seasonal and yearly variation in prey use occurs, with murids being common in spring and summer, while other mammals predominate in winter (Bester 1982). When six weeks old, cubs already hunt insects (Bester 1982).

Cape Foxes also scavenge, eat carrion and occasionally take young lambs and goat kids less than three months (Stuart 1981, Bester 1982), but not poultry. Although some authors (Roberts 1951, Bothma 1966b) recorded no evidence of stock killing by Cape Foxes in their particular study areas, the seasons when samples were taken could have influenced their conclusions, as the majority of sheep farmers follow fixed lambing times. The highest incidence of lamb losses to the Cape Fox has been documented from the Free State, where Bester (1982) recorded that they may take 4.5% of the lamb crop; lambs killed by the Cape Fox are seldom older than four months.

Food is located mainly by hearing and smell. Animals forage singly (Bester 1982, Mills 1997), but occasionally may gather in loose groups at an abundant food source (Stuart 1981). Foraging is almost exclusively nocturnal, with activity peaks shortly after sundown and just before dawn. Much prey is obtained by rapid digging with the front paws, often preceded by intensive listening bouts. Caching prey is common (Bester 1982).

Social and Reproductive Behaviour Cape Foxes live in monogamous pairs (Bester 1982), but forage singly. Interactions between adults are rare; only 2.5% of time is spent in social contact (Bester 1982). Home-ranges in the Free State vary from 1.0 to 4.6 km² and overlap widely in some parts of the range (Bester 1982), but the area around the den forms a territory. In some parts of the range, such as the SW Kalahari, group territories can occur.

A series of behaviours eliminates aggression, but allogrooming is absent. A submissive crouch and inguinal presentation occur

(Le Clus 1971). Cubs exhibit a range of play behaviour, including solitary play, eliciting play from siblings, and to express dominance and submission (Bester 1982). Vocalizations (a high-pitched howl and a bark) are more common during the breeding season and when cubs disperse (Bester 1982). Facial expressions, but not tail positions, play a prominent role in visual communication (Bester 1982).

Young are born in burrows, which the adults may excavate on their own, enlarge existing ones of other species (such as Southern African Springhare *P. capensis* or South African Ground Squirrel *Xerus inauris*) or use alternatives such as rock crevices or even dense vegetation (Stuart 1981, Bester 1982). M. G. L. Mills (pers. comm.) has recorded dens with two litters in the S Kalahari, and Bester (1982) recorded eight pups in one den in the Free State, which is perhaps an indication of a similar occurrence. The male can provision the ♀ just after birth of pups, and both parents – especially the ♀ – provision young. Both parents will defend the pups against potential predators. The ♀ may bark when a potential predator approaches a den occupied by pups (Bester 1982). Helpers are absent or rare.

Reproduction and Population Structure Breeding appears to be aseasonal in some areas, but strongly seasonal in others. The majority of births take place in spring and summer (Aug to Oct), towards the end of the dry season when insect and rodent numbers are low. Smithers (1971) recorded a gravid ♀ in Oct, while births have been recorded in Aug and Sep in W South Africa (Stuart 1981), and Aug–Oct, with a peak in Sep, in the Free State (Bester 1982). Gestation lasts 51–52 days (Brand 1963). Litter-size in the Free State and Kalahari is much the same, with a mean of 2.9 (range 1–6, n = 16) and 2.8 (range 2–4, n = 5), respectively (Bester 1982). One litter is born per year. Weaning takes place at about 16 weeks and pups disperse at around five months of age (Bester 1982). Longevity is unknown, but unlikely to exceed six or seven years in the wild.

Predators, Parasites and Diseases Predators include Black-backed Jackals, Lions *Panthera leo*, Leopards *Panthera pardus* (see Mills 1984), Caracals *Caracal caracal* and Ratels *Mellivora capensis*. Some of these predators, such as Black-backed Jackals, are also competitors, and some separation in prey use is evident where they co-exist with these species (Bothma *et al.* 1984, Kok 1996, Kok & Nel 2004).

The following parasites have been recorded from animals in South Africa: fleas (*Ctenocephalides conatus* and *Echidnophaga gallinacea*), ticks (*Haemaphysalis leachi*, *H. silacea*, *H. zumpti*, *Rhipicephalus capensis*, *R. evertsi*) and tapeworms (*Taenia endotheoracicus*, *Joyeuxiella* sp. and *Mesocestoides* sp.) (Stuart 1981, Horak *et al.* 2000). Cape Foxes have a very low incidence of rabies, compared with other southern African canids (Swanepoel *et al.* 1993).

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Cape Fox suffers direct and indirect mortalities from problem animal control activities, particularly in South Africa and S Namibia. For example, in the Free State 4000 of these foxes were killed during organized control operations in 1974, and an average of 2000–3000 in each subsequent year (Bester 1978). However, direct and indirect problem animal control measures do not seem to have had a major impact on populations of the Cape Fox, even though they have resulted in declines in some areas. The illegal but widespread

and indiscriminate use of agricultural poisons on commercial farms poses the greatest threat. Cape Fox have several key populations in national parks and nature reserves, including Etosha and Skeleton Coast National Parks (Namibia), Central Kalahari G. R. (Botswana), Kgalagadi Transfrontier Park (South Africa and Botswana), and Addo, Augrabies Falls, Bontebok, Golden Gate, Karoo, Mountain Zebra and West Coast National Parks (South Africa) (Stuart & Stuart 2004). Expansion of semi-arid karroid vegetation has resulted in range extensions.

Vulpes pallida PALE FOX (PALLID FOX, AFRICAN SAND FOX)

Fr. Renard pale; Ger. Blassfuchs

Vulpes pallida (Cretzschmar, 1827). In: Rüppell, Atlas Reise Nordl. Afr., Zool., Säugeth. (dated 1826), 1 (2): 33, pl. 11. 'Kordofan' [Sudan].

Pale Fox *Vulpes pallida*.

Taxonomy Thomas (1918) associated *V. pallida* with other desert foxes Rüppell's Fox *V. rueppellii* and Fennec Fox *V. zerda*, a grouping supported by Clutton-Brock *et al.* (1976), who suggest these desert foxes are also closely related to the Bengal Fox *V. bengalensis* and Cape Fox *V. chama*. Five races have been described, four of which are listed here, the subspecies *V. p. cyrenaica* being extralimital (following Coetzee 1977). However, there is insufficient specimen material available to assess the validity of the described forms, and according to Rosevear (1974) variation may be clinal. Synonyms: *cyrenaica*, *edwardsi*, *harterti*, *oertzeni*. Chromosome number: not known.

Description Small very pale fox with longish legs and large ears. Face pale with black eye-rings, relatively long whiskers and elongated muzzle. Large ears rounded at tip, white on inside and rufous-brown on outer surface. Creamy-white to sandy-fawn body, back sometimes flecked with black or rufous, darker mid-dorsal line. Flanks paler than dorsal pelage, merging into white or buffy-white undersides, rufous legs. Coat relatively thin and short. Tail long and

Vulpes pallida

bushy, at least half as long as body, reddish-brown with distinctive black tip and a dark patch above tail gland.

Small skull with a relatively short maxillary region, and well-developed upper molars (Clutton-Brock *et al.* 1976). Bullae are slightly larger, the nasals appreciably longer, and the carnassials 1–3 mm shorter than in Rüppell's Fox (Rosevear 1974).

Geographic Variation

V. p. pallida: Sudan.

V. p. edwardsi: Mali, Senegal.

V. p. harterti: Burkina Faso, NW Nigeria.

V. p. oertzeni: Chad, Niger, NE Nigeria, N Cameroon.

Lateral, palatal and dorsal views of skull of Pale Fox *Vulpes pallida*.

Similar Species

Vulpes vulpes. Sympatric only in N Sudan. Larger, with shorter legs and ears dark backed and more pointed.

V. zerda. Saharan distribution, but sympatric in northern part of Pale Fox's range. Smaller with proportionately longer ears (but shares dark tail tip and dark patch above tail gland).

V. rueppellii. Northern limit in Africa is the northern fringes of the Sahara Desert. Tail lacks black tip (usually white), with larger ears.

Distribution Endemic to Africa; present in the semi-arid Sahel, south of the Sahara, reaching the northern Guinean savanna zones. Ranges from S Mauritania, Senegal and Gambia through Niger and N Nigeria to Sudan, Somalia and the Red Sea. Presence in Guinea remains to be confirmed (Barnett & Prangley 1997).

Habitat Typically inhabiting very dry country within an ecological band lying between true desert and the sub-Saharan savannas. Habitat includes sandy and stony marginal deserts, semi-deserts and savannas, and extending to some extent southwards into moister Guinean savanna areas. May occur near human habitation and cultivated fields where food is more readily available than in natural habitats (Rosevear 1974).

Abundance One of the least known African canids. Widespread, and may be locally common.

Adaptations Pale Foxes tolerate heat well, although they are unable to bear completely waterless conditions. They can survive lengthy hot, dry seasons, presumably on fruits and the residual moisture of their prey.

Foraging and Food Well-developed molars suggest Pale Foxes are essentially insectivorous and herbivorous, eating mainly arthropods,

berries, and wild fruit such as melons, but also vertebrates. In Niger, they consumed (in order of frequency of occurrence in faecal samples) arthropods (Coleoptera, Orthoptera, Scorpiones), small mammals (gerbils and jerboas), plants, reptiles and birds. Remains of agama lizards, and a Chestnut-backed Sparrow-Lark *Eremopterix leucotis* were found outside a burrow in Chad. Pale Foxes forage solitarily at night, moving between grass tussocks looking for insects (C. Sillero-Zubiri pers. obs.). Pairs at the burrow left in different directions to forage in separate areas of their home range.

Social and Reproductive Behaviour Active from dusk till dawn, resting during the day in extensive burrows. Little is known of their social organization, but they have been observed individually and in pairs and living gregariously at communal burrows (Rosevear 1974, Coetzee 1977, C. Sillero-Zubiri pers. obs.). A group of one ♀ and two ♂ got along amicably in captivity (Nowak 1999).

Reproduction and Population Structure Reproduction in Niger took place in spring (Apr–Jun), just before the rainy season (C. Sillero-Zubiri pers. obs.). A captive ♀ gave birth to a litter of four in Jun (Bueler 1973). Young are born in extensive self-dug burrows, 2–3 m deep and up to 15 m long, opening into inner chambers lined with dry vegetation. Burrows may be aggregated into 'towns', consisting of 15–20 openings in a 15 m x 15 m area (C. Sillero-Zubiri pers. obs.). Faecal latrines are located just outside these burrows. Burrow systems are often near villages or under tracks (Dorst & Dandelot 1970, Nowak 1999). Gestation period in captivity is 51–53 days. Three to six young are born, and weaning takes 6–8 weeks. A captive ♂ lived to 16 years of age (Weigl 2005).

Predators, Parasites and Diseases Uncertain, but may be susceptible to canid-related diseases such as rabies. Probably taken by birds of prey (skulls were found in the nest of a kite near Khartoum; Anderson 1902), particularly nocturnal species such as Pharaoh Eagle-owl *Bubo ascalaphus*.

Conservation IUCN Category: Data Deficient (will be moved to Least Concern in 2012). CITES: Not Listed.

No major threats known, although they may be persecuted locally, since they are known to kill domestic fowl (Rosevear 1974). Present in several protected areas, including Ouadi Rimé–Ouadi Achim Faunal Reserve in Chad. This is the least known of all the canids, and studies on distribution, status and ecological requirements are needed.

Measurements

Vulpes pallida

HB: 440 (415–475) mm, n = 7

T: 207 (170–230) mm, n = 7

E: 62 (55–71) mm, n = 5

WT: 1.2 (1.0–1.5) kg, n = 6

Vulpes rueppellii RÜPPEL'S FOX (SAND FOX, RÜPPEL'S SAND FOX)

Fr. Renard famélique (Renard de Rüppell); Ger. Rüppellfuchs (Sandfuchs)

Vulpes rueppellii (Schinz, 1825). In: G. Cuvier, Das Thierreich 4: 508. 'Vatherland Dongola' [Sudan].

Rüppell's Fox *Vulpes rueppellii*.

Taxonomy This species is closely related to the Red Fox *Vulpes vulpes* and the extralimital Bengal Fox *Vulpes bengalensis* and Arctic Fox *Alopex lagopus* (Geffen *et al.* 1992a). The specific name has been misspelled in various ways (e.g. *V. rüppelli*: Ellerman & Morrison-Scott 1951), and is most commonly cited as *V. rueppelli* (Coetsee 1977, Corbet 1978). The specific name *rueppellii* is the genitive form of 'rueppellius', the latinization of Rueppell's name (Grubb 2004a, P. Grubb pers. comm.). Many subspecies have been described (e.g. Allen 1939, Coetsee 1977), but the variability of specimens seems high (Hüfnagl 1972, Rosevear 1974) and the species has been considered monotypic (Larivière & Seddon 2001), which is the approach provisionally followed here. Synonyms: *caesia*, *cufrana*, *cyrenaica*, *famelicus*, *sabaea*, *sabbar*, *somaliae*, *zarudnyi*. Chromosome number: $2n = 40$, with X chromosome metacentric and Y chromosome very small (Matthey 1954).

Description A small fox, with broad ears, short legs and bushy tail. Head colour beige to pale sand. Ears and face usually pale, with most animals having black whisker patches running up to the eye (variations can occur). Lacks darker markings on the back of the ears. Colour of the back, flanks, upper thigh and tail (except tip) varying from pale sandy to greyish and even sometimes reddish, with a more or less silvery sheen due to black speckling. Flanks and ventral pelage usually paler. Legs beige to fawn in colour. Fur very fine and soft with a thicker, darker coat in winter and a lighter colour coat in summer. Plantar and digital pads almost completely covered by hairs. Tail full and bushy, tip usually white. Males larger than ♀♀. Females have three pairs of nipples.

Skull not unlike a small version of the Side-striped Jackal *Canis adustus*, but without such well-developed occipital crests. Braincase rounded, postorbital processes blunt and narrow, zygomatic arches strong and bullae relatively large (though not so expanded as in the Fennec Fox *Vulpes zerda*) (Rosevear 1974).

Geographic Variation Rosevear (1974) remarked on the considerable uniformity of appearance, despite the animal's wide east-westerly range, noting that it would be difficult to find any significant distinction between specimens from Afghanistan and the Hoggar Mountains in Algeria (with the possible exception of specimens from north-east Africa, which may prove to be slightly smaller).

Similar Species

Vulpes zerda. Much smaller, with shorter legs; paler and finer fur; very large ears; shorter and black-tipped tail; skull with larger tympanic bullae. Saharan distribution.

V. pallida. Size slightly smaller; tip of tail black. Confined to Sahelian regions, until the southern edge of Sahara.

V. vulpes. More robust and larger, with longer limbs and tail; ears shorter, with back of ears dark; white tail tip. Confined to North Africa, until the northern edge of Sahara, and Nile Valley.

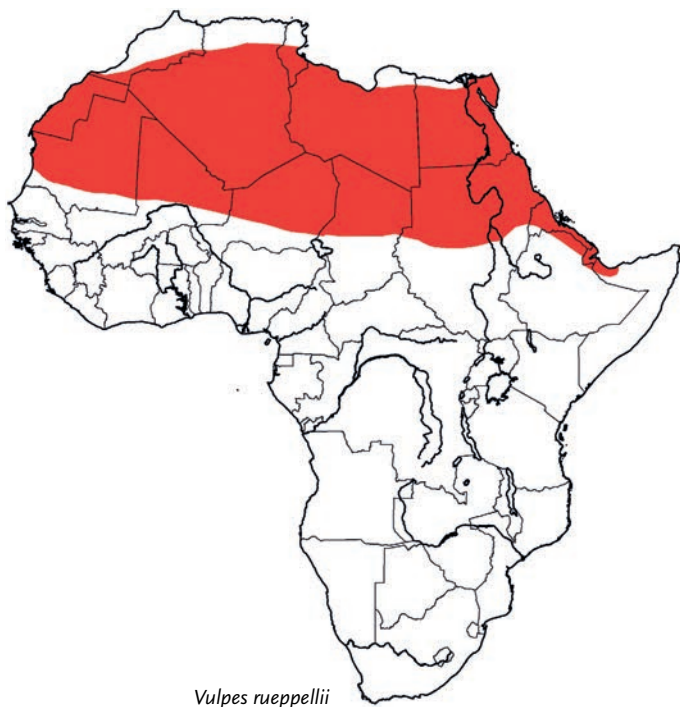

V. cana. Seems to prefer rocky and even precipitous mountain slopes; tail very bushy and long. Mostly Asiatic, but known in S Sinai and E Egypt (Saleh & Basuoni 1998).

Distribution Widespread in desert and semi-desert regions of North Africa (north of 17° N) from Morocco and Mauritania to Egypt (including Sinai) and north-east Africa, south to NW Somalia (Valverde 1957, Hüfnagl 1972, Rosevear 1974, Osborn & Helmy 1980, Aulagnier & Thévenot 1986, De Smet 1988, Kowalski & Rzebik-Kowalska 1991, Dragesco-Joffé 1993, Cuzin 1996). Northern limit is the northern fringes of the Sahara Desert. Also present in arid regions across the Arabian Peninsula eastwards to Pakistan and Afghanistan, and north-west to the Negev and Jordan (Larivière & Seddon 2001, Cuzin & Lenain 2004); a recent record for Syria is probably the first confirmation of their presence in this country (Serra *et al.* 2007). Suspected to have undergone an expansion of its historical distribution area due to desertification, offset by competition with the Red Fox due to expanding human settlements in the northern fringe of distribution area.

Habitat Typical habitat includes sand and stone deserts. The Rüppell's Fox seems to avoid the extreme arid regions in the middle of the Sahara, and, in Niger (Dragesco-Joffé 1993) and Morocco (F. Cuzin pers. obs.), this species is not found in large sand dune areas, where the Fennec Fox is the only other reported canid species; however, in Algeria, it occurs in large ergs (De Smet 1988). The species

Lateral view of skull of Rüppell's Fox *Vulpes rueppellii*.

is more abundant on the fringes of the Sahara, in mountain massifs and near oases. On the northern fringe of the Sahara, Rüppell's Fox may be found in areas with up to 150 mm annual rainfall. In Morocco (including Western Sahara), the general habitat comprises sparse to very sparse vegetation cover, dominated by small brushes (*Hammada scoparia*, *Panicum turgidum*, *Fagonia* spp.) mostly concentrated in wadis (with *Acacia* spp., *Balanites aegyptiaca*, *Maerua crassifolia* and *Capparis decidua* trees, and locally *Argania spinosa*). They also occur in coastal areas, with extremely sparse vegetation, and without any trees. It is able to survive in areas without any available water in Algeria (De Smet 1988) and in S Western Sahara (F. Cuzin pers. obs.), although animals were found only near water in Niger (up to 20 km) (Dragesco-Joffé 1993). In S Morocco, observations are inversely related to the distance of available water (Cuzin 2003), due to competition with the Red Fox.

Abundance Densities usually low, but higher in areas where food is more freely available, for example, near human settlements, or springs, when the Red Fox is absent (Valverde 1957, Osborn & Helmy 1980, K. De Smet pers. comm.). In the Air (Niger), Dragesco-Joffé (1993) suggests that the density of Rüppell's Foxes is higher in areas where other carnivores, such as the Golden Jackal *Canis aureus*, Caracal *Caracal caracal*, Sand Cat *Felis margarita*, Striped Hyaena *Hyaena hyaena* and Fennec Fox, are absent. In Saudi Arabia, in a large, fenced, protected area of 2244 km², recorded densities were 0.68/km², with lower population estimates outside the fenced reserve (Lenain 2000).

Adaptations Mainly crepuscular/nocturnal, although some animals are active during daytime in winter in Western Sahara (F. Cuzin pers. obs.) and in Tunisia (K. De Smet pers. comm.). In Saudi Arabia (Lenain 2000), this species leaves the den site usually within an hour following sunset. This is followed by alternating periods of activity and inactivity throughout the night, the latter usually taking place in the early hours of the morning. Foxes return to the den site often before sunrise and remain in the den throughout the day.

The ability to survive in extremely arid environments, where the opportunity to drink is extremely rare, appears to be facilitated by various ecological, behavioural and physiological adaptations (though not to the extent seen in the Fennec Fox). Behaviour of captive specimens is variable: some never drank (Petter 1952), while others did (Osborn & Helmy 1980). The diet, which includes plant material, fruits and roots (Rosevear 1974, Lenain 2000), likely provides much of their moisture requirements, and behavioural (in particular, activity patterns) and morphological adaptations (coat colour, presence of hair on feet, large ears) aid in thermoregulation. The role of physiological mechanisms (such as urinary concentrating ability) has yet to be established.

Two kinds of den are used: breeding dens, used by a pair for reproduction, and resting dens, used by a single animal for resting during daytime (Olfermann 1996). Dens are commonly located under slabs of rock or dug at the base of trees or bushes (Lindsay & Macdonald 1986, Harrison & Bates 1991, Kingdon 1997). In areas with few shelters (e.g. S Western Sahara), the species may use very exposed dens, often in the middle of plains (some of these burrows are dug by Ratels *Mellivora capensis*). In such areas, any disturbance induces the flight of the animal (F. Cuzin pers. obs.), and, in Niger, Dragesco-Joffé (1993) states that they often prefer to flee from their den in case of danger. In Oman, study animals changed den sites frequently (on average once every five days), likely as an anti-predator strategy or perhaps due to resource availability in other areas of a home-range (Lindsay & Macdonald 1986). Lenain (2000) recorded an instance where a shift occurred due to cooling: a male Rüppell's Fox used a shallow scrape in a sabkha-type substrate (packed silt), with a maximum depth of 70 cm. This type of substrate offers effective cooling, and midday temperatures may be 12–15° C lower inside the den than outside.

They are reportedly able to squirt the noxious contents of their anal glands at potential aggressors (Rosevear 1974).

Foraging and Food Rüppell's Fox is a generalist predator, the diet comprising a high invertebrate content as evidenced from scat and stomach analysis. Items consumed include a substantial insectivorous component (mostly Coleoptera and Orthoptera), as well as rodents, birds, lizards, snakes and occasional wild fruits, such as dates (Valverde 1957, Osborn & Helmy 1980, Kowalski 1988). In Saudi Arabia, small mammals are an important component of the diet and, in the absence of these, Rüppell's Foxes turn to Coleoptera (Lenain 2000). Their diet apparently is very opportunistic. In Saudi Arabia, scats contained remains of desert locusts (*Schistocera gregaria*), which were abundant during some study periods (Olfermann 1996, Lenain 2000). Frequent occurrence of plant material in scats may be a result of foraging for water (Lenain 2000). Local nomads report that Rüppell's Foxes prey on lambs and young goats in the Sahara in Egypt (Osborn & Helmy 1980), Niger (Dragesco-Joffé 1993) and in Hoggar (K. De Smet pers. comm.), and on chickens in Saudi Arabia (Lenain 2000). They are able to partially digest bones and teeth of prey (Denys *et al.* 1992).

Rüppell's Foxes are solitary foragers (Dragesco-Joffé 1993, F. Cuzin pers. obs.) and nocturnal visits to scavenge at temporary or permanent human settlements are common (Valverde 1957, Osborn & Helmy 1980, Kowalski 1988, F. Cuzin pers. obs.). Captive animals cached prey (Petter 1952). They are known to climb palms to obtain fruits (Osborn & Helmy 1980).

Social and Reproductive Behaviour Very little information available from Africa, but detailed studies have been conducted in Oman and Saudi Arabia. Adults are usually organized as monogamous pairs, but they may occur in groups (e.g. 3–15 in Arabia; I. Linn pers. comm.). The latter may represent extended family groups, and grouping may be incidental, caused by close aggregation of dens in the few areas where suitable sites are available.

In Saudi Arabia, pairs have home-ranges that overlap extensively; there is no overlap between adults of the same sex (Olfermann 1996). Olfermann (1996) recorded mean annual home-range as 16.3 km², and Lenain (2000) recorded a home-range size of 10.2 km². In Oman, home-ranges are very expansive, covering some 69 km² and social units spatially separate (Lindsay & Macdonald 1986). Males have significantly larger seasonal home-ranges than ♀♀ (Lindsay & Macdonald 1986, Olfermann 1996). Vocalization mainly comprises a series of 6–10 high-pitched barks (Petter 1952, F. Cuzin pers. obs.); they may chatter and groan when content (Petter 1952, Haltenorth & Diller 1980).

Reproduction and Population Structure Tracks of two adult animals obviously engaged in a courtship display were found in S Morocco in Nov, a few days after heavy rainfall (F. Cuzin pers. obs.), whereas, in Saudi Arabia, mating takes place from Dec to Feb (Olfermann 1996, Lenain 2000), which usually coincides with the first rains after the harsh summer period. Captures of young cubs have been made in Mar in Western Sahara (Valverde 1957), and Petter (1952) recorded very young animals in the area of Beni Abbès (Algeria) in May. In Saudi Arabia, young cubs were caught as early as Mar, but peaks of captures were made from Jul to Aug following the dependency period (Lenain 2000). Gestation lasts 7–8 weeks and litter-size is 2–3 in the Mahazat as-Sayd protected area in Saudi Arabia, although ♀♀ have been recorded above ground with as many as six cubs (Olfermann 1996).

Young cubs remain dependent on their parents for an undefined period, after which they venture out from the den site area. Young disperse at 6–7 months of age, on average some 32 km; both sexes reach sexual maturity at around 9–10 months (Olfermann 1996). The maximum confirmed age in the wild is seven years, but it could be higher (Olfermann 1996); one captive specimen was still alive after 14.3 years (Weigl 2005).

In Saudi Arabia, sex ratio of juveniles favours ♂♂ (1.7 : 1 and 1.6 : 1 in two consecutive years) (Olfermann 1996), while, in Egypt, among 67 museum specimens, 58% were ♂♂ (corresponding to a sex ratio of 1.4 : 1) (Osborn & Helmy 1980).

Predators, Parasites and Diseases Fragments of the jaws of a young fox were found in pellets of a Pharaoh Eagle-owl *Bubo ascalaphus* in Mauritania by Heim de Balsac & Heim de Balsac (1954), and predation by Golden Eagle *Aquila chrysaetos* has been observed in Morocco (F. Cuzin pers. obs.). In Saudi Arabia, predation by avian predators such as the Steppe Eagle *Aquila nipalensis* and Pharaoh Eagle-owls was recorded by Olfermann (1996); Lenain & Ostrowski (1998) recorded the death of a Rüppell's Fox in a cage trap as a result of a Ratel, but this was probably opportunistic. Susceptibility to disease is poorly known. In Saudi Arabia, Lenain (2000) reported seroprevalence to canine distemper virus, canine parvovirus and canine rotavirus; this species is also infected by rabies (S. Ostrowski pers. comm.). They may be infested by the tick *Rhipicephalus sanguineus* and/or by different species of fleas (Olfermann 1996, Lenain 2000).

Rüppell's Fox *Vulpes rueppellii* action drawing.

Conservation IUCN Category: Least Concern. CITES: not listed.

Poisoned baits are used indiscriminately to control predators in Niger (Dragesco-Joffé 1993) and Morocco (Cuzin 1996) and some mortality of Rüppell's Fox is attributed to poisoning. Individuals also are accidentally killed by jaw-traps used against jackals (Dragesco-Joffé 1993). They are occasionally killed for food by nomads (Osborn & Helmy 1980, F. Cuzin pers. obs.), but rarely sold for fur. Impact of insecticides is unknown, but potentially harmful.

In the northern fringe of the Sahara, competitive exclusion by Red Foxes, which occur near new permanent human settlements, leads to local extirpation of Rüppell's Fox in very productive biotopes (Cuzin 2003). Rüppell's Foxes may only be able to compete in the harshest desert areas, where the Red Fox is not able to survive, or in protected areas where Red Fox control is taking place (Yom-Tov & Mendelssohn 1988, Cuzin 2003). Rüppell's Fox occurs in a number of protected areas throughout its range, including the Ahaggar and Tasili n'Ajjer National Parks (Algeria), Sidi Toui N. P. (Tunisia), Banc d'Arguin N. P. (Mauritania), Nefhusa N. P. (Libya), and Gebel Elba Conservation Area in Egypt (Cuzin & Lenain 2004).

Rüppell's Foxes are held in captivity. Attempts to breed them have not been very successful, although they have been successfully bred in the Hai Bar Breeding Centre, Eilat, Israel (E. Geffen pers. comm.).

Measurements

Vulpes rueppellii

Vulpes vulpes **RED FOX**

Fr. Renard roux; Ger. Rotfuchs.

Vulpes vulpes Linnaeus, 1758. Syst. Nat., 10th edn, 1: 40. 'Europe, Asia, Africa, antrafodiens'; restricted by O. Thomas (1911), to 'Sweden (Upsala)'.

Red Fox *Vulpes vulpes*.

Taxonomy Highly polymorphic species, with numerous described subspecies many of doubtful validity (see Larivière & Pasitschniak-Arts 1996). Synonyms (Africa only): *aegyptiaca*, *algeriensis*, *anubis*, *atlantica*, *barbarus*, *niloticus*, *vulpecula*. Chromosome number: $2n = 34$; the X chromosome is a submetacentric and the Y chromosome subtelocentric (Rausch & Rausch 1979).

Description Medium-sized canid, and the largest fox in the genus *Vulpes*. Sexes similar colour, ♂♂ about 15% heavier than ♀♀ (Macdonald 1987). Muzzle slender and pointed with white on upper lip. Ears large, pointed, erect and black-backed. Pupil of eye elongate vertically. Pelage reddish-brown but may vary from brown to russet-red to yellowish-grey (see Geographic Variation). Some individuals dark grey-black under throat and belly; underfur of ♀♀ during breeding season may appear pink-tinged. Throat and/or chest may have white markings. Legs long and slender. Lower legs black, may be splashed with white. Tail long, thick and bushy, sometimes with white tip. *Vulpes v. aegyptiaca* has dorsal stripe, reddish to reddish-brown, 50–80 mm wide, extending from eye to basal one-third of tail, broadest on shoulders (forming a cross) and on pelvis, darkened between ear and shoulder by black, and black-tipped, guard hairs (Osborn & Helmy 1980). Adult pelage generally paler in summer than in winter (Lloyd 1980, Osborn & Helmy 1980). Conspicuous moult in spring, sometimes giving piebald appearance. New hairs

grow first on lower legs, then spread upwards, to flanks by early Jul, back and tail by late Aug. Summer coat begins to thicken in early winter. Limbs plantigrade. There are five toes on the forefoot (although four show in the spoor); fur shows between pads; claws conspicuous (two front claws close together). Scent glands include: supracaudal (or violet) gland (upperside of tail, 70 mm from root); paired anal sacs (open via 2 mm diameter ducts either side of anus); facial glands around chin and angle of jaw; and interdigital glands between toes and pads of feet. Four pairs of nipples.

Skull long and slender, with a long, narrow rostrum (with a slight depression below the frontal region). The frontal sinuses are slightly inflated, the auditory bullae are prominent, and the paroccipital processes small. Canines are long and slender; the medial incisors show slight lobes (Larivière & Pasitschniak-Arts 1996).

Geographic Variation There are three main colour morphs: Red, Silver (black with variable amount of frosting due to silver tips on guard hairs) and Cross (greyish-brown with long black guard hairs forming a prominent stripe down back and another across shoulders) (Banfield 1987, Johnson & Hersteinsson 1993). The melanistic variants (Cross and Silver) are known to occur in some parts of North America, Russia and where the progeny of imported North American foxes have been released in Scandinavia (Lloyd 1980). Less common mutations include Samson fox (lacks guard

hairs entirely, thus appearing woolly), and Bastard fox (smoky-blue colour between red and black).

Across the species' wide distribution range, there is considerable geographic variation in size: adult head–body length may range from 455 to 900 mm, tail length from 300 to 555 mm and body weight from 3 to 14 kg (Nowak 1999). The species exhibits a temperature- and latitude-correlated size gradient in Palaearctic region, but there is little change in size apparent in the southern part of range, in the Saharo-Arabian region, where the species is sympatric with smaller Rüppell's Fox *Vulpes rueppellii* (Dayan *et al.* 1989). Individuals probably largest in Scotland, and smallest in remote Saudi Arabia. Skull measurements of specimens from N Algeria are much smaller than those from central Europe (Kowalski & Rzebik-Kowalska 1991), and the species is substantially smaller in Middle East deserts (Macdonald *et al.* 1999) than in Europe. Individuals from North America also smaller (Voigt 1987).

Many subspecies have been described (44 are listed by Larivière & Pasitschniak-Arts [1996]), on the basis of regional variation, but these have doubtful ecological significance as evidenced by successful introductions and re-introductions around the world. Indeed, Corbet (1978) wrote that 'the continuity of range is such that it is doubtful whether any discrete, definable sub-species can be recognized'. However, a recent review of North American Red Foxes indicated native subspecies are considerably distinct from introduced European Red Foxes, the latter having displaced the former in many areas (Kamler & Ballard 2002). Three subspecies have been recognized in Africa (and see Coetsee 1977): *V. v. aegyptiaca* (N Libya, Egypt and Sinai, and N Sudan), *V. v. atlantica* (Atlas Mts, Mitidja, wooded parts of Algeria) and *V. v. barbarus* (Barbary Coast, north-western Africa – Morocco, from Tangiers south-west to Mogador and Marrakech). The validity of these as distinct forms is doubtful.

Similar Species

Vulpes pallida. Similar body structure, but smaller with longer legs and ears; pale fawn body and ears, tail reddish-brown with black tip. Sympatric in N Sudan.

V. rueppellii. Smaller, with short legs and broad ears; pale sandy colour, back of ears pale brown, black patches on face, tail tip white. Sympatric in some parts of Africa, but better adapted to deserts, probably due to smaller size and ability to survive in waterless areas (Osborn & Helmy 1980).

V. cana. Smaller, with relatively longer tail. In Africa, recorded only from Wadi Qiseib in Egypt.

Distribution Has the widest geographical range of any member of the order Carnivora and indeed among any non-commensal mammal species, covering nearly 70 million km², being distributed from the Arctic Circle throughout Europe, greater part of Palaearctic Asia and North America. Absent from Iceland, the Arctic islands, some parts of Siberia, and extreme deserts. The European subspecies was introduced into E United States and Canada in the seventeenth century, and subsequently spread throughout most of North America, apparently displacing native subspecies in many areas (Kamler & Ballard 2002). Red Foxes were introduced to Australia in 1800s, and they have also been introduced to the Falkland Is. (Malvinas) and Isle of Man (UK), although the species may subsequently have disappeared there.

Vulpes vulpes

In Africa, the species is known from late Pleistocene and Holocene (Kowalski & Rzebik-Kowalska 1991), and today occurs throughout North Africa mainly in the coastal belt from the hills of Morocco through N Algeria, Tunisia, Libya, Egypt (from Sallum to Alexandria, in the Delta and the Nile Valley south to the Sudanese Border, in the Fayoum, and in Cairo and surrounds), and N Sudan towards Khartoum (Hufnagl 1972, Osborn & Helmy 1980, Aulagnier & Thévenot 1986, Kowalski & Rzebik-Kowalska 1991, Cuzin 2003, Hoath 2003).

Habitat In Africa, occurs in arid areas, bushes, steppe regions, stony deserts and river beds, cultivated and urban land, but not sand desert (Kowalski & Rzebik-Kowalska 1991). Elsewhere recorded in habitats as diverse as tundra, desert and forest. Natural habitat is dry, mixed landscape, with abundant 'edge' of scrub and woodland. Also abundant on moorlands, mountains (even above the treeline, known to cross alpine passes), deserts, sand dunes and farmland from sea level to 4500 m (Macdonald & Reynolds 2004). In parts of their range, they appear closely associated with humans, occurring in urban areas (including city centres, such as London and Paris), residential areas and intensive agricultural areas (e.g. North Dakota, USA) (Macdonald & Reynolds 2004). In Egypt, they are frequently encountered at major tourist sites, such as the Step Pyramid (Hoath 2003).

Abundance Densities highly variable. There are no recorded densities in Africa, but, in the United Kingdom, density varies with habitat quality; between one fox/40 km² in Scotland and 1.17/km² in Wales, but can be as high as 30 foxes/km² in some urban areas where food is superabundant (Harris 1977, Macdonald & Newdick 1982, Harris & Rayner 1986). Social group density is one family/km² on farmland, may vary between 0.2 and 5 families/km² in suburbs, may be as low as one family/10 km² in barren uplands (Macdonald 1981, Lindsay & Macdonald 1986). Fox density in mountainous rural areas of Switzerland is 3 foxes/km² (Meia 1994).

Lateral, palatal and dorsal views of skull of Red Fox *Vulpes vulpes*.

Adaptations Generalist conformation and lack of specialist adaptations make the Red Fox widely successful. Its weakest element, exploited by man and other predators, is the period of vulnerability for the young while they are tied to their breeding den. Red Foxes have great endurance, galloping for several kilometres if pursued, and have been recorded sprinting at 60 km/h; they also swim well (Haltenorth & Roth 1968, Macdonald & Barrett 1993). Can locate sounds to within one degree at 700–3000 Hz, although less accurate at higher frequencies. Adapted to pounce on prey with great precision, manipulating take-off angle to adjust length of jump and force of landing. Have relatively longer hindlegs than other members of the canid family, thereby increasing their propulsive force. Dense, but short, fur covers approximately one-third of body's surface area, particularly face, dorsal part of head, nose, ears, lower legs and paws; probably functions as major heat exchange surface for thermoregulation (Klir & Heath 1992). Nose is used for evaporative cooling and probably forms part of brain cooling mechanism as described in domestic dogs (Klir & Heath 1992). Physiology of their senses and physical size and agility mean foxes are well suited to preying on small rodents.

Underground dens are used to shelter cubs while very young. They dig their own dens or enlarge burrows of other species; dens usually have several openings. In Egypt, clay hills or *karms*, excavations from Roman cisterns, south of Burg el Arab are well-known burrowing sites. Foxes also burrow in palm groves, fields, gardens, quarries and beneath walls, stables, houses, ruins and tombs (Osborn & Helmy 1980). In a study of den use on Djerba I., SE Tunisia, dens were found in grassland, cultivated land (olive plantations and palm groves) and suburban areas (Dell'Arte & Leonardi 2008).

Foraging and Food Much of what is known of the ecology of the Red Fox comes from studies extralimital to Africa (but see Osborn & Helmy 1980, Dell'Arte & Leonard 2009), and much of

the information that follows is derived from those studies. Red Foxes are adaptable and opportunistic omnivores, feeding on vertebrates (lizards, rodents, hares, birds), carrion, invertebrates, fruit, eggs and plant material, as well as scavenged fish, crabs and refuse. They typically prey upon birds and mammals up to about 3.5 kg (equivalent to an adult brown hare) and require about 500 g of food per day, caching excess food and having a highly developed memory for location of hoards (Macdonald 1977a, 1981). In Egypt, stomachs of Red Foxes have contained green figs, various bird, plant and insect remains, and rodents (including *Gerbillus* sp. and *Dipodillus simoni*) (Osborn & Helmy 1980); Flower (1932) mentions one stomach full of mole crickets. Availability of water may be a factor limiting the distribution of Red Foxes in Egypt to the Nile Valley and Delta, the Western Mediterranean Coastal Desert, oases, and northern parts of the Eastern Desert and Sinai Peninsula (Osborn & Helmy 1980).

Mainly nocturnal and crepuscular; more diurnal where undisturbed. Independent and generally solitary foragers, although individuals may forage in close proximity where resources are clumped. Accounts of cooperative hunting, e.g. of young ungulates, have not been studied systematically (Macdonald 1980a). Often cache prey.

Considered a major predator of ground-nesting colonial birds, such as terns, and their effect on harvestable game-bird populations can be significant. Also prey upon hand-reared and released game-birds. Lambs may be taken but such losses typically constitute only a small percentage (<2%) of all lambs born (Macdonald *et al.* 2000).

Social and Reproductive Behaviour The basic social unit is a pair, but groups of up to six members (usually one adult ♂ and 2–5, probably related, ♀♀) may share a territory, depending on habitat. Pairs occupy large territories in impoverished habitats. Range size is habitat-dependent and can cover from <40 ha (e.g. urban foxes in Oxford, UK) to >4000 ha, depending on habitat (reviewed by Voigt & Macdonald 1984). One fox in an Omani desert had a range spanning 5000 ha (Lindsay & Macdonald 1986). There are reports of overlapping ranges in some urban (e.g. Harris 1979) and rural environments (Meia & Weber 1996), and of drifting territories in other urban settings (Doncaster & Macdonald 1991).

Red Foxes communicate using facial expressions, vocalizations and scent-marking. Twenty-eight categories of vocalization have been described; calls are used to communicate over long distances and also at close quarters. Individuals have characteristically different voices. Scent-marking involves urine and faeces (urine-marking is sometimes confined to dominant ♀♀ within a group), anal sac secretions, the supracaudal gland (more active in ♂♂ during breeding season) and glands around lips, in angle of jaw and between pads of feet. Faeces often deposited on prominent sites, e.g. stones, tussocks of grass and trail junctions. Faeces sometimes similar to those of domestic dogs, but darker, more tightly packed and smell differently; they often comprise visible clumps of undigested fur or feather, and, in season, traces of beetle elytra and fruit pips (Macdonald & Barrett 1993).

Mating behaviour highly variable; may include monogamous pairs, a single ♂ with two breeding ♀♀ (that may or may not share a communal den), or a single breeding ♀ with several non-breeding female helpers (probably related to breeding vixen). There is only ever one breeding ♂ in the group, although additional matings occur outside the group. Territorial ♂♂ make frequent excursions beyond

Red Fox *Vulpes vulpes* juvenile.

their territories during mating season, during which itinerant ♂♂ also make territorial incursions (Macdonald 1987).

In high-density populations where interactions with a dominant vixen are frequent, subordinate ♀♀ do not usually breed, although they may breed successfully in low-density populations (in the UK, usually only one or two ♀♀ in a group breed) (Macdonald 1980b, 1987). Both parents, and sometimes other ♀♀ in the group, care for young (Macdonald 1979b). The ♂ provides food to the lactating ♀, which is generally confined to the den prior to weaning. Both parents care for and provision young with weaned food. Non-breeding ♀♀ may also feed, groom and tend cubs and have been known to adopt them if orphaned (Macdonald 1979b). If two ♀♀ breed within a group, they may share a den and litters may be communally suckled.

There is socially mediated suppression of reproduction among ♀♀, lowest productivity occurring where fox density is high or food supply poor. Where food is not limited, social status itself can suppress reproduction, with only the dominant ♀ breeding. Behavioural mechanisms by which this occurs include harassment of subordinates, infanticide and cannibalism of subordinate vixens' cubs, and possibly dominant ♂ courting only dominant ♀♀ (Macdonald 1977b, 1980b). A hormonal mechanism whereby stress leads to lowered productivity through foetal reabsorption has also been identified (Hartley *et al.* 1994).

Reproduction and Population Structure There is limited information on reproduction in Red Foxes in Africa. Four pups were recorded in Mar in Egypt (Osborn & Helmy 1980), and Hufnagel (1972) mentions that the young are born in Feb or Mar in Libya. The information that follows is taken from Macdonald & Reynolds (2004). Males are seasonally fecund. In the UK, mating takes place from Dec to Feb; onset of breeding correlated with day length and so starts earlier at more southerly latitudes. Females are in oestrus for three weeks, but fertilization is possible over three days. Gestation period is 49–55 days. Births occur from Mar to May in UK. Litter-size varies with food availability, typically ranging between 3 and 12 (Voigt & Macdonald 1984). Birth-weight is around 100 g. Cubs are born blind, deaf and with dark brown fur. Eyes open at 11–14 days and are blue until about one month old, then brown to amber. Fur colour as adult by two months. Lactation lasts for four weeks, and cubs are fully weaned at Week 6–8. Sexual maturity is reached at 9–10 months. Fox populations that are dense relative to food

resources are generally less productive than those that are less dense. A single litter per year is the norm.

Juveniles may disperse at between six and 12 months of age, mostly between Oct and Jan. All or most ♂♂ disperse but proportion of each sex dispersing varies between habitats and may depend on extent of mortality. Males typically disperse further than ♀♀ (e.g. ♂♂ 13.7 km, ♀♀ 2.3 km in Welsh hills [Lloyd 1980, Trehwella *et al.* 1988]). Dispersal distance correlates positively with home-range size (Macdonald & Bacon 1982). In the UK, distances are generally between <5 km and >50 km, but distances up to 394 km have been recorded in the USA (Ables 1975).

Sex ratio in a sample of 174 museum specimens of *V. v. aegyptiaca* was 1 : 1 (Osborn & Helmy 1980). Foxes have been known to live up to nine years in the wild; a wild-caught ♀ was still living in captivity at an estimated 21.3 years of age (Weigl 2005).

Predators, Parasites and Diseases High juvenile and subordinate adult mortality, but lower adult mortality. Although mortality is variable between populations, roughly 75% die in their first year; adult mortality is approximately 50% per year. The Red Fox has few natural predators, although large birds of prey and large carnivores are known predators in some parts of the range.

Red Foxes are a widespread reservoir of rabies (Chomel 1993), especially in central Europe, SE Canada and NE USA (Larivière & Pasitschniak-Arts 1996). Populations are locally and periodically reduced by rabies epizootics (mortality estimated at 60–80% by simulation models; Voigt *et al.* 1985), although recovery appears swift (e.g. Western Europe, USA; Wandeler *et al.* 1974). Oral vaccination is regarded by the World Health Organization and European Union as an ongoing experiment; oral vaccines successfully used in some European countries (Kappeler *et al.* 1988), but the method has failed in some areas (Funk *et al.* 2001).

The Red Fox is host to a wide range of parasites (see Larivière & Pasitschniak-Arts 1966 for review). One of the most serious parasites is the skin-dwelling mite (*Sarcoptes scabiei* var. *vulpes*), which causes sarcoptic mange. This disease is locally and temporally prevalent. Mange appeared in Finland in 1967 and spread to Norway and Sweden in the 1970s and 1980s, where it reduced fox populations by over 70% (Holt & Berg 1990, Lindström 1992). Since then, mange has spread across most of Europe including England, wiping out over 90% of the fox population in Bristol, UK, in the early 1990s (McDonald *et al.* 1997), and south-west to Spain (Gortazar *et al.* 1998) and New York (Tullar *et al.* 1974). Mange may also have been responsible for population declines in Saqqara, Egypt in 1995/1996 (Hoath 2003). Several other diseases are recorded, including canine distemper, parvovirus, toxoplasmosis, bovine tuberculosis and paratuberculosis, but these do not appear to be major determinants of fox density (Little *et al.* 1982, Voigt 1987, Beard *et al.* 1999).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Red Foxes are widely regarded as a pest and unprotected, except that most countries/states where trapping/hunting occurs have regulated closed and open seasons and restrictions on capture methods. As such, across much of their range, the major cause of mortality (particularly high among dispersers) is attempted pest control by people (through shooting, secondary poisoning etc.); in Morocco, 21,409 animals were destroyed between 1959 and 1972 at an annual average of

approximately 1600 animals, mainly through strychnine poisoning (Aulagnier 1990). Red Foxes are also hunted with dogs in France, Belgium, Portugal, Italy, Germany, Switzerland, Australia, USA and Canada, although this is not reported in any North African country.

Red Foxes have been extensively hunted and trapped for their fur. The worldwide trade of wild-caught foxes in 1985–86 was 1,543,995 pelts. In the USA, Red Fox made up 45% of this trade (worth \$50 million in 1983). Many individuals killed by vehicles in modern landscapes; juveniles and dispersers are particularly vulnerable (Macdonald & Reynolds 2004). Despite these and other potential threats, their versatility and eclectic diet are likely to ensure their persistence despite changes in landscape and prey base (Macdonald & Reynolds 2004).

Vulpes zerda FENNEC FOX

Fr. Fennec; Ger. Fenek (Wüstenfuchs)

Vulpes zerda (Zimmermann, 1780). Geogr. Gesch. Mensch. Vierf. Thiere 2: 247. 'Es bewohnt die Soara und andere Theile von Nordafrika hinter des Atlas, der Ritter Bruce behautet, man Fände es auch in tripolitanischen' [Sahara].

Fennec Fox *Vulpes zerda*.

al. 1992b). Synonyms: *arabicus*, *aurita*, *brucei*, *cerda*, *cerdo*, *denhamii*, *fennecus*, *saarensis*, *zaarensis*. Chromosome number: 2n = 64; the X chromosome is a large submetacentric and the Y chromosome is very small (Matthey 1954, Wurster & Benirschke 1968).

Description The Fennec Fox is the smallest canid, with extremely large ears that give it the greatest ear to body ratio in the family Canidae. The muzzle is slender and delicate. The large ears are darker on the back and white or nearly so inside; ear edges are white. Eyes large and dark, with dark streaks extending from the inner eye down and outward to either side of the muzzle. Pelage is typically sandy or cream-coloured, although it may have a light fawn, red or grey cast; the underfur is about 28 mm in length. Underparts are paler, almost white. Upper parts of slender limbs reportedly coloured reddish-sand in individuals from North Africa, whereas those from further south are nearly white in these areas. The coat is very thick, long and soft; dense fur on the feet extends to cover the pads (hairs up to 13 mm in length). The tail is short, rufous, well furred (tail hairs up to 35 mm) with a darker tip and a slightly darker spot covering the caudal gland. Females have three pairs of nipples.

Skull small, typically vulpine, but with very large tympanic bullae. Rostrum delicate, width less than 50% of braincase. Zygomatic arches widely flared anteriorly. Postorbital region wide, and postorbital process small. Sagittal crest only detectable as a low elevation in front of lambda, and temporal ridges small. The canines are small and slender, but sharp (Harrison 1968, Clutton-Brock *et al.* 1976).

Taxonomy Monotypic (Coetzee 1977). Included in the genus *Fennecus* by Ellerman & Morrison-Scott (1951), Stains (1975), Coetzee (1977) and Nowak (1999), although Wozencraft (1993, 2005) placed *Fennecus* in the genus *Vulpes*, an arrangement in agreement with other authorities (e.g. Clutton-Brock *et al.* 1976, Corbet 1978, Geffen *et al.* 1992b) and followed here. Genetic analysis confirms that Blanford's Fox *Vulpes cana* is the sister taxon to this species (Geffen *et*

Lateral view of skull of Fennec Fox *Vulpes zerda*.

Geographic Variation None recorded.

Similar Species

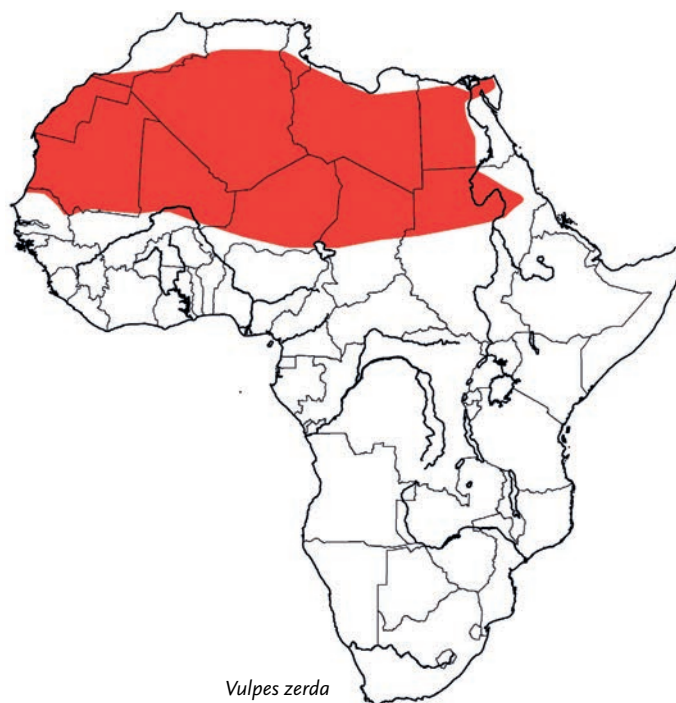

Vulpes rueppellii. Larger, but with smaller ears; upper parts silvery-grey, and the tip of the tail is white. Northern limit in Africa is the northern fringes of the Sahara Desert.

V. pallida. Larger; upper parts pale sandy-fawn suffused with black hairs (also has dark tail tip). Sympatric in southern parts of Fennec Fox range.

V. cana. Tail longer. In Africa, recorded only from Wadi Qiseib in Egypt.

Distribution Widespread in the sandy deserts and semi-deserts of North Africa from Morocco and Mauritania through Algeria, Tunisia, Libya and Egypt south to the Sudan; also in N Sinai (Saleh & Basuony 1998). Common throughout the Sahara, and may occur to the Sahelian areas in the south at around 14°N (Dragesco-Joffé 1993, Granjon *et al.* 1995). The distribution of Fennec Foxes extralimital to the African continent is unclear. Al-Robaee (1982) collected a specimen from near Jabal Sanam, south-west of Basrah in Iraq. References to Fennec Fox sightings in the United Arab Emirates were based on an animal in the Al Ain zoo (Al-Robaee 1982), which was, in fact, a Rüppell's Fox *V. rueppellii* (Gasparetti *et al.* 1985). A subadult Fennec Fox, apparently from Kuwait, is in the British Museum collection (Harrison & Bates 1991), but the true origin of this animal is in doubt. Thesiger (1949) reported Fennec Fox tracks in the region of Abu Dhabi, but whether the tracks were accurately identified is uncertain. Current distribution likely unchanged from historical range; the only documented regression concerns the northern Moroccan Sahara, where the Fennec Fox disappeared during the 1960s from four localities, which were restricted sandy areas close to permanent human settlements (F. Cuzin pers. obs.).

Habitat Subsists in arid desert environments. Stable sand dunes are believed to be ideal habitat (Dorst & Dandelot 1970, Coetzee 1977), presumably offering the ideal substrate for burrowing, although animals also live in very sparsely vegetated sand dunes near the Atlantic coast (Cuzin 2003). In the Sahara, sparse vegetation is usually dominated by *Aristida* spp., and *Ephedra alata* in large sand dunes. In small sand dunes, the vegetation is dominated by *Panicum turgidum*, *Zygophyllum* spp. and sometimes by trees such as *Acacia* spp. and *Capparis decidua* (F. Cuzin pers. obs.). Annual rainfall is less than 100 mm per year on the northern fringe of their distribution, but on the southern fringe they may be found up to the Sahelian areas that receive as much as 300 mm rainfall per year. They are able to live independently of water sources (Dekeyser & Derivot 1959, in Noll-Banhölzer 1979a, b, Cuzin 2003).

Vulpes zerda

Abundance Assumed to be locally common based on the observations that the Fennec Fox is still often trapped and sold in parts of North Africa. In S Morocco, they are commonly seen in all sandy areas away from permanent human settlements (F. Cuzin pers. obs.).

Adaptations Well adapted to desert living. Primarily nocturnal, although crepuscular activity is also reported (Gauthier-Pilters 1967). In S Morocco, animals were commonly active in winter until around mid-morning (F. Cuzin pers. obs.). The pale, sandy-coloured, dense fur presumably provides camouflage and serves to protect against cold night-time temperatures, whereas the well-furred feet facilitate walking on hot, sandy substrates and facilitate locomotion in loose sand. The exceptionally large ears likely help in heat dissipation, but may also aid in locating insects and small vertebrates (Ewer 1973) as Fennec Foxes have exceptional hearing ability (facilitated by their well-developed tympanic bullae) (Dragesco-Joffé 1993). Nocturnal activity patterns, the use of burrows during the day, and the moisture content of their prey probably contribute to their ability to go without drinking water (Schmidt-Nielsen 1964, Dragesco-Joffé 1993, F. Cuzin pers. obs.).

Dens in the wild are always dug in sand, in open areas or places sheltered by plants such as *Aristida pungens* and *Calligonum comosum* (Dragesco-Joffé 1993, Incorvaia 2005, F. Cuzin pers. obs.). Dens may be huge and labyrinthine, especially in the most compacted soils, covering up to 120 m², with as many as 15 different entrances (Dragesco-Joffé 1993). Bueler (1973) reports that dens may be close together or even interconnected. In soft sand, dens are usually small and simple, with just one entrance and one tunnel leading to a chamber (Dragesco-Joffé 1993). In case of danger, animals prefer to flee from this type of den. In captivity, Fennec Foxes often bury faeces by pushing loose substrate with their noses or hindfeet (Gauthier-Pilters 1962), presumably to conceal their presence. In the wild, finding fresh faeces is rare, probably because of this behaviour.

The Fennec Fox also shows some physiological adaptations to its extreme environment. In captive animals, both body temperature and heart rate decrease at mid-day and increase at night as animals become active. Body temperature of resting animals is ca. 37.6 °C, and heart rate ca. 100–115 beats/min; the thermoneutral zone ranges from 23 to 37.8 °C, and panting occurs above this range (Noll-Banholzer 1979a, Maloïy *et al.* 1982). Vasodilation occurs under heat stress and vasoconstriction in cold conditions. Under cold conditions (10–20.8 °C), piloerection and shivering were observed (Maloïy *et al.* 1982). Newborn animals are sensitive to cold, but seem incapable of thermoregulation. In addition, the kidneys filter extremely high concentrations of urea with little water loss (Noll-Banholzer 1979b, Gasperetti *et al.* 1985). When exposed to high heat stress, captives deprived of water decrease their activity and food intake and lose weight (Noll-Banholzer 1979b).

Foraging and Food Fennec Foxes are omnivorous, and are reported to consume insects (locusts, beetles) and other arthropods (scorpions), small rodents (e.g. *Jaculus jaculus*, *Gerbillus* spp. and *Meriones* spp.), lizards (e.g. *Acanthodactylus* spp.), geckos (e.g. *Stenodactylus* spp.), skinks (e.g. *Scincus albifasciatus*), eggs, small birds (e.g. larks and sandgrouse), various fruits and some tubers (Dragesco-Joffé 1993, Incorvaia 2005, F. Cuzin pers. obs.). They appear to be quite opportunistic: in the Moroccan Sahara, during an exceptionally cold morning in June, one Fennec Fox killed and ate at least four skinks, as the weather was too cold for the skinks to escape quickly (F. Cuzin pers. obs.). Captives have also been reported to capture and kill an adult rabbit (Gauthier-Pilters 1962).

Fennec Foxes hunt alone (Coetzee 1977), probably because solitary hunting of small prey is more efficient. They have not been seen using the ‘mouse jump’ hunting strategy typical of most fox species (Ewer 1973), but reportedly dig to find insects and small vertebrates. Because the jaw muscles are not very strong, killing relatively large prey (such as *Jaculus* or *Meriones*) may take up to five minutes (Dragesco-Joffé 1993). Like other foxes, they do cache food by burying. They are very opportunistic and commonly visit temporary human settlements during the night in search of food (Dragesco-Joffé 1993, F. Cuzin pers. obs.). In Niger, some individuals have been reported raiding poultry coops (Dragesco-Joffé 1993).

Social and Reproductive Behaviour Fennec Foxes are thought to be moderately social, but this evidence is based primarily on captive animals. The basic social unit is believed to be a mated pair and their offspring, and, like some other canids, the young of the previous year may remain in the family even when a new litter is born (Gauthier-Pilters 1967). Captive animals engage in high levels of affiliative behaviour, and typically rest in contact with each other. Play behaviour is common, even among adults, although ♂♂ begin to show more aggression and urine-marking when oestrus approaches. During the prooestrous and oestrous periods, members of a pair approach each other more frequently and spend more time in proximity. There is an increased frequency of mutual sniffing of each other’s muzzles and genitals, followed by mounting and copulation. Most remarkable is the exceptionally long copulatory tie lasting up to 165 min (Valdespino 2000, Valdespino *et al.* 2002). The ♂ becomes very aggressive and protective of the ♀ after mating and provisions her during pregnancy and lactation (Sowards 1981).

He is usually solicitous of the pups and may help guard and care for them. Vocalizations include barks, both soft and high-pitched, catlike purring, yapping and squeaking (Gauthier-Pilters 1967).

Reproduction and Population Structure In the wild, they are reported to mate in Jan and Feb and give birth in Mar and Apr (Gauthier-Pilters 1967), but these data are from only one site; captive Fennecs from Algeria bred in Feb, Mar and Apr, and gave birth in May and Jun (Saint Girons 1962). In captivity, births can occur year round, although most litters are born between Mar and Jul (Bauman 2002). Data from captivity are more extensive than those from the wild, but, because captive animals are maintained in a broad range of environmental conditions, inter-oestrous intervals vary considerably. Individual differences also likely contribute to this variability. Fennec Foxes most commonly have one litter per year, but a second litter is possible under some conditions (Koenig 1970, Valdespino *et al.* 2002).

The monoestrous cycle is characterized by a pro-oestrous phase of about six days and a one- to two-day oestrus, relatively short for a canid (Gauthier-Pilters 1967, Koenig 1970, Valdespino *et al.* 2002). There is no sanguineous discharge in association with oestrus or pro-oestrus. In non-fertile cycles, ovulation is followed by an approximately 50-day dioestrous period, also called pseudopregnancy because it is equivalent in hormonal pattern and duration to gestation (Asa & Valdespino 1998, Valdespino 2000).

Gestation lasts 50–52 days (Petter 1957, Volf 1957, Saint Girons 1962, Koenig 1970); however, 62- and 63-day gestations were reported for two animals at the Strasbourg Zoo (Gangloff 1972). Litter-size is 1–4 (Petter 1957, Gauthier-Pilters 1967, Koenig 1970, Gangloff 1972, Bauman 2002). Young are born blind and fully furred; eyes open at 8–11 days (Gangloff 1972) and weaning takes place at 61–70 days (Koenig 1970). First mating is reported at nine months (Bekoff *et al.* 1981) to one year (Gauthier-Pilters 1967) for both sexes. Longevity in the wild is unknown, but, in captivity the recorded longevity is 14 years for ♂♂ and 13 years for ♀♀ (Bauman 2002).

Predators, Parasites and Diseases In the wild, jackals, Striped Hyenas *Hyaena hyaena* and domestic dogs are reported to prey on Fennec Foxes (Gauthier-Pilters 1967), although this is anecdotal and possibly questionable. Fennec Foxes are fast and able to change direction very quickly, and nomads consider them very difficult to capture, even for the saluki, a local greyhound-like dog (Monteil 1951, Dragesco-Joffé 1993). However, Eagle-owls (*Bubo* spp.) may prey on young foxes (Dragesco-Joffé 1993). There is significant mortality of neonates in captivity, generally attributed to the sensitivity of the parents to disturbance (Petter 1957, Volf 1957, Gangloff 1972). The Fennec Fox is partly sympatric with, and thus may face competition from, Rüppell’s Fox (Lindsay & Macdonald 1986); in S Morocco encounters between these species are rare, as Rüppell’s Fox rarely goes into large sandy areas (F. Cuzin pers. obs.).

Fennecs are thought to be susceptible to pathogens and parasites that affect domestic dogs. There is some evidence that modified-live canine distemper vaccine may induce canine distemper in Fennec Foxes (Montali *et al.* 1994), but the newer sub-unit vaccines should not (R. Junge pers. comm.). Parasites recorded include trematodes (*Alaria alata*, *Joyeuxiella echinorhynchoides*, *Taenia crassiceps*) and nematodes (*Ancylostoma braziliense*, *A. caninum*, *A. duodenale*,

Cyathospirura seurati, *Oxyntema crassispiculum*, *Physaloptera cesticillata*, *Rictularia cahirensis*, *Spirocerca lupi*, *Spirura rytipleurites*, *Streptopharagus numidicus*, *Toxascaris*, *Toxocara masculior*, *Uncinaria stenocephala*) (see Larivière 2002a for references).

Conservation IUCN Category: Least Concern. CITES: Appendix II.

In Morocco, young foxes are captured in their burrows for sale to tourists, for photographic exhibition (Cuzin 2003), or even for meat (Schmidt-Nielsen 1964); adults may also be trapped for their fur. They occur in a number of protected areas throughout their range, including Ahaggar and Tassili n'Ajjer National Parks in Algeria, Banc d'Arguin and Diawling National Parks in Mauritania, Sidi Toui N. P. in Tunisia, Zellaf N. R. in Libya, and Bir El Abd Conservation Area in Egypt (Asa *et al.* 2004).

The North American Regional Studbook (Bauman 2002) lists 839 individuals held in captivity from 1900 to 2001. In 2001, there were 131 individuals in 51 institutions. The Australian Regional Studbook lists 81 historically, with only 12 in the captive population at present. Although Fennec Foxes occur in European zoos, there is no studbook or management plan. Fennec Foxes are also kept as pets and bred privately.

GENUS *Otocyon*

Bat-eared Fox

Otocyon Müller, 1836. Arch. Anat. Physiol., Jahresber. Fortschr. Wiss. 1835: [1836].

Otocyon is a monotypic genus, distributed in eastern and southern Africa in semi-arid and arid habitats, especially open grasslands, open scrub, *Acacia* savanna and shrublands. *Otocyon* was previously included in a separate subfamily, the Otocyoninae (Simpson 1945, Ellerman *et al.* 1953), on account of its unique dentition. Clutton-Brock *et al.* (1976), followed by other authors, have allied it with the typical canids,

although acknowledging its unique characters. Whereas typical canids have two upper and three lower molars, *Otocyon* typically have 3–4 upper and 4–5 lower molars, to yield a full dentition of 46–50, the highest amongst living eutherians, except odontocetes.

Otocyon megalotis BAT-EARED FOX

Fr. L'Otocyon; Ger. Löffelhund

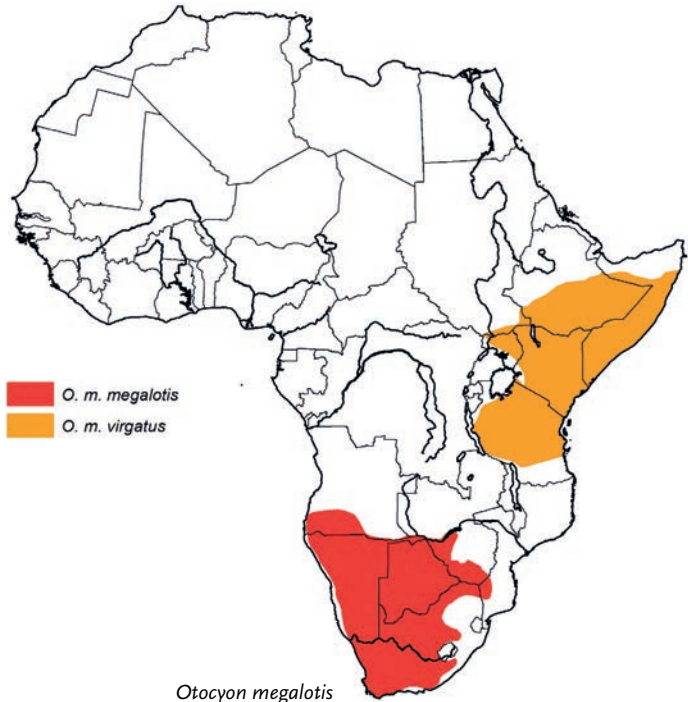

Otocyon megalotis (Desmarest, 1822). Mammalogie. In: Encyclop. Meth., 2 (Suppl.): 538.
'le Cap de Bonne-Espérance' [Cape of Good Hope, South Africa].

Bat-eared Fox *Otocyon megalotis*.

Taxonomy Two subspecies have been recognized (Coetzee 1977; and see Clarke 2005). Synonyms: *auritus*, *caffer*, *canescens*, *lalandii*, *steinhardti*. Chromosome number: $2n = 72$ (Wayne *et al.* 1987).

Description Small and slightly built with slender legs, but with fluffy pelage and a long bushy tail. Conspicuously large ears and short, sharp muzzle. Back of ears, front part of snout, face-mask, front legs and lower part of back legs, and tip and mid-dorsal part of tail black. A whitish band extends across the forehead to below and up the frontal rim of ears. Some individuals have a broad dark mid-dorsal band. Lower jaw, throat, chest and underparts buffy. Pelage paler in older individuals. Body and tail fur thick and soft; on upperparts with a black base and white tip, giving a grizzled or grey appearance; sides appear more buff. Underfur on the upper body about 30 mm long, while the dense over-layer of guard hairs measures about 55 mm. A sprinkling of tactile hairs up to 65 mm long occurs amongst guard hairs (Skinner & Chimimba 2005). They have an annual moult, which in southern Africa takes place between Aug and Sep and again between Jan and Feb (Smithers 1971). Females may weigh more than ♂♂ (see Smithers 1971). There are three pairs of abdominal nipples (Lynch 1983, Pauw 2000), although Skinner & Chimimba (2005) mention two pairs inguinal; the reasons for this discrepancy are unclear.

Skull elongated, narrowing evenly from the sides of the braincase to the front of the narrow muzzle. Supratemporal ridges well developed and extend backwards as a broad beading, to form a wide U-shape. Unique amongst living eutherians (except the odontocetes) in having 4–5 lower molars, and unique amongst living canids in having 3–4 upper molars (Guilday 1962). Supernumerary molars yield a dentition of $I^{3/3}$, $C^{1/1}$, $P^{4/4}$, $M^{3-4/4-5} = 46-50$ (unlike the

*Otocyon megalotis*

typically canid total of 42), the largest number for any non-marsupial land mammal. P^3 and P^4 are in contact in contrast to other canids (Roberts 1951).

Geographic Variation

O. m. megalotis: southern Africa, from Angola to Mozambique and South Africa

O. m. virgatus: East Africa, from S Sudan, Ethiopia and Somalia to Tanzania.

Similar Species

Vulpes chama. Sympatric in southern Africa. Somewhat smaller; silver-grey upperparts, underparts off-white to very pale fawn, head and back of ears reddish-fawn; tail very bushy with a black tip.

Distribution Endemic to Africa, occurring as two discrete populations, separated by about 1000 km, across the arid and semi-arid regions of eastern and southern Africa (Kingdon 1977, Skinner & Chimimba 2005). Occurs from S Sudan, Ethiopia and Somalia down through Uganda and Kenya to SW Tanzania, and then again from Angola through Namibia and Botswana to Mozambique and South Africa. No confirmed records from Zambia (Ansell 1978). The two ranges were probably connected during the Pleistocene (Coe & Skinner 1993). This disjunct distribution is similar to that of the Aardwolf *Proteles cristatus* and Black-backed Jackal *Canis mesomelas*. Range extensions linked to changing rainfall have occurred in southern Africa in recent years (e.g. Stuart 1981, Marais & Griffin 1993).

Habitat Mainly open grasslands, especially short-grass areas with bare patches, open arid or semi-arid *Acacia* savanna, open scrub and arid, semi-arid or winter rainfall (fynbos or Cape macchia) shrublands (Kingdon 1977, Nel & Mackie 1990, Skinner & Chimimba 2005). The range of both subspecies overlaps almost completely with that of *Hodotermes* and *Microhodotermes*, termite genera common in the diet (Mackie & Nel 1989, Maas 1993a). In Serengeti N. P. the species is common in open grassland and woodland boundaries, but not short-grass plains (Lamprecht 1979, Malcolm 1986).

Abundance Common in conservation areas in southern and eastern Africa, less common outside and in more arid areas in South Africa. Within a specific habitat, numbers can fluctuate dependent on rainfall, food availability (Nel *et al.* 1984), breeding stage or disease (Maas 1993a, b). In the SW Kalahari, regular counts along a 21 km stretch of dry river bed, with an area of ca. 10 km², recorded 7–140 individuals (or 0.7–14/km² (Nel *et al.* 1984, Nel 1996). In the Limpopo Province, South Africa, densities were 5.7 foxes/km², and in the nearby Mashatu G. R., Botswana, 9.2 foxes/km² in the breeding season and 2.3 foxes/km² at other times (Berry 1978). At Tussen-die-Riviere G. R., Free State, South Africa, Mackie (1988) recorded densities that varied from 0.3 to 0.5 foxes/km² over a three-year period, while Kuntzsch (1992) found densities that ranged from 1.1 to 2.0 foxes/km² in the central Karoo, Northern Cape, South Africa. Hendrichs (1972) recorded a density of 0.3–1.0 foxes/km² in Serengeti N. P.

Adaptations Bat-eared Foxes show a number of morphological and behavioural adaptations to their insectivorous diet. Huge ears are used to locate insects and underground larvae (Smithers 1971) and may aid thermoregulation (Maas 1993b). Insectivory has not only affected the number of teeth (see Description), but also their shape; milk dentition is typically canid, with unreduced carnassials, but in adults the carnassial shear is lost and molars become the most

bunodont, verging on zalambdodont, of any canid (see Kieser 1995). A modification in the insertion point of the digastric muscle (in this case, in a flange situated vertically below or slightly in front of the glenoid) facilitates very rapid chewing (Kingdon 1977), up to five bites per second (Maas 1993b). In southern Africa, nocturnal foraging during summer changes to a diurnal pattern in winter, when subzero night temperatures are common (Nel 1990), mirroring similar changes in the activity of *Hodotermes mossambicus*; in eastern Africa, nocturnal foraging is the norm (Lamprecht 1979, Malcolm 1986, Maas 1993a, Wright 2004). By day, especially in winter, foraging peaks at the height of insect and termite activity (Nel 1990).

Group members huddle by night or in the early morning to escape the cold, or seek shade to escape the worst heat, or lie in the open, facing multiple directions, to ease predator detection. Dens are used for shelter and breeding and are excavated by breeding adults or adapted from disused dens of other mammals (e.g. springhares *Pedetes* spp., Aardvark *Orycteropus afer*, South African Ground Squirrel *Xerus inauris*, termite mounds and warthog holes *Phacochoerus* spp.; Lamprecht 1979, Maas 1993a). Dens have several entrances and chambers, and tunnels up to 3 m long (Smithers 1971, Berry 1978). Dens are carefully maintained throughout the year, although maintenance at breeding dens increases markedly in Aug (Smithers 1971) shortly before the birthing season. Apart from regular breeding dens, Bat-eared Foxes in Serengeti N. P. utilize 'foraging dens' for the protection of cubs in different parts of the territory (Maas 1993a). Breeding dens can be clustered: in the SW Kalahari, six dens were found in a 0.5 km² section of the river bed in 1976 (J. A. J. Nel pers. obs.); each den was occupied by an adult pair and 2–3 cubs (16 in total). Two further dens were nearby.

In some parts of the range, polygyny, allo-suckling and communal breeding occurs because insect prey has a high renewal rate, the cost of food sharing is low, and dispersal risk high amidst limited breeding territories (Maas 1993a). In Serengeti N. P., for example, allo-suckling and communal breeding occurs between closely related ♀♀ (Maas 1993a; and see Social and Reproductive Behaviour). In southern Africa, communal breeding is rare (Pauw 2000), but family groups can also coalesce, with up to ten non-suckling juveniles and three adults (J. A. J. Nel pers. obs.).

Foraging and Food Insectivorous. Food consists primarily of insects, with harvester termites *Hodotermes mossambicus* and *Microhodotermes viator* and beetles predominating and with smaller numbers of orthopterans, beetle larvae and ants (Berry 1978, Nel 1978, Lamprecht 1979, Stuart 1981, Koop & Velimirov 1982, Malcolm 1986, Mackie 1988, Maas 1993a, Skinner & Chimimba 2005). Other termite species are also taken, for example *Macrotermes* spp. in Botswana and Tanzania (Wright 2004, Skinner & Chimimba 2005). In open shrub savanna in Botswana other taxa such as arachnids can be more common, while fruit is taken seasonally (Nel 1978, Skinner & Chimimba 2005) but can be important in open shrub vegetation with scattered trees (Kuntzsch & Nel 1992). Small mammals, birds, eggs, reptiles and fruit are eaten sporadically in southern Africa (Nel 1978, Kok & Nel 1992, Kuntzsch & Nel 1992, Skinner & Chimimba 2005, Klare *et al.* 2011) but rarely in eastern Africa (Lamprecht 1979, Maas 1993a, Wright 2004). Seasonal changes in the proportion of particular taxa occur (Nel 1978, Nel & Mackie 1990, Maas 1993a, Klare *et al.* 2011). In Serengeti N. P. dung beetles are the main source of food during the wet season when termite activity is reduced (Waser 1980,

Lateral, palatal and dorsal views of skull of Bat-eared Fox *Otocyon megalotis*.

Bat-eared Fox *Otocyon megalotis* facial features.

Maas 1993a). When both are scarce, beetle larvae are often dug up from the ground (Maas 1993a). *Hodotermes mossambicus* is patchily distributed throughout the Serengeti and may constitute a limiting resource in this part of the species' range (Maas 1993a). Although the animals' water requirements may be met by the high water content of their insect prey or, in southern Africa, berries during the summer (Nel 1978, Kuntzsch & Nel 1992), water constitutes a critical resource during lactation (Maas 1993a).

Food is located primarily by sound (Nel 1978) but also by smell (Smithers 1971) while walking slowly with the nose close to the ground and the ears cocked forward. Foraging routes are mostly up- or crosswind (J. A. J. Nel pers. obs.). Foraging and feeding rates are higher when feeding on termites, concentrated in patches, than on other more dispersed insects (Nel 1990): they cover a mean of 1.3 km/h and have feeding bouts of 9.7 ± 8.5 sec/bout when feeding on termites, compared with 0.8 ± 0.3 km/h and 4.2 ± 1.7 sec/bout when feeding on dispersed insects. They also spend more of their foraging time ($69 \pm 11.7\%$) feeding when preying on termites than when preying on non-patch food ($4.3 \pm 2.4\%$) (Nel & Mackie 1990). When feeding on termite patches the foxes feed close together, but spread out to 200 m apart when feeding on other insects (Nel 1978, Maas 1993a).

Group members call each other to rich food patches with a low whistle. Males gradually initiate cubs into foraging, while ♀♀ forage independently (Nel 1978) till weaning (Maas 1993a). Social learning by cubs seems to be involved when first foraging (Nel 1999). Bat-eared Foxes do not cache food. They also do not take domestic stock, contrary to claims by farmers, or poultry. They do not scavenge or take carrion but will feed on maggots in carcasses. Stenkewitz & Kamler (2008) reported feeding associations between Bat-eared Foxes and at least four species of insectivorous birds, including the Southern Anteater-chat *Myrmecocichla formicivora*, Crowned Lapwing *Vanellus coronatus*, Double-banded Courser *Rhinoptilus africanus* and Northern Black Korhaan *Eupodotis afraoides*.

Social and Reproductive Behaviour Bat-eared Foxes in southern and East Africa live predominantly as monogamous pairs with cubs, with little extra-pair paternity (Nel *et al.* 1984, Wright *et al.* 2010; but see Pauw 2000), while those in eastern Africa have been reported living both in monogamous pairs (Wright *et al.* 2010) and in stable family groups that consist of a ♂ and up to three closely related ♀♀ with cubs (Maas 1993a). Group size varies with time of year, with a mean of 2.7 ($n = 623$) in the SW Kalahari. Average adult group size in Serengeti N. P. is 2.4 (± 0.1 , $n = 18$), and prior to dispersal of pups 6.0 (± 0.4 , $n = 18$; Maas 1993a). In Serengeti N. P., the

Bat-eared Fox *Otocyon megalotis*.

additional ♀♀ in the extended family groups are philopatric daughters, sometimes from several generations, which form a hierarchy based on age; all ♀♀ in such 'super families' breed (Maas 1993a).

Groups forage as a unit, and have home-ranges from less than 1 km² to more than 6 km². In southern Africa, home-ranges overlap widely (Nel 1978, Mackie & Nel 1989). In East Africa, they can either overlap (Malcolm 1986, Wright *et al.* 2010), changing little in size during the year, or, as in Serengeti, where they centre around harvester termite colonies, they can be defended as territories that are patrolled and urine-marked during part of the year (Lamprecht 1979, Maas 1993a). Group size determines the outcome of clashes during territorial conflict (Maas 1993). Territory inheritance is frequent in the Serengeti and neighbouring groups can be closely related, with animals visiting each other from time to time (Maas 1993a).

Bat-eared Foxes engage in frequent and extended allogrooming sessions, which serves to strengthen group cohesion (Maas 1993a). In the SW Kalahari it increases markedly (as does urine-marking) during courtship, when huddling, playing and mutual chasing are also more common than other times. Vigorous and extended social play is very common not only in cubs but also in adults even after the young have dispersed (B. Maas pers. comm.).

Communication is primarily visual, with a variety of ear and tail positions, emphasized by dark markings, used for displays (Nel & Bester 1983, B. Maas pers. obs.). The unique inverted U-position of the tail is indicative of a range of states of arousal including fear, play and alarm (Nel & Bester 1983). Vocalizations are mostly soft and sparingly used (Lamprecht 1979, Nel & Bester 1983), except when the animals are highly alarmed or excited during play (Maas 1993a). Urine marking is used on territory boundaries in East Africa (Maas 1993a) and for double marking during pair bonding (Nel & Bester 1983).

Pair-bonding and mating takes place from Jul to Sep in southern and East Africa with up to ten copulations per day for several days, and with a copulatory tie lasting ca. 4 minutes, followed by a peculiar post-copulatory play. Although the behaviour of partners is highly coordinated during the mating season, genetic data from a Kenyan population revealed that five of 44 cubs were sired by ♂♂ other than their social fathers (H. Wright pers. comm.). Small cubs nurse inside

the den, later outside, and first emerge for brief periods when they are 8–12 days old. Cubs are sometimes moved between dens (Maas 1993a, Pauw 2000).

Young cubs are initiated into foraging by the ♂ (Nel 1978), who spends more time close to the cubs than ♀♀, grooming, guarding and playing with them and defending them against predators (Wright 2006). Maternal investment during lactation is high in Bat-eared Foxes compared with other canids, but due to an insectivorous diet mothers and/or cubs cannot be provisioned directly (Maas 1993a; but see Pauw 2000). However, the high level of male parental care enables ♀♀ to maximize their foraging time. The importance of male care is illustrated by the fact that, in a Kenyan population, lactating ♀♀ spent >85% of the night actively foraging (Wright 2004), and the amount of time ♂♂ spent at breeding dens influenced cub survival to weaning (Wright 2006). The disparity in care between the sexes becomes less prominent after weaning (Berry 1978, Maas 1993a, Wright 2004), which in the SW Kalahari takes place after the first rains and subsequent flush of insects.

In eastern Africa, where there is more than one ♀, nursing effort per cub is higher in daughters than in ♂-females (Maas 1993a). The nuclear family group, consisting then of a mated pair and their cubs (in southern Africa), persists till the next Jun when cubs disperse and the pair, which mates for life, reaffirms their pair bond (Nel & Bester 1983).

Reproduction and Population Structure Bat-eared Foxes are sexually mature at 8–9 months. Births occur at the onset of the wet season, timed with the period of peak insect densities, from Sep to Dec in southern Africa (Smithers 1971, Lynch 1983, Nel *et al.* 1984) and Aug to Oct in East Africa (Malcolm 1986, Maas 1993a), after a gestation period of 60–75 days. They have a single litter per year. Litter-size is 1–6 (usually five); in Serengeti N. P. average litter-size is 2.6 (n = 90), although cubs raised per super-family averages 3.6 (n = 48) subject to annual variation potentially linked to food availability (Maas 1993a). The number of cubs to emerge from the den in ‘super-families’ is inversely related to the number of breeding ♀♀. Neonates weigh between 99 and 142 g. Lactation lasts 14–15 weeks (Lamprecht 1979). Longevity has been recorded at 17 years in captivity (Weigl 2005), and to nine years in the wild (Kamler & Macdonald 2006).

Predators, Parasites and Diseases Predators include raptors (e.g. Martial Eagle *Polemaetus bellicosus*, Spotted Eagle-owl *Bubo africanus*, Giant Eagle-owl *B. lacteus*), African Rock Python *Python sebae*, Spotted Hyaena *Crocuta crocuta*, Brown Hyaena *Hyaena brunnea*, Striped Hyaena *H. hyaena*, African Wild Dogs *Lycaon pictus* (see Rasmussen 1996) and Leopards *Panthera pardus* (see Bothma & Le Riche 1982). Pups may fall prey to Black-backed Jackals (Pauw 2000) and Ratels *Mellivora capensis* (Begg *et al.* 2003a). During droughts, or in the absence of suitable breeding territories (Maas 1993a), lack of food can cause starvation, or decrease ability to avoid predators. In southern Africa Bat-eared Foxes coexist widely with Black-backed Jackals and Cape Foxes with little overt aggression, perhaps due to food niche separation between the species. However, Bat-eared Foxes will displace Cape Foxes at dens or while feeding with cubs, and will mob and chase away Black-backed Jackals approaching breeding dens (J. A. J. Nel pers. obs.).

Little information on parasites, but Horak *et al.* (2000) recorded *Amblyomma marmoreum* (unusual on a wild carnivore smaller than a Lion *Panthera leo* and considered as evidence of stress in the host

animal) and *Haemaphysalis leachi/zumpti* from animals in the S Free State; *Haemaphysalis* spp. and *Ixodes pilosus* were also present on an animal taken in the Eastern Cape, South Africa (Horak *et al.* 1987).

Rabies (Maas 1993b, Nel 1993, Thomson & Meredith 1993) and canine distemper (Roelke-Parker *et al.* 1996) can cause drastic declines in populations. In Serengeti N. P. 90% of mortality in one population was caused by disease and 3% each by predation and road accidents (n = 94). Trichinellosis and canine parvovirus (CPV-2b) have been recorded (Pozio *et al.* 1997, Steinel *et al.* 2000).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Primary threats include unwarranted persecution by farmers, and the effects of disease such as rabies and canine distemper. In addition, persistent drought can depress insect numbers leading to reproductive failure and precipitous drops in numbers. Unnatural mortality due to road kills can be numerous in South Africa, Namibia and Tanzania. Limited hunting and trapping for fur has taken place in some parts of their range, such as in Botswana, where treated pelts are sold as blankets (‘macloutsie’). Bat-eared Foxes are widespread and apart from healthy populations in farming areas enjoy protection in a number of national parks and other protected areas in their distribution areas, including Awash, Omo and Mago National Parks (Ethiopia), Masai Mara National Reserve (Kenya), Serengeti N. P. (Tanzania), Kidepo N. P. (Uganda), Etosha N. P. (Namibia), Kgalagadi Transfrontier Park (South Africa/Botswana), Hwange N. P. (Zimbabwe) and Augrabies Falls, Karoo, Namaqua, West Coast and Mountain Zebra National Parks (South Africa) as well as numerous smaller reserves (Nel & Maas 2004).

Superfamily MUSTELOIDEA

MUSTELIDS

Musteloidea Fischer, 1817. Mém. Soc. Imp. Nat. Moscou 5: 372

Superfamily Musteloidea includes the families Mustelidae, Procyonidae, Ailuridae and Mephitidae. In Africa, it is represented only by the family Mustelidae, discussed below.

Family MUSTELIDAE

WEASELS, POLECATS, OTTERS, RATEL AND ALLIES

The Mustelidae (which contains weasels, polecats, minks, otters, martens, badgers and relatives) is a polygeneric family distributed throughout all continents except Antarctica and Australasia (though they have been introduced into New Zealand). The family Mustelidae is closely related to the Procyonidae (raccoons), Ailuridae (Red Panda *Ailurus fulgens*) and Mephitidae (skunks). These four families comprise the superfamily Musteloidea, which in turn is most closely related to the Pinnipedia (Fulton & Strobeck 2006, Sato *et al.* 2006, 2009). Mustelids occur in very varied habitats ranging from tropical rainforests to Arctic tundra and from deserts to inland waterways and coastal waters. This is the largest family of the order Carnivora. Wozencraft (2005) lists 22 genera and 59 species. As considered here, eight genera and 11 species occur in Africa.

A discussion of the classification of the Mustelidae, as currently understood, requires some elaboration on extralimital taxa. Until recently, five extant mustelid subfamilies in total have generally been recognized following Simpson (1945), namely Mustelinae, Lutrinae, Mellivorinae, Melinae and Mephitinae, although some have followed Pocock (1922) and recognized more subfamilies, including Ictonychinae, Guloninae, Helictidinae and Taxidiinae. There is now substantial evidence in support of a close relationship between the weasels, polecats and minks of the genera *Mustela* and *Neovison* (subfamily Mustelinae) and the otters (subfamily Lutrinae). Further, despite the treatment of Wozencraft (2005), who included taxa previously placed in Mellivorinae, Melinae, Ictonychinae, Guloninae, Helictidinae and Taxidiinae in Mustelinae, the distinctiveness of the subfamilies Mellivorinae (containing the Ratel *Mellivora capensis*),

Ictonychinae (African Striped Weasel) (top), Lutrinae (African Clawless Otter) (middle) and Mellivorinae (Ratel) (bottom).

Tentative phylogenetic tree of African Mustelidae (modified after Sato *et al.* 2012 and Wolsan & Sato 2010).

African Striped Weasel *Poecilogale albinucha* myology.

Melinae (containing the badgers of the genera *Meles* and *Arctonyx*), Ictonychinae (containing the polecats and weasels of the genera *Ictonyx*, *Poecilictis*, *Poecilogale*, *Vormela* and *Lyncodon*, and the grisons *Galictis*), Guloninae (containing the martens *Martes*, Fisher *Pekania pennanti*, Tayra *Eira barbara* and Wolverine *Gulo gulo*), Helictidinae (containing the ferret-badgers *Melogale*) and Taxidiinae (containing the American Badger *Taxidea taxus*) is also well evidenced at present (Koepfli *et al.* 2008, Wolsan & Sato 2010, Sato *et al.* 2012). The elevation of the skunks (including the stink badgers *Mydaus*) to the level of family agrees with Wozencraft (2005) and is now also well supported (Sato *et al.* 2009, 2012, Eizirik *et al.* 2010).

Mustelids are very small to medium-sized carnivorans, ranging in overall length and weight from 0.15 m and 0.025 kg (as in the Least Weasel *Mustela nivalis*, the smallest member of the order Carnivora) to 2.3 m (in the Giant Otter *Pteronura brasiliensis*) and 45 kg (in the Northern Pacific Sea Otter *Enhydra lutris*); sexual dimorphism in size (♂♂ larger than ♀♀) is pronounced in most species. Head and pinnae are usually small, neck and body long. Legs short, with five digits each; claws usually present, curved and non-retractile. In most otters, the minks and two species of South American weasels, the digits are webbed for swimming. Anal glands are usually present and well developed, with a large sac. The skull has a very short rostrum and long braincase (rostral length less than one-third of braincase length, as in the otters and mustelines) to a very long rostrum and short braincase (both about equal in length, as in the Hog Badger *Arctonyx collaris*). Other cranial features include: no alisphenoid canal; auditory bulla single-chambered; and middle ear with the mustelid suprameatal fossa (Wolsan 1993, 1999). Dental formula $I^{3/2-3}, C^{1/1}, P^{2-4/2-4} M^{1/1-2} = 28-38$; shearing blade of the upper carnassial without a slit-like notch; second lower molar, if present, small and single-rooted. Baculum (os penis) present in ♂♂.

Mustelids vary greatly in adaptations and biology. They are terrestrial, semi-arboreal (such as the martens and Tayra) or semi-aquatic (as the otters, minks and some South American weasels). They may be carnivorous or omnivorous, foraging both day and night or being either diurnal or nocturnal; in the northern part of their range, some remain inactive for several days, weeks or months during winter. Except during the mating season or when accompanied by young, most are solitary and territorial; some live in pairs and some in family or social groups. Secretion from the anal glands is used as a territory marker and, in species with striking, mostly black and white pelage patterning, in defence. Breeding is seasonal or non-seasonal. Copulation is vigorous, repeated and often very prolonged (which induces ovulation). Gestation lasts from four weeks to 12.5 months (as in the Stoat *Mustela erminea* and North American River Otter *Lontra canadensis*), including, in many species, a period of delayed implantation from a few days to 11

African Striped Weasel *Poecilogale albinucha*. Myology of skull musculature with diagrams of stress/reinforcement lines in the skull inserted.

months. There are 1–18 (usually 1–6) young per litter and between one and three (usually one) litters a year.

Four subfamilies are represented in Africa: Ictonychinae, Lutrinae, Mellivorinae and Mustelinae. The African ictonychines comprise three genera, each with a single species. They are adapted for terrestrial life, lightly built and skunk-like in appearance, with the tail length about two-thirds of head-and-body length. The pelage is black and white. In the skull, the pterygoid hamulus is fused with the auditory bulla. The upper dentition is characterized by the absence of a first premolar, with the second premolar being either present or absent; the carnassial is narrow relative to its length, with a small, antero-posteriorly short lingual wing; and the molar is short relative to its bucco-lingual width, with a small metacone. In the lower dentition, the second premolar is either present or absent; the carnassial is narrow relative to its length, with or without a metaconid and with a small talonid; and the second molar is either present or absent.

The African otters comprise three genera and four species (see genus accounts). These otters, like others in the subfamily, are adapted for aquatic life, with a streamlined body, and similarly broad head and neck; the tail is long (tail length exceeds the half of head-and-body length), thick and muscular to aid in swimming. A very dense underlayer of fur provides insulation in water. The pelage is largely brown to black. In the skull, the pterygoid hamulus is not fused with the auditory bulla. The upper dentition in all four species is characterized by the presence of the first and second premolars; the carnassial is broad relative to its length, with a large, antero-posteriorly long lingual wing; and the molar is long relative to its bucco-lingual width, with a large metacone. In the lower dentition, the second premolar is present; the carnassial is broad relative to its length, with both the metaconid and talonid large; and the second molar is present.

The Ratel *Mellivora capensis* is the single extant genus and species of the subfamily Mellivorinae. It is adapted for terrestrial life, heavily built and badger-like in appearance, with the tail length about one-third of head-and-body length. The pelage is largely black, dark grey and white. In the skull, the pterygoid hamulus is not fused with the auditory bulla. The upper dentition is characterized by the absence of a first premolar, with the second premolar being present; the carnassial is broad relative to its length, with a small, antero-posteriorly short lingual wing; and the molar is short relative to its bucco-lingual width, with a small metacone. In the lower dentition, the second premolar is present; the carnassial is narrow relative to its length,

without a metaconid and with a small talonid; and the second molar is absent.

The African mustelines comprise one genus containing three species. They are adapted for terrestrial life, lightly built and weasel-like in appearance, with the tail length about one-third of head-and-body length. The pelage is largely pale yellow to dark brown. In the skull, the pterygoid hamulus is not fused with the auditory bulla. The upper dentition is characterized by the absence of a first premolar, with the second premolar being present; the carnassial is narrow relative to its length, with a small, antero-posteriorly short lingual wing; and the molar is short relative to its bucco-lingual width, with a small metacone. In the lower dentition, the second premolar is present; the carnassial is narrow relative to its length, without a metaconid and with a small talonid; and the second molar is present.

The fossil record of Mustelidae (including stem mustelids) ranges from the late Oligocene onward in Europe, from the early Miocene onward in Africa, Asia and North America and from the late Pliocene onward in South America. The earliest known African mustelids are *Luogale rusingensis* from Kenya (Schmidt-Kittler 1987) and *Namibictis senuti* from Namibia (Morales *et al.* 1998), both dated between 20 and 17 mya. Although the earliest record of Mustelidae is from Europe, the family appears to have its origin in south-eastern Asia at the beginning of the late Oligocene, about 28.4 mya (Sato *et al.* 2009, 2012, Eizirik *et al.* 2010). The earliest mustelids (such as the

late Oligocene *Plesictis plesictis* and *Bathygale sicaulensis*) were small predators and the predatory mode of life has prevailed within the family during its history. This adaptation has only involved niches for small to medium-sized predators except for the late Miocene to Pliocene interval when the largest mustelids that ever lived shared the niche for large predators in Eurasia, North America and also Africa, from where the gigantic mellivorine *Ekorus ekakeran* and the gigantic lutrines of the genus *Enhydriodon* are known (Werdelin 2003a, Werdelin & Lewis 2005). The last are parts of the extensive late Miocene–Pliocene African radiation of the tribe Enhydriodontini (Werdelin & Lewis 2005, Pickford 2007). The largest African Enhydriodontini were the largest mustelids known, with a body mass of 250 kg or more (Lewis 2008). The earliest record of omnivory (represented by *Stromeriella depressa*) is from the early Miocene and since that time this adaptation has repeatedly been developed within the family. All subfamilies had diverged by the end of the Miocene (Sato *et al.* 2012). Although mustelids attain great diversity in the tropics, they are the most common carnivorans of the temperate regions. In Africa, the diversity of mustelids is lower than on any of the other continents, but the spectrum of their habitats is very wide, ranging from rainforests to deserts and including freshwater and coastal waters.

Mieczysław Wolsan

Subfamily MUSTELINAE – Weasels, Polecats

Mustelinae Fischer, 1817. Mém. Soc. Imp. Nat. Moscou 5: 372.

The Mustelinae (which contains weasels, polecats and minks) is widespread in Eurasia and North America and also occurs in North Africa and N South America (introduced into New Zealand), in habitats ranging from rainforests to tundra and from semi-deserts to freshwater and riparian areas. This is the most diverse subfamily of the family Mustelidae: there are currently two genera and 18 species (Wozencraft 2005). One genus (*Mustela*) and three species occur in Africa.

Mustelines are very small to small mustelids, ranging in overall length and weight from 0.15 m and 0.025 kg (as in the Least Weasel *Mustela nivalis*) to 0.75 m and 2 kg (as in the Steppe Polecat *Mustela eversmannii*). The head is small, flat-topped and roughly triangular, the vibrissae long, and the pinnae short and rounded. The neck and body are very long and slender, with legs very short and the tail length from one-fourth to two-thirds of the head-and-body-length; the elongated body shape is an adaptation that enables penetration of confined spaces (especially burrows) in search of prey. Sexual dimorphism in size is more pronounced in Mustelinae than in any other mustelid subfamily. This strong dimorphism appears to be an adaptation for the different roles of the two sexes in reproduction: large males being favoured by competitive mating and small females because of lower energetic requirements and greater efficiency in hunting small prey – vital advantages when rearing young (Erlinge 1979). In northern populations of the Stoat *Mustela erminea*, Long-

tailed Weasel *Neovison frenata* and the Least Weasel, the pelage turns white in winter.

The skull is long, narrow and dorso-ventrally flattened, with a short rostrum and long braincase (rostral length is about or less than one-third of braincase length); the middle-ear cavity is mostly filled with a spongy bone. Dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{1/2} = 34$. The upper and lower carnassials are long and narrow, with a long shearing blade; the lower carnassial lacks a metaconid and has a short, cutting talonid. The upper molar is elongated transversely and constricted antero-posteriorly, smaller than or about equal in size to the upper carnassial.

Most (including all African) mustelines are purely or largely terrestrial; the American Mink *Neovison vison*, European Mink *Mustela lutreola*, Amazon or Tropical Weasel *Neovison africana* and Colombian Weasel *N. felipei* are semi-aquatic. They are strictly or almost strictly carnivorous (including specialist and opportunistic hunters), promiscuous and, except during the mating season or with young, solitary and territorial. Gestation lasts from four weeks to 12.5 months (as in the Stoat), including, in some species, delayed implantation lasting up to 11 months. Litter-size is 1–18 (usually 1–8) with 1–3 (usually one) litters per year.

Mieczysław Wolsan

GENUS *Mustela*

Weasels, Polecats

Mustela Linnaeus, 1758. Syst. Nat., 10th edn, 1: 45.

Mustela is a polytypic genus distributed widely in North Africa, Eurasia, North America and N South America (introduced into New Zealand), in habitats ranging from rainforests to tundra and from semi-deserts to freshwater and riparian areas. This is the largest genus of the order Carnivora comprising 17 species (see Wozencraft 2005), of which three occur in Africa: the Least Weasel *M. nivalis* occurs in Morocco, Algeria and Tunisia; the Egyptian Weasel *M. subpalmata* is found only in Egypt; and the European Polecat *M. putorius* occurs only in Morocco.

In Africa, both the Least Weasel and Egyptian Weasel (both contained in the subgenus *Gale*) are characterized by small size; face without a dark mask across the eyes; tail not bushy; skull long and narrow, without noticeably projecting mastoid processes; and auditory bulla long, narrow and approximately rectangular. The European Polecat is contained in the subgenus *Putorius* and characterized by larger size; face with a dark mask across the eyes; tail bushy; skull short and broad, with noticeably projecting mastoid processes; and auditory bulla short, broad and approximately triangular.

Mustela nivalis LEAST WEASEL (COMMON WEASEL)

Fr. Belette; Ger. Wiesel (Mauswiesel)

Mustela nivalis Linnaeus, 1766. Syst. Nat., 12th edn, p. 69. Vesterbotten, Sweden.

Least Weasel *Mustela nivalis*.

The allopatric Least Weasel and Egyptian Weasel (below) have a relationship that is still uncertain. This issue and their common biology are discussed in the profile that follows.

Robbie A. McDonald

Mustela subpalmata EGYPTIAN WEASEL

Fr. Belette égyptienne; Ger. Ägyptischer Wiesel

Mustela subpalmata Hemprich & Ehrenberg, 1833. Symb. Phys. Icon., Mamm. 3 (2).

In: 'Herpestes leucurus'; K verso. 'In domibus aegyptiacis Cahirae et Alexandriae murium vulgaris socius.'

Taxonomy The Least Weasel *M. nivalis* is a Holarctic species with a single African subspecies, *M. n. numidica*. This subspecies has been treated as a distinct species, of which the form *M. numidica subpalmata* from Egypt was considered a race on the grounds of its larger size (Allen 1939, Frechkop 1963). Subsequent authors have continued to recognize *numidica* as only a subspecies of *M. nivalis*, due to the general increase in the species' body size with decreasing latitude (Ellerman & Morrison-Scott 1951, Coetzee 1977). More recently, *numidica* has been thought to be sufficiently similar to southern European forms to be part of *M. n. vulgaris* (Van Zyll de Jong 1992). However, based on cranial morphology, the Egyptian Weasel *Mustela subpalmata* is a strong candidate for consideration as a distinct species (Van Zyll de Jong 1992, Reig 1997, Abramov & Baryshnikov 2000)

Egyptian Weasel *Mustela subpalmata*.

Lateral, palatal and dorsal views of skull of Least Weasel *Mustela nivalis*.

and was treated as such by Wozencraft (2005). This classification is followed here, but the two species are treated under *M. nivalis* for convenience; the information presented pertains to both species, unless indicated.

Synonyms (*nivalis*): *africana* Gray (not of Desmarest), *atlas*, *numidica*; (*subpalmata*): none.

Chromosome number for *M. n. nivalis* and *M. n. vulgaris*: $2n = 42$ (Zima & Král 1984). Chromosome number for *M. subpalmata*: not known.

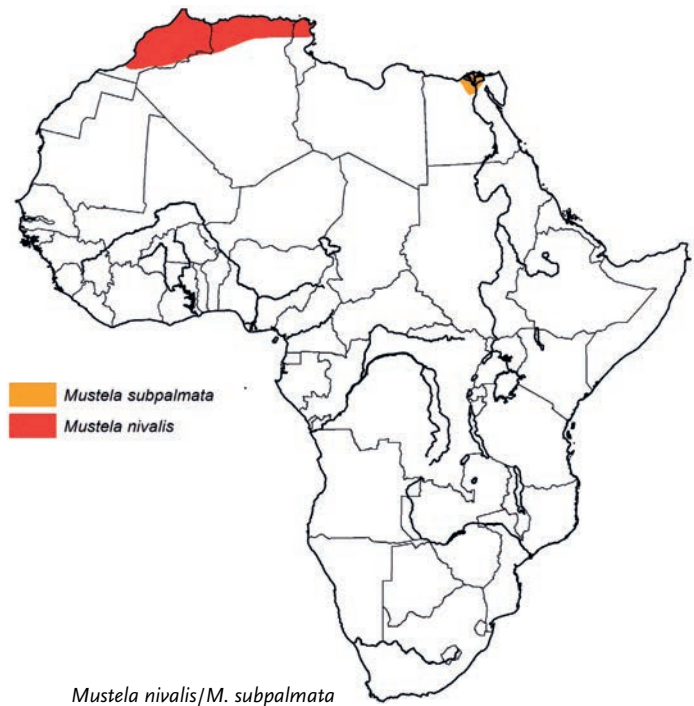

Description Small, elongated, slender body with pointed muzzle, short legs and short (one-quarter of body length, though slightly longer in *Mustela subpalmata* at approximately 30–40% of body length) furred tail. Conspicuous black eyes; rounded but flattened ears. Long, cat-like vibrissae. Dorsal pelage dull chestnut brown, ventral pelage white to creamy-yellow sometimes with spots of brown distributed in individually recognizable patterns. Irregular margin between dorsal brown and ventral pale fur. Distinct brown pads on paws. Males markedly larger than ♀♀. Usually four pairs nipples, visible only in adult ♀♀.

Skull flattened with broad, delicate zygomatic arch and large, rounded braincase. Sagittal and nuchal crests and postorbital constriction more pronounced in older animals than in younger animals. Small incisors, large canines, four premolars and molars in upper row, five on lower jaw. Molars have pronounced carnassial shear.

Geographic Variation None recorded.

Similar Species

Mustela putorius. In Africa, known from Morocco only. Larger, with marbled brown and cream pelage; face with a dark mask across the

eyes; skull short and broad, with noticeably projecting mastoid processes; auditory bulla short, broad and approximately triangular. *Poecilictis libyca*. Larger, stockier build, with characteristic striped black and white pelage.

Distribution Least Weasels are at the southernmost part of their Holarctic range in Africa and are confined to Morocco, Algeria and Tunisia; they may have been introduced by humans (Dobson 1998). The Egyptian Weasel is endemic to Africa and lives in the lower Nile Valley of Egypt, between Beni Suef in the south and Alexandria and the Delta in the north (Handwerk 1993). Morphology and biogeographical relationships with fossil record of the Middle East suggest Egyptian populations are a natural relict (Dayan & Tchernov 1988).

Habitat In north-west Africa, Least Weasels mostly inhabit regions with moderate rainfall (>500 mm), including coastal regions, irrigated farmland, forests and higher altitude zones up to 2600 m in the Moroccan High Atlas. In regions with lower rainfall (<500 mm), they are restricted to humid localities, including, for example, oases at the northern fringe of the Sahara (Aulagnier 1990, Kowalski & Rzebik-Kowalska 1991, Cuzin 1996, 2003).

Egyptian Weasels are largely commensal with humans. They are often trapped in underground larders and even in cars (Flower 1932, Osborn & Helmy 1980, Handwerk 1993, Hoath 2003).

Abundance In Morocco, Least Weasels are common outside of zones of intensive agriculture (Aulagnier 1990). Populations are stable or may have declined slightly between late 1980s and 1990s (Cuzin 1996). Information elsewhere is very scarce. Egyptian Weasels are considered common to abundant in parts of Cairo with densities of 0.5–1.0/ha estimated from trapping (Handwerk 1993). Populations volatile, and vary annually and seasonally in relation to prey availability.

Adaptations Specialized for pursuit of rodents, their elongated body-shape allowing entry to tunnels and narrow crevices.

Foraging and Food In north-west Africa, Least Weasels mainly eat small mammals (including *Apodemus*, *Gerbillus* and *Meriones*, possibly *Crociodura*) and birds, including hens (F. Cuzin pers. comm.).

Egyptian Weasels are opportunistic feeders, their diet comprising an unusually high percentage of fruit and vegetables, mainly grapes, dates and beans ($\approx 50\%$), as well as domestic hens and ducks ($\approx 20\%$) (Handwerk 1993). Rodents and domestic rabbits were less significant, as were invertebrates and fish (Osborn & Helmy 1980, Handwerk 1993). They also scavenge from waste heaps. Egyptian Weasels are active mainly at night and in the early evening, but also occasionally by day in seasonally variable bursts of activity alternated with prolonged rest periods (Handwerk 1993).

Social and Reproductive Behaviour Solitary and territorial. Larger male territories encompass a number of female territories, and territories are marked with faeces and urine. Mating is vigorous and prolonged, since ovulation is stimulated by the baculum (os penis) during copulation. Vocalizations include chattering and trilling during courtship and family play; they have a sharp, barking alarm call.

Reproduction and Population Structure There is direct implantation and gestation of approximately 4–5 weeks. When sufficient food is available there can be 2–3 litters a year, and young ♀♀ can breed in the year of birth. In Egypt, breeding occurs around Apr and Aug (Handwerk 1993). Litters have been recorded in Aug (four kits; Handwerk 1993) and early Dec (five kits; Flower 1932). Kits born naked and helpless, develop killing behaviour by approximately ten weeks and reach independence shortly afterwards. Few live more than one year.

Predators, Parasites and Diseases Likely predators include foxes, raptors and crows. A range of bacterial and viral diseases affects weasels and there are a few specific parasites. Two species of flea have been recorded, *Xenopsylla cheopis* from Rabat, Morocco (Jordan 1931) and *X. ramesis* from Mecharia, Algeria (Hopkins & Rothschild 1953).

Conservation IUCN Category: Least Concern (*Mustela nivalis*); Least Concern (*M. subpalmata*). CITES: Not listed.

Although issues of conflict with humans arise where predation of domestic animals is a problem, there is little cause for concern for either species, since they are both common and adaptable. In Morocco the species is commercially utilized for witchcraft purposes (F. Cuzin pers. comm.).

Measurements

Mustela nivalis numidica

GLS (♂♂): 42.9 mm, n = 4

North-west Africa (Van Zyll de Jong 1992)

Two further ♂♂ had GLS 43.2, 45.4 mm; one ♀ had GLS 39.0 mm (Alcover & Jaume 1983)

No other measurements available for Africa

Mustela subpalmata

HB (♂♂): 289 (252–301) mm, n = 9

HB (♀♀): 242 (232–259) mm, n = 5

T (♂♂): 117 (109–129) mm, n = 9

T (♀♀): 99 (94–110) mm, n = 5

HF c.u. (♂♂): 50 (45–55) mm, n = 9

HF c.u. (♀♀): 39 (34–42) mm, n = 5

E (♂♂): 21 (20–23) mm, n = 9

E (♀♀): 18 (15–20) mm, n = 5

WT (♂♂): 390 (355–425) g, n = 6*

WT (♀♀): 209 (190–230) g, n = 5*

GLS (♂♂): 50.0 (48.2–51.2) mm, n = 7

GLS (♀♀): 43.2 (41.8–43.9) mm, n = 5

Egypt (Osborn & Helmy 1980)

*Handwerk 1993

Other recorded mean GLS measurements include: 48.6 mm (n = 8) for ♂♂ and 43.6 mm (n = 8) for ♀♀ (Van Zyll de Jong 1992); 48.8 mm (n = 22) for ♂♂ and 42.5 mm (n = 13) for ♀♀ (Reig 1997)

Mustela putorius EUROPEAN POLECAT

Fr. Furet; Ger. Frettchen

Mustela putorius Linnaeus, 1758. Syst. Nat., 10th edn, 1: 46. 'inter Europae rupes et lapidum acervos', restricted by Thomas (1911) to 'Scania, S Sweden'.

European Polecat *Mustela putorius*.

Taxonomy Monotypic. There has been some past debate over whether African populations (known only from Morocco) are true European Polecats or merely feral populations of their domesticated form (*furo*). Owen (1984) and Aulagnier & Thévenot (1986) are strongly of the opinion that Moroccan populations are ascribable to the latter. Owen (1984) even brought Moroccan ferrets to the United Kingdom and bred them for many years noting 'their colour and behaviour were similar to those of British specimens, except that no white specimens were bred'. However, while this animal could represent a feral exotic, recent fossil evidence suggests otherwise.

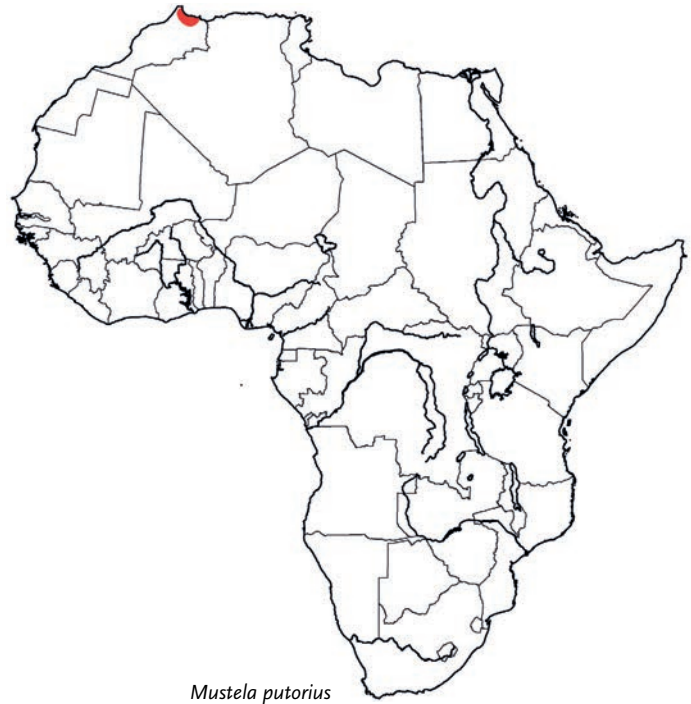

Lateral, palatal and dorsal views of skull of European Polecat *Mustela putorius*.

The only fossil record known is from El Harhoura I. (Temara), where two skulls and various post-cranial elements were ascribed to *M. putorius* by Aouraghe (2000). Dating for this site is poor, but the finds are ascribed to the late Pleistocene, and Aouraghe (2000) suggests that *M. putorius* may represent a relictual element within the fauna. Based on this evidence, we provisionally retain *M. putorius* as an African species (and see Wozencraft 2005). However, the possibility that Moroccan polecats are ancestral to ferrets cannot be excluded. The species is included in the subgenus *Putorius* (Abramov 2000).

Discrimination of feral ferrets from European Polecats is difficult because the two forms are closely related and a continuum of morphological variation may exist. For the purposes of discrimination, reliance upon the narrower postorbital constriction in ferrets is now questionable following work on British specimens (Kitchener *et al.* 1999). MtDNA markers apparently are also not considered reliable discriminants (Davison *et al.* 1999). Kitchener *et al.* (1999) developed a system of scoring pelage characteristics to discriminate between European Polecats and feral ferrets in Britain. Although free-living ferret populations occur on the British Isles, on some Mediterranean islands and New Zealand, few data are available on the species in the wild (King *et al.* 1996, Clapperton 2001).

Chromosome number: $2n = 40$ (FN = 68) (Fredga 1967), although animals from Morocco have not, to our knowledge, been karyotyped.

Description Slender, elongated body with short legs and tail; head with a short muzzle, small (normally light-coloured) ears, and small but pronounced brown eyes. Body colour of Moroccan populations is dark brown, with black guard hairs with lighter coloured underfur. Underbody, legs and tail are black to dark brown; face has a 'bandit mask' across the eyes (as is typical of other European

Mustela putorius

Polecat populations); albino forms are unknown in Morocco. Claws of fore- and hindfeet robust and moderately elongated. If similar to animals from elsewhere in the species' range, ♂♂ considerably larger than ♀♀ (about 50% heavier). Up to five pairs of nipples.

Skull typically mustelid, robust and rather flat, with marked postorbital constriction. Sagittal crest more developed in ♂♂ and older animals (Heráň 1974). Incisors small, canines large and almost straight.

Geographic Variation None recorded.

Similar Species

Mustela nivalis. Smaller, with ventral pelage white; face without dark mask across the eyes; skull long and narrow, without noticeably projecting mastoid processes; auditory bulla long, narrow and approximately rectangular.

Poecilectis libyca. Distinct black and white markings; lives in much drier habitat.

Distribution In Africa, there are records of European Polecats only from Morocco. Cabrera (1932) cites localities in Rif, between Chefchaouen and Oued Nekkour, and, further in the east, Brosset (1960) cites one locality in Beni Snassen. In 1986 and 1987, wild animals were seen in two localities of the area of Chefchaouen (western Rif) (Cuzin 1996). According to Cabrera (1932), wild animals were frequently caught for hunting rabbits, while Owen (1984) notes that the inhabitants of the Rif have bred these animals for the hunting of rabbits 'from time immemorial'; this was done in secret to avoid punitive Spanish game laws. Loche (1867) included this species on the list of mammals occurring in Algeria, but it has never been officially recorded (Kowalski & Rzebiak-Kowalska 1991).

Extralimittally, European Polecats are widespread in the western Palaearctic up to the Ural Mts in Russia, but are absent from Ireland, northern Scandinavia, and much of the Balkans and eastern Adriatic

coast. However, feral populations of the domesticated form (the ferret) have become established in a number of areas, including, for example, northern Britain, the Azores and New Zealand.

Habitat In Morocco the European Polecat lives in the most broken mountains of the Rif, and perhaps still in the Beni Snassen mountains. All these areas are comparatively wooded and rainy (from 400 mm up to more than 1100 mm of annual rainfall), compared with neighbouring areas. The altitudinal range of the area where animals may be found is from sea level up to 2400 m.

Abundance The European Polecat apparently inhabited the western and central Rif area in the eighteenth century (Shaw 1738, in Cabrera 1932) and, even though formal data are lacking, Cabrera (1932) suggested that populations were decreasing, and this trend was attributed by local people to the fact that ♀♀ rearing young were killed for catching the young. Presently, Cuzin (1996) suggests populations may be decreasing, although data are scarce.

Adaptations Slender body size is an obvious adaptation for entering the burrows of prey, and they can also enlarge burrows with their robust claws. The anal glands produce a noxious fluid that the animal sprays at potential predators.

Foraging and Food European polecats are solitary hunters that are active primarily at night (daytime activity tends to be underground). In Morocco they are said to eat small rodents, birds and their eggs (Aulagnier & Thévenot 1986) and probably rabbits. Little information is available from elsewhere, but in New Zealand ferrets take lagomorphs, rodents, birds, reptiles and invertebrates (King *et al.* 1996, Clapperton 2001). Feeding ecology is plastic, but some New Zealand studies suggest that ♂♂ may take more lagomorph and large rodent prey than ♀♀. In Britain both sexes prey heavily upon rabbits and rabbit burrows are commonly used as daytime resting sites (Birks & Kitchener 1999).

Social and Reproductive Behaviour No information available from the African part of the range, and little known from the wild elsewhere. Solitary, territorial and polygamous. Males have larger home-ranges than ♀♀, and scent-mark with anal gland secretions; home-range of ♂♂ may overlap those of ♀♀. The animal is active and alert, often standing erect on its hindlimbs when wary.

Reproduction and Population Structure Assuming reproductive biology is similar to that of other European polecats, Moroccan animals are likely to breed once a year without courtship. Spring mating vigorous, with ovulation stimulated by the os baculum, or possibly by the violent nature of mating, in which ♂ uses his teeth to grip back of neck of ♀ for many minutes, restraining her while copulation occurs (J. Birks pers. comm.). No delayed implantation and gestation is roughly 42 days. Young born May or Jun, wean at about three weeks, attain full adult dentition at 12 weeks and become independent from mother at three months of age.

In captivity can live more than ten years (Weigl 2005), although six is more usual. In New Zealand feral ferrets aged at least four years have been captured. Mortality of dispersing juveniles is high, especially from disease and starvation (Clapperton 2001).

Predators, Parasites and Diseases No information available on wild populations in Africa, but they are likely to be preyed upon by larger carnivores and birds of prey. Presumably subject to infection by wide range of viral and bacterial diseases, as well as protozoan, nematode, helminth and arthropod parasites.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Not protected in Morocco. Possibly captured in some areas for rabbit hunting. There is a need for up-to-date information on the distribution and status of populations in North Africa.

Measurements

Mustela putorius

HB: 350–450 mm

T: 120 mm

Sh. ht: 45–60 mm

Morocco (Aulagnier & Thévenot 1986)

Sample sizes were not given, but presumably measurements are based on several animals in alcohol held in the Museum de l'Institut Scientifique, Rabat. There are no weight data from Morocco available; elsewhere, mean weight is 1.2 kg for ♂♂ and 0.8 kg for ♀♀ (Johnson *et al.* 2000)

Key References Aulagnier & Thévenot 1986; Cabrera 1932; Cuzin 1996.

Huw I. Griffiths & Fabrice Cuzin

Subfamily ICTONYCHINAE – Striped Weasels, Zorilla

Ictonychinae Pocock, 1922. Proc. Zool. Soc. Lond. 1921: 835.

The Ictonychinae (the polecats, weasels and grisons) is a polygeneric subfamily distributed widely in Africa and South America and also occurring in Eurasia and S North America, in a wide variety of habitats ranging from rainforests to deserts. As considered here, there are six genera (the African *Ictonyx*, *Poecilictis* and *Poecilogale*, Eurasian *Vormela*, South American *Lyncodon* and South and S North American *Galictis*) and seven species (Sato *et al.* 2012). Wozencraft (2005) included the Libyan Striped Weasel *Poecilictis libyca* in the genus *Ictonyx* (and see Rosevear 1974). However, evidence from DNA

sequences indicates that *Ictonyx* so circumscribed is paraphyletic with respect to *Poecilogale* (Koepfli *et al.* 2008, Sato *et al.* 2012).

Ictonychines are small to medium-sized mustelids, ranging in overall length and weight from 0.3 m and 0.20 kg (as in the Libyan Striped Weasel) to 0.76 m and 3.8 kg (as in the Greater Grison *Galictis vittata*). The pelage is contrastingly coloured black and white in the African species. Dental formula is $I^{3/3}, C^{1/1}, P^{2-3/2-3}, M^{1/1-2} = 28$ or 34.

Members of the subfamily are primarily terrestrial and carnivorous. Except during the mating season or with young, they

are mostly solitary, but occasionally travel or hunt in pairs or small groups. Gestation lasts from 30 days (as in the African Striped Weasel *Poecilogale albinucha*) to 11 months (as in the Marbled Polecat *Vormela peregusna*), including, in the latter species, delayed implantation. Litter-size is 1–8, with usually one litter born per year.

Three genera, each containing a single species, occur in Africa. *Ictonyx* and *Poecilictis* have the second upper and lower premolars

present; fourth lower premolar with a posterior accessory cusp; lower carnassial with the metaconid; and second lower molar present. *Poecilogale* has the second upper and lower premolars absent; fourth lower premolar without a posterior accessory cusp; lower carnassial without a metaconid; and second lower molar absent.

Mieczysław Wolsan

GENUS *Poecilictis* Libyan Striped Weasel

Poecilictis Thomas & Hinton, 1920. Ann. Mag. Nat. Hist. (9)5:367.

The genus *Poecilictis* is monotypic, represented by a single species, the Libyan Striped Weasel *P. libyca*, from North Africa. The species is often treated as congeneric with *Ictonyx* (see Rosevear 1974, Niethammer 1987, Wozencraft 1993, 2005), but is here included in its own genus based on recent molecular evidence (Koepfli *et al.* 2008, Sato *et al.* 2012), and in line with earlier authors (e.g. Thomas & Hinton 1920, Ellerman & Morrison-Scott 1951, Coetzee 1977,

Corbet 1978, Osborn & Helmy 1980, Baryshnikov & Abramov 1997, 1998). Compared with *Ictonyx*, the Libyan Striped Weasel is smaller, and shaggier in appearance, with four to five black stripes on back (cf. three in *Ictonyx*); the palms and soles of the feet are haired.

Michael Hoffmann and Mieczysław Wolsan

Poecilictis libyca LIBYAN STRIPED WEASEL

Fr. Zorille de Lybie; Ger. Streifenwiesel

Poecilictis libyca (Hemprich & Ehrenberg, 1833). Symb. Phys. Mamm. vol. 1, pt. 2, sig. K, verso. 'Libyae' [Libya].

Libyan Striped Weasel *Poecilictis libyca*.

Taxonomy Highly polytypic species, with as many as six described subspecies (Coetzee 1977, Corbet 1978). Rosevear (1974) suggested a strong possibility that two, if not three, species are really involved, namely *libyca*, *vaillantii* and *oralis*. Niethammer (1987) drew attention to the near absence of any overlap, at least in skull length, between populations north and south of the Sahara Desert. Synonyms: *alexandrae*, *frenata*, *multivittata*, *oralis*, *rothschildi*, *vaillantii*.

Chromosome number: not known.

Description Small, elongated, black-and-white-striped shaggy animal, with short legs and a long tail. Black head, with short ears, short muzzle and a white band encircling the head, passing between the eyes and ears. Back and flanks mostly buff to white (buff to orange in Egyptian animals; M. Saleh pers. comm.). Three black longitudinal stripes beginning behind the ears, the middle one subdividing into two to three additional stripes, all of them fusing on the rump (variations can occur, and pelage may seem spotted, while white long hairs may hide stripes). Black stripes produced by relatively short black under-hairs, and white stripes by long all-white guard hairs. Throat, belly and legs black to brownish. Palms and soles haired. Front claws elongated, with bevelled tips. Long, bushy black and white tail with long, bicoloured guard hairs. Tip of tail and underside darker. Anal glands produce a noxious fluid. One pair abdominal nipples, one pair inguinal.

Skull short (up to 48 mm, cf. 72 mm in Zorilla *Ictonyx striatus*) and broad, triangular when seen from above. Mastoid and paroccipital processes obsolete; tympanic and mastoid bullae strongly inflated (Osborn & Helmy 1980). There is virtually no overlap in skull length between North African and Sahelian populations (Niethammer 1987). Dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{1/2} = 34$.

Geographic Variation

North Saharan populations:

P. l. libyca (including *alexandrae*, see Osborn & Helmy 1980): Egypt and Lybia.

P. l. vaillantii: Morocco, Algeria, Tunisia and Western Sahara.

Lateral, palatal and dorsal views of skull of Libyan Striped Weasel *Poecilictis libyca*.

South Saharan populations:

P. l. multivittata: C Sudan, and possibly E Chad.

P. l. oralis: coastal Sudan.

P. l. rothschildi: south-western Sahara to N Nigeria.

Similar Species

Ictonyx striatus. Restricted to sub-Saharan Africa, the most northerly observations being made in SE Egypt (Osborn & Helmy 1980, Saleh & Basuony 2005); apparently sympatric in parts of the Sahel. Larger (HB: 300–380 mm), with three long black stripes on the back, the medium one not subdivided in the lumbar region; palm and sole naked; postorbital swelling conspicuous.

Poecilogale albinucha. South of the Equator. Smaller, with much shorter legs, and shorter pelage; top of head and tail all white; pale dorsal stripes usually off-white to yellowish, seldom pure white.

Distribution Endemic to Africa, being found only in desert fringes, mountains and oases, and sub-deserts of the northern part of the continent from Morocco and Senegal to Egypt and Eritrea. Apparently absent in hyper-arid regions of central Sahara, except in Aïr (Niger), Murzuk and Jebel Uweinat (Libya). Their range apparently overlaps with that of the Zorilla in some regions, such as N Nigeria and in C and E Sudan (Niethammer 1987). Rosevear (1974) recorded Zorilla and Libyan Striped Weasel occurring in the same areas, but the former was generally more abundant; he mentions both species caught at Farniso (N Nigeria) and several other collection areas for Libyan Striped Weasel in Nigeria and Sudan

Poecilictis libyca

have records nearby for Zorilla. Although specimens and records are lacking, ranges could possibly overlap throughout the breadth of the Sahel belt (C. Stuart & T. Stuart pers. comm.).

Habitat Sand and stone deserts, sub-desert and cultivated land. General habitat is sparse to very sparse vegetation cover, dominated by small bushes, except in cultivated areas. In Morocco, mainly present in habitats with less than 150 mm of annual rainfall, except in coastal dunes, where annual rainfall may reach 250 mm (Cuzin 2003). Present in large ergs, and may live far from waterholes.

Abundance Limited information on the population status of this species. Not uncommon, and appears to be abundant in coastal dunes (Atlantic and also Mediterranean coastal zone). In S Morocco, in a Saharan habitat, after important rains, tracks of individual animals were found in every dry river bed (at an average distance of 0.6 km) (F. Cuzin pers. obs.). Given their dependence on highly unstable prey populations, they are probably subject to periodic fluctuations in numbers.

Adaptations As with the Zorilla, the anal glands produce a noxious, skunk-like fluid that the animal sprays at potential predators. Consequently, while it has been suggested that their colouring may act as a disruptive camouflage, the distinctive contrasting black and white colouration almost certainly acts as a warning to potential aggressors. They have long, well-developed claws for digging, and an elongated body shape probably enables this species to enter holes or burrows for catching rodents and other small prey. Their dentition is similar to the Zorilla, with a carnassial shear adapted to slicing, and a large I³ that probably aids the canine in holding larger prey. Basically ground-living, although they exhibit some climbing ability (Sitek 1996). Large bullae suggest good hearing. Niethammer (1987) has pointed out the likely role of competitive displacement in this species. In North Africa, the Libyan Striped Weasel has the Zorilla niche all to itself and its measurements overlap those of small

Zorillas. However, in the Sahelian zone, both species occur together, and in this part of their range Libyan Striped Weasels are substantially smaller, with no overlap in size with Zorillas.

This species digs single burrows into level surfaces or at the base of dunes, or in rocky or clay substrata, and hides in rock crevices or in the burrows of other animals (Kingdon 1997). In Niger, an excavated burrow in sand showed a unique narrow gallery, which was 3 m long, at 0.7 m under the ground surface, leading to a small chamber (Dragesco-Joffé 1993).

Foraging and Food Exclusively carnivorous, preying on small mammals (rodents, mainly *Gerbillus* spp.), birds resting or nesting on the ground, lizards and insects (Rosevear 1974, Dragesco-Joffé 1993). Local people report them taking poultry. They are solitary foragers, moving rather slowly, or with small jumps with the back arched. The kill is achieved by biting the occipital region of the prey's skull (Hufnagl 1972, Dragesco-Joffé 1993). Detailed comparisons in diet between northern and southern populations might help illuminate the nature of this species' accommodation to sympatry with the Zorilla in the southern, more ecologically diverse parts of its range.

Social and Reproductive Behaviour Nocturnal and predominantly solitary. Sitek (1996) noted that a captive pair would get on amicably (however, during pregnancy and rearing, animals were separated). This species is reportedly quite aggressive, and will spit and hiss when agitated. When threatened, it does not immediately flee, but faces its aggressor, bristles its hair, erects its tail and then turns its hindquarters toward the aggressor. An advancing predator will be squirted with the offensive smelling anal secretions. They may also feign death (Sitek 1996).

Reproduction and Population Structure Time of mating unknown, but probably very variable. In Algeria, one ♀ with two young cubs was found in Apr (Petter 1959). In Tunisia, two young were recorded in Aug (Hufnagl 1972). In Niger, cubs were found in Aug (wet season) and Nov (Dragesco-Joffé 1993). In Egypt, a ♀ contained advanced embryos in Sep (Hoogstraal 1964). In West Africa, parturition occurs from Jan to Mar (Rosevear 1974). Gestation is probably 37 days or slightly less (Petter 1959), although Rosevear (1974) quotes variable lengths between 37 and 77 days. There is no delayed implantation. Litters are usually 2–3 young (Petter 1959, Rosevear 1974, Dragesco-Joffé 1993, Sitek 1996) and birth-weight is 5 g (Sitek 1996). Young are born blind, although their ears are not sealed down, and they are covered with very short hair. Petter (1959) mentions some weasels covered with white hair, the skin being invisible. The dark patterning

develops at about three weeks, and the eyes open at about 3.5 weeks. Captive animals took solid food after five weeks, weighed 250 g at two months, and were separated from their mother at three months. An inter-litter interval of 40 days has been recorded for captive animals (Sitek 1996). No information on lactation or the age at which animals attain sexual maturity. Longevity is up to six years in captivity (Rosevear 1974, Haltenorth & Diller 1980, Weigl 2005).

Predators, Parasites and Diseases Probably very few predators. Pharaoh Eagle-owl *Bubo ascalaphus* seems to be the main predator: remains of animals killed by owls were found in Niger (Dragesco-Joffé 1993), and the skulls of these animals were found in owl pellets of eagle-owls in S Morocco (F. Cuzin pers. obs., M. Thévenot pers. comm.). Susceptibility to diseases unknown.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Protected by law in Morocco, Algeria and Tunisia. There are no obvious major threats, but on the northern fringe of its distribution area they may suffer competition with Least Weasels *Mustela nivalis* in the most productive habitats (e.g. in Morocco). There is no evidence of them being utilized for food (Cuzin 2003), but in S Tunisia they are killed for witchcraft, in the belief that they are capable of increasing human male fertility, and there is even some limited international trade across the border into Libya (K. De Smet pers. comm.). Road kills have been recorded in Morocco, including Western Sahara (F. Cuzin pers. obs.) and in Tunisia (K. de Smet pers. comm.).

Fabrice Cuzin

GENUS *Ictonyx*

Zorilla

Ictonyx Kaup, 1835. Das Thierreich in Seinen Hauptformen 1: 352.

The genus *Ictonyx* includes a single species, the Zorilla or Striped Polecat *I. striatus*, which has a wide sub-Saharan range, but excludes true desert and tropical lowland forests. The Zorilla is one of the most easily recognized of all of Africa's small carnivores, particularly with its distinctive pitch black and white striped pelage; there is a

variable white blaze on the forehead between the eyes and a white spot at the base of each ear. As elaborated on elsewhere in this work, the Libyan Striped Weasel *Poecilictis libyca*, from North Africa, is not here included in *Ictonyx* because this would render *Ictonyx* paraphyletic (Koeppfli *et al.* 2008, Sato *et al.* 2012).

There has been considerable controversy and debate over the correct name for this genus (e.g. Ellerman & Morrison-Scott 1953, 1954, Hershkovitz 1953, 1955, 1963, China 1963, Holthuis 1963), eventually resolved once the observation was made that *Zorilla*, often used as the generic name for the Striped Polecat, was in fact based on a misidentified type, namely the Eastern Spotted Skunk *Spilogale*

putorius (see China 1966, Hershkovitz 1966, Van Gelder 1966). *Zorilla* was eventually suppressed under the plenary powers of the International Commission on Zoological Nomenclature in 1967 (for full discussion, see Grubb 2001, Wozencraft 2005).

Chris Stuart & Tilde Stuart

Ictonyx striatus ZORILLA

Fr. Zorille commun; Ger. Zorilla (Streifeniltis, Band-iltis)

Ictonyx striatus (Perry, 1810). Arcana, Mus. Nat. Hist., Signature Y, Fig. [41] [1810]. Type locality given as 'South America'. Obviously an error, and fixed by Hollister (1915) as 'Cape of Good Hope' [South Africa].

Zorilla *Ictonyx striatus*.

Ictonyx striatus

Taxonomy More than 20 subspecies have been described (Allen 1939), but the validity of most is questionable. The majority are based on variations in pelage colouration and markings but these vary considerably within any one population. Roberts (1951) listed four species of *Ictonyx* for southern Africa (*striatus*, *limpopoensis*, *orangiae* and *kalaharicus*), one monotypic and the rest comprising 11 subspecies; these species were all considered conspecific with *striatus* by Ellerman *et al.* (1953), who listed 12 subspecies. Coetzee (1977) listed ten subspecies from southern Africa (grouped under *I. s. striatus*), seven from north-eastern Africa (grouped under *I. s. erythrae*) and a single subspecies (*I. s. senegalensis*) from North and West Africa, but noted that they probably are invalid. Pending a revision, no subspecies are recognized here. Synonyms: *africana*, *albescens*, *arenarius*, *capensis*, *elgonis*, *erythrae*, *ghansiensis*, *giganteus*, *intermedius*, *kalaharicus*, *lancasteri*, *limpopoensis*, *maximus*, *mustelina*, *nigricaudus*, *obscuratus*, *orangiae*, *ovamboensis*, *pondoensis*, *pretoriae*, *senegalensis*, *shoae*, *shortridgei*, *sudanicus*, *variegata*, *zorilla*. Chromosome number: $2n = 38$ (Graphodatsky *et al.* 2002).

Description One of the most easily recognized small carnivores in Africa. A distinctly marked mustelid with long, shiny black body pelage broken by four, distinct, white dorsal stripes (making three prominent black stripes). Stripes extend from the top of the head and converge again at the base of the tail. Rhinarium small, muzzle bluntly pointed. On the forehead, between and extending above the eyes, is a white patch that varies greatly in size and shape. Another white patch is located above and between each eye and the base of the ear. In some individuals the white spots merge to form a continuous band.

Much variation in the size and shape of the white facial markings (Kingdon 1977). Tips of ears rimmed by short white hairs. Underparts, legs and feet black. Tail predominantly white but liberally flecked with black hairs. Hairs of the guard coat range from some 6 mm on the head, 50 mm on the hindquarters and up to 80 mm on the tail (Skinner & Chimimba 2005). Underfur fine and silky, being pure white on the white pelage and pure black on the black pelage. Albinos have been recorded (Shortridge 1934). Five digits on each foot, and claws on all front digits are long, curved and strong, up to 18 mm along the curve; claws on hindfeet average 10 mm and less curved (Skinner & Chimimba 2005). Palms and soles of feet naked. Anal glands are present, although Martinoli *et al.* (2006) report that anal glands were absent from all three animals (two adult ♂♂ and a subadult ♂) captured in Arusha N. P., Tanzania. In southern Africa, ♂♂ are larger and heavier than ♀♀ (Smithers 1971, Rowe-Rowe 1978a, Stuart 1981, Lynch 1983, 1989), which seems to be borne out from measurements of Egyptian animals (Saleh & Basuony 2005).

Typically mustelid skull, solid, and robustly structured (up to 72 mm in length). Braincase broad posteriorly, and rostrum short and blunt. Ear bullae very broad and flat, tapering to a point anteriorly.

Zorilla *Ictonyx striatus* individual variation in facial patterns.

Mastoid and paroccipital processes prominent, zygomatic arches are thin and weak, and postorbital processes reduced to small knobs (Skinner & Chimimba 2005). Dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{1/2} = 34$. Outer upper incisor (I^3) much larger than others.

Geographic Variation An example of the confusion surrounding geographic variation and the recognition of subspecies is discussed by Smithers (1971) when comparing individuals from the same populations, stressing the great level of individual variation in hair length, breadth of dorsal striping and the extent of white hairs on the tail, not to mention variability in facial markings. Certainly, for southern Africa, and possibly throughout its range, individual variation is so great that at this stage recognition of any subspecies seems at best tenuous.

Similar Species

Poecilictis libyca. Possibly sympatric in extreme north-east and north-west of range, and perhaps in parts of the Sahel. Smaller; four to five black dorsal stripes; palms and soles haired; postorbital swellings inconspicuous.

Poecilogale albinucha. Range overlaps south of Equator. Smaller, with shorter legs; body sinuous and elongated; shorter pelage; top of head and tail all white; pale dorsal stripes usually off-white to yellowish, seldom pure white; normally one lower molar, for a total of 28–30 teeth.

Lateral, palatal and dorsal views of skull of Zorilla *Ictonyx striatus*.

Distribution Endemic to Africa, south of the Sahara. Has a wide distribution, ranging from Mauritania and Senegal in the west to Sudan, Ethiopia and Djibouti in the east, and south to South Africa (Rosevear 1974, Kingdon 1977, Skinner & Chimimba 2005). Within this range, it is absent only from the equatorial forests of the Congo basin and West Africa, and certain regions of the Horn of Africa. Although present throughout the Sahel zone, the species is absent from the Sahara. The northernmost limit of distribution is extreme SE Egypt, from where the species has long been known from two specimens obtained in 1954 in Wadi Daraweena (see Osborn & Helmy 1980). Subsequently, Saleh & Basuony (2005) confirmed the presence of the species in open acacia forest of the Wadi Adaldeib north-east of Gebel Elba.

Habitat Has a wide habitat tolerance, being found in open grassland, savanna woodland, thornbush, rocky areas, forest and even desert (provided there is some scrub cover). Zorillas range from sea level to more than 4000 m (alpine zone of Mt Kenya; Coe 1969, Young & Evans 1993). In arid and semi-arid areas, they are commonly associated with drainage lines. In the south of their range they occur in the Namib and Kalahari Deserts, in the former penetrating even the driest areas along seasonal water-courses. They occur in many agricultural areas, including the wheatlands of SW South Africa, exotic plantations in KwaZulu–Natal (South Africa), and pastoral areas of the Kenyan highlands. According to Estes (1991), the species is most common on open rangeland where domestic or wild ungulates keep grass short by grazing.

Zorilla *Ictonyx striatus* skeleton.

Zorilla *Ictonyx striatus* myology.

Abundance Common over much of its extensive range, although locally uncommon. Easily overlooked as they are not trapped easily, but frequently seen as a road casualty. Hendrichs (1972) estimated density at one individual per 5–10 km² in East Africa.

Adaptations No sagittal crest, but two low ridges run from the centre of the supra-occipital crest, widening anteriorly to join the knoblike postorbital processes. These, together with the broadened braincase, provide a broad area of attachment for the powerful temporalis muscles that operate the robust lower jaws (Skinner & Chimimba 2005). Also has well-developed neck muscles, characteristic of efficient predators. The teeth of the Zorilla can deal with both cutting and crushing (presumably arthropod exoskeletons) although less sharp and pointed than those of the African Striped Weasel *Poecilogale albinucha*, suggesting their diet is less carnivorous; little evidence of competition between these two species, although where they co-occur African Striped Weasels may be less common (Kingdon 1977). Carnassial shear is adapted to slicing, while broad upper molar occludes with lower two molars to provide a surface for crushing. Outside incisor in upper jaw (I³) distinctly larger than the remainder and probably aids the canine in holding larger prey (Skinner & Chimimba 2005).

Long, strong curved claws on front feet are well adapted for digging. Although animals may excavate their own burrows in softer substrates, it is more common for them to use those abandoned by other species, lie up in rock piles or crevices, stone walls, hollow logs, amongst vegetation tangles and drift debris on river banks. In some areas, such as the South African central Karoo plain, they may take up residence under the floors of buildings and amongst scrap piles in farmyards. Almost exclusively terrestrial, but has been known to climb trees (Fitzsimmons

1919) and to swim well (Shortridge 1934). Nocturnal, only becoming active well after sunset and typically seeking shelter before sunrise (Smithers 1971, Rowe-Rowe 1975b, Rautenbach 1982).

The conspicuous pelage patterning and distinctive markings are presumed to serve as a warning to potential aggressors, as this carnivore can release a nauseating fluid from the anal glands. The excretion of the ♂ consists of a light, yellow oil and a colourless, translucent aqueous phase, with a strong and penetrating odour, as a result of the various sulphur compounds (Apps *et al.* 1988, Wheeler *et al.* 1997).

Foraging and Food Insects and small murids form the bulk of the diet but Zorillas also take a wide range of other invertebrates (including spiders, scorpions, hunting spiders, millipedes and centipedes), as well as reptiles, birds and amphibians (Smithers 1971, 1983, Rowe-Rowe 1975b, 1978a, Stuart 1981, Rautenbach 1982, Lynch 1983, 1989, Saleh & Basuony 2005). In all studies, insects dominate their diet – 62% and 61% occurrence in 21 and 36 stomachs from KwaZulu–Natal (Rowe-Rowe 1978b) and Zimbabwe/Botswana (Smithers 1983), respectively – especially beetle adults and larvae, grasshoppers and crickets. On the other hand, a single stomach from the Kalahari contained mostly reptile remains (Viljoen & Davis 1973).

There are regional as well as seasonal differences in diet but, as Zorillas are largely opportunistic foragers and hunters, diet is to a large extent a reflection of abundance and availability. The fact that many invertebrate and vertebrate prey items are subterranean dwellers for much, or all, of their time indicates that digging plays an important role in foraging. Captive animals showed similar dietary preferences, rejecting certain foods offered including snails, millipedes, toads and crabs; interestingly, they did consume shrews (Rowe-Rowe 1978b).

Zorillas are solitary and nocturnal foragers, and food is located mainly by smell and hearing (although some prey, such as large rodents, are located by sight). When foraging they move at a sustained trot with nose to the ground (Estes 1991, C. Stuart & T. Stuart pers. obs.). With few exceptions, foraging only begins well after sunset (Smithers 1971, C. Stuart pers. obs.). During foraging they move purposefully, stopping frequently to smell and listen, and insects, larvae and fossorial vertebrates are then dug out using front feet/claws (Rowe-Rowe 1978b). Slow-moving prey located on the surface are simply picked up with the mouth, whereas prey such as beetles or moths may be either bitten or pinned to the ground with a foot.

Larger prey, such as frogs and lizards, are stalked and bitten on the head, or initially held down by the front paws prior to biting; lizards and amphibians are eaten whole, lizards from the head first (Rowe-Rowe 1978b). Rowe-Rowe (1978b) describes how Zorillas kill snakes, which they usually consume head first (though sometimes tail or flanks are consumed first). Small rodents are initially bitten randomly and then usually killed with a bite to the neck (Rowe-Rowe 1978b, C. Stuart pers. obs.); larger rodents require more bites, and are then skinned and eaten, leaving the skull and other large bones too hard to crush (Rowe-Rowe 1978b). Birds are killed with a quick bite to the head; large birds are eaten from the head, and small birds are consumed whole. Captive animals offered eggs learned to break them open by biting or rolling the egg against a hard object (Rowe-Rowe 1978b). They have been recorded taking carrion (Shortridge 1934). Lautenbach (2005) records a rather remarkable instance of a Zorilla attacking a newborn Nyala *Tragelaphus angasi*.

Social and Reproductive Behaviour Solitary, although pairs are sometimes sighted and groups made up of a ♀ and her young are not uncommon (Rowe-Rowe 1975b, 1978a, Stuart 1981). Little information available on home-range sizes, or distances moved in the wild. Within their home-range Zorillas appear to have knowledge of the refuges available, for when disturbed, they make for these directly and quickly disappear into their shelter (Skinner & Chimimba 2005).

In threatening situations, the animal raises the body and tail hairs until erect, tail curved over the back, and turns rump to the perceived attacker. If the threat persists, a loud barking call accompanies the ejection of a foul-smelling fluid from the perineal glands (Rowe-Rowe 1975b, 1978a). Although the use of anal glands appears to be the ultimate defence in confrontation with larger enemies, when under extreme stress they may sham death for more than half an hour (Shortridge 1934, Kingdon 1977, C. Stuart pers. obs.).

In captivity ♂♂ were aggressive towards each other, culminating in fighting (Rowe-Rowe 1975b). During copulation, which lasts for between 25 and 106 minutes, ♀ calls frequently with loud yaps (Rowe-Rowe 1978c). Mating appears to induce ovulation (Irven 1993).

Six different adult vocalizations have been recognized, associated with greeting (one call), threat (two calls), defence (two calls) and mating (one call) (Channing & Rowe-Rowe 1977). Threat calls consist of a warning call emitted when another animal approaches either food or young, or when an intruder approaches. The warning call is followed by an aggression call, if the former fails to repel the intruder. Aggression calls may precede fighting. Defence calls are used as either submission or release calls. The former are emitted during early stages of displaying if an animal recognizes that the other animal is dominant, and non-receptive ♀♀ use it when ♂♂ attempt to copulate. Release calls are used by the losing ♂ at the end of a male–male fight. The mating call is

Zorilla *Ictonyx striatus*.

uttered by ♀ ♀ continually during copulation, and has three variations (Channing & Rowe-Rowe 1977). Juveniles also emit three calls: two types of distress calls, one each used before and after about 2.5 weeks of age, and a contact call (Channing & Rowe-Rowe 1977).

Reproduction and Population Structure In KwaZulu–Natal births are recorded in spring and summer (Oct and Nov; Rowe-Rowe 1978c), but elsewhere in South Africa pregnant ♀ ♀ and back-aged juveniles have been noted for Apr, Aug, Sep, Nov and Dec (Stuart 1981, Rautenbach 1982). Kingdon (1977) has recorded young in Feb, Jun, Sep and Oct in East Africa. A. J. Hopson (in Rosevear 1974) believed that in the L. Chad area the Zorilla may breed during the rains since young were observed from Sep to Nov. Saleh & Bsauony (2005) predicted births in early winter in SE Egypt, based on an observation of a mating pair in Aug. Rowe-Rowe (1978c) stated that if a captive ♀ successfully rears a litter, she will not produce a second litter until the following season; if, on the other hand, the young die at an early age, she will mate again.

Zorillas are probably polygamous and ♀ ♀ have their first litter from an age of ten months. The gestation period is 36 days ($n = 3$) (Rowe-Rowe 1975b) and litter size is one to three in wild-caught ♀ ♀, although litters of five are recorded from captivity (Rowe-Rowe 1978c). Young are born in an altricial state (birth mass 10–15 g) and at birth the dark stripes are apparent in the pink skin. The eyes open during the sixth week and the lower canines erupt at about 32 days, which is when they start to eat solid food. By Week 8 the young are fully mobile and capable of killing their own prey, and adult size is attained at about Week 20 (Rowe-Rowe 1978c). Longevity in captivity is about 14 years (Jones 1982, Weigl 2005), but in the wild this is unlikely to exceed five years.

Disparity in sex ratios has been recorded (Smithers 1971, Rowe-Rowe 1978a, Stuart 1981, Rautenbach 1982, Lynch 1983; and see summary in Larivière 2002b). Of a total of 183 sexed Zorillas from southern Africa, 68% were ♂ ♂ and 32% ♀ ♀. Rowe-Rowe (1975b) concluded that ♂ ♂ are more active than ♀ ♀, and appeared more willing to investigate unfamiliar objects. Perhaps this does explain the higher number of ♂ ♂ than ♀ ♀ killed on the roads, as ♂ ♂ are more mobile and most likely to be on roads and threaten oncoming vehicles (D.T. Rowe-Rowe pers. comm.).

Predators, Parasites and Diseases Known predators include Caracals *Caracal caracal*, Black-backed Jackals *Canis mesomelas*, Leopards *Panthera pardus* (Stuart 1981) and Brown Hyenas *Hyaena brunnea* (Mills 1978a), but direct predation, or scavenging, appears to be rare.

A malarial parasite was recorded from one of five specimens caught in traps in Senegal (Leger & Bedier 1923), and Round (1968) listed two nematode species, *Filaria martis* and *Hepaticofilaria pachycephalum*. Hill & Carter (1941) mention that most specimens are parasitized by worms that inhabit the frontal sinus and frequently erode the bone. Horak *et al.* (2000) recorded *Haemaphysalis leachi/zumpti* from an animal in the Free State, and *H. zumpti* from an animal in the Eastern Cape. There is no information on diseases, although they may carry rabies.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Despite heavy mortality on roads, populations remain stable. Increasing rural human populations and the concomitant increase in numbers of dogs are a threat to its existence in many areas, and Zorillas are sometimes killed for preying on poultry (Rowe-Rowe 1992a,

Kingdon 1997). None the less, they remain common across their wide distribution, are present in numerous protected areas, and unlikely to be threatened in the near future.

Measurements

GENUS *Poecilogale*

African Striped Weasel

Poecilogale Thomas, 1883. Ann. Mag. Nat. Hist. 11: 370.

A monotypic genus that was originally assigned to *Zorilla* (Gray 1864), a designation followed by others (Bocage 1865, Peters 1865). However, Thomas (1883) reassigned the species to *Poecilogale* and this is now generally accepted. It has a wide, largely sub-equatorial, range

on the African continent and should not be mistaken for any other species within this region.

Chris Stuart & Tilde Stuart

Poecilogale albinucha AFRICAN STRIPED WEASEL

Fr. *Poecilogale* à nuque blanche; Ger. Weißnackenwiesel (Kappeniltis)

Poecilogale albinucha (Gray, 1864). Proc. Zool. Soc. Lond. 1864: 69, Plate X. 'It was without any habitat.'

Emended by Coetzee (1977) as 'Cape Colony', Zambia.

African Striped Weasel *Poecilogale albinucha*.

Taxonomy Six subspecies have been described, but Coetzee (1977) noted that their validity is probably questionable as they are based on minor and variable aspects of appearance (and see Meester *et al.* 1986). Synonyms: *africana*, *bechuanae*, *doggetti*, *flavistriata*, *lebombo*, *transvaalensis*. Chromosome number: not known.

Description The smallest African mustelid occurring south of the Sahara. Characterized by extremely slender form, very short legs and strongly contrasting black and white striping on dorsum. It is proportionally the longest African mammal (Estes 1991). Head typically mustelid, with short rounded ears and short snout. When walking or running the back is arched. Overall pelage colour is pitch black with four off-white to yellowish stripes that run from nape to base of tail, converging on neck into two broad bands and forming completely white cap on top of head. Overall dorsal stripe colouring and width are variable throughout their range and within any one population. Changes in colouration of pale dorsal stripes have been recorded (Ansell 1960b, Stuckberry 1967) but do not appear to be linked with factors such as age or season. Body hair short and coarse, and hairs of guard coat average

10 mm in length. Tail bushy with white hairs dominant; tail guard hairs average 30 mm in length, and are black at their base with predominantly white over much of length. There are five digits on each foot, with the claws on the front feet longer and more strongly curved than those on the hind. They are equipped with two perineal glands from which they can eject a yellowish fluid with a very heavy, sweet, pungent smell. One pair abdominal nipples, and one pair inguinal; occasionally extra pair inguinal (Rowe-Rowe 1972a). Males consistently larger than ♂♂, up to 50% greater in body weight (Rowe-Rowe 1978a).

Skull typically musteline, elongated, and the rostrum short and broad. Braincase ovoid, postorbital bars incomplete, orbits small and zygomatic arches weak (Skinner & Chimimba 2005). Dental formula is $I^{3/3}, C^{1/1}, P^{2/2}, M^{1/1} = 28$. Occasionally, there is an additional lower molar. The carnassials are sharp and the canines long.

Geographic Variation African Striped Weasels vary in size, width and colouration of the pale dorsal stripes throughout their range and within any given population. Rautenbach (1982), for example, besides pointing out that the ranges of three putative subspecies from the

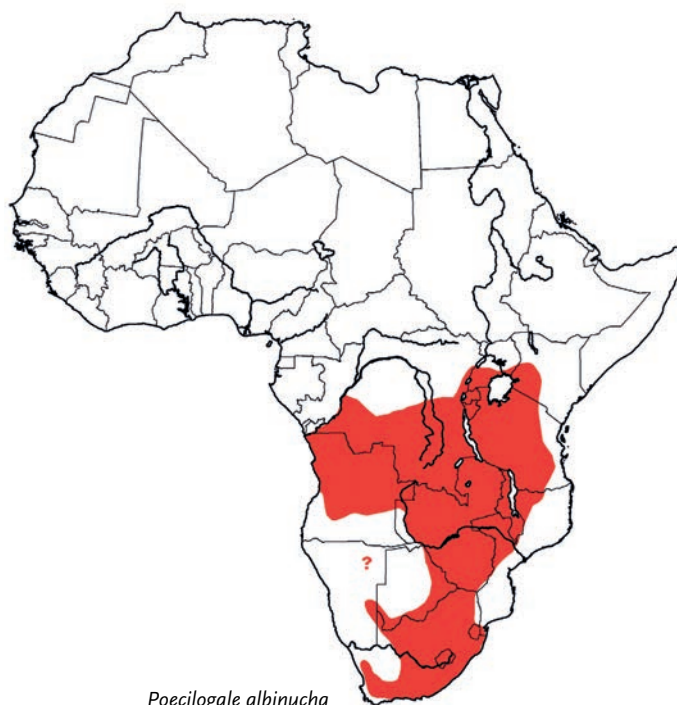

Lateral, palatal and dorsal views of skull of African Striped Weasel
Poecilogale albinucha.

former Transvaal in South Africa are largely unknown, also collected specimens of undescribed dorsal colouration phases. It seems unlikely that, with current knowledge, there is much geographic variation. Kingdon (1977) mentions that animals observed in W Uganda tend to be slightly larger than in other areas of East Africa; this observation is supported by data from L. Kivu (Rahm & Christiaensen 1963).

Similar Species

Ictonyx striatus. Sympatric south of the equator. Larger; shaggy and long pelage; black and white striping less clearly defined, lacks white cap on top of head and has variable white patches on face; tail more clearly mixed black and white; proportionally shorter in the body and longer in the leg; body not sinuous or elongated; normally two lower molars, 34 teeth.

Distribution Endemic to Africa. Restricted almost entirely to south of the Equator, from SW Uganda and Kenya to the Western Cape in South Africa (Kingdon 1977, Ansell 1978, Ansell & Dowsett 1988, Skinner & Chimimba 2005). The highest frequency of records comes from SE South Africa, where most research has been done. In the south-west of the same country, where this species was unknown until 1998, there have been three documented records based on road kills, suggesting range expansion (Stuart & Stuart 1998a). They are now also known to occur in the western extension of the Kalahari within the Kgaligadi Transfrontier Park (Stuart & Stuart 1990) and SE Namibia (C. Stuart & T. Stuart pers. obs.). Because of its secretive nature it has probably been overlooked in many areas, especially in light of the recent records from locations that were previously considered to be unsuitable. Its presence in the SW Kalahari indicates that it could well occur over large tracts of Botswana, as well as E Namibia.

Poecilogale albinucha

Habitat Although they probably have a wide habitat tolerance, they are mainly found in savanna associations, usually with a strong grass component. In N Angola and DR Congo they have been recorded from lowland rainforest. The few records from arid south-western Africa are associated with semi-desert grassland. In the south and south-west of their range they occupy areas of Cape fynbos (Stuart & Stuart 1998a). Road casualties recorded from the extreme south-west were in a mix of fynbos, cultivated fields and pastures, while road kills in Swaziland were also collected in commercially cultivated fields (Monadjem 1998). A sighting from Nyika N. P. was made in montane grasslands at approximately 2300 m (Medland & Dudley 1995). Rowe-Rowe (1990a) states that this mustelid is particularly associated with moist grassland areas experiencing an annual rainfall that exceeds 600 mm. It would seem to reach its highest densities in such areas, but in recent times it has been found in areas of the Kalahari that receive less than 500 mm per annum, as well as in the C Karoo with annual mean precipitation lower than 300 mm (Stuart & Stuart 1990).

Abundance Rare to uncommon throughout its range, although densities are considered to be higher in KwaZulu-Natal in South Africa (Rowe-Rowe 1975b). Highest densities appear to be reached in moist higher rainfall grasslands. It has been suggested that it is probably only common in habitats with perennially dense rodent populations (Estes 1991).

Adaptations The African Striped Weasel has an elongated cranium and relatively weak zygomatic arch, with broad attachments for the powerful temporalis muscles that operate the robust lower jaws. It also has well-developed neck muscles, characteristic of efficient predators. The carnassials are adapted to slicing predominantly murid prey. The long, slender body and short legs are ideally suited to entering small rodent burrows, which they frequently do, when hunting. They are terrestrial and apparently not good climbers, although Rowe-

Rowe (1972a) stated they would do so in captivity with some awkwardness.

Although individuals will make use of existing rodent burrows, which they may or may not modify, they have been shown to be active and efficient burrowers under captive conditions (Rowe-Rowe 1990a). Rowe-Rowe (1975b) described a burrow 50 mm in diameter, almost vertical for about 100 mm, then horizontal for up to about 200 mm, terminating in a chamber 100–150 mm in diameter. A captive kept by the authors (also recorded by Rowe-Rowe 1972a, 1975b) constructed shallow burrows in sand, digging the sand with its forepaws and sharp claws and then moving it back in 'caterpillar' fashion under the belly and out between the hindlegs. Rowe-Rowe (1972a) discussed how two together, in turn, would help to excavate a burrow.

The distinctive and contrasting black and white pelage probably serves as a warning to would-be attackers that they can expect to be sprayed with the unpleasantly smelling product of the perineal glands. This fluid, although rather unpleasant, does not have the pungency of that produced by the Zorilla *Ictonyx striatus*. Before ejection, the hair on the tail and on the lower part of the back is raised and the tail held vertically. Under stress the fluid can be ejected to a distance of up to 1 m but usually shorter distances are involved (Alexander & Ewer 1959). It has been suggested that the African Striped Weasel's similarity to the Zorilla may indicate a case of mimicry, but Kingdon (1977) holds that it is more likely to be a case of functional convergency in mustelids.

African Striped Weasels are predominantly nocturnal, but are occasionally seen in daylight. Rowe-Rowe (1978b) recorded six of 35 sightings during daylight. On two separate occasions he saw an adult (presumed ♀) with two well-grown young at 09:00h (KwaZulu-Natal) and 10:00h (Eastern Cape) (D. T. Rowe-Rowe pers. comm.).

Foraging and Food Mainly solitary, nocturnal hunter that feeds predominantly on small rodents that it may catch on the surface but frequently seeks out in their burrows. Mainly a small mammal hunter, with a predilection for rodents (but also shrews), but birds may also be taken (Rowe-Rowe 1978c). There are no reliable records of invertebrates, amphibians or reptiles being taken.

The African Striped Weasel is a specialized hunter that is capable of killing rodents up to its own size, but smaller species dominate

in its diet (Rowe-Rowe 1978c). Under captive conditions a weasel killed young domestic rabbits averaging 500 g on three occasions; the weasel apparently had no difficulty in handling and killing prey twice its own size (Stuart 1981). Rowe-Rowe (1978c) found that African Striped Weasels in captivity relied more on scent than sight to locate prey; Ansell (1960b) noted that a captive weasel used vision a great deal. Killing generally follows a set pattern in which the prey is taken using a well-directed bite to the back of the neck, followed by a lateral rolling action causing the prey to lose its footing. In the process the spine is broken by the vigorous kicking and treading against the prey with the hindfeet, which is referred to as 'curl, clasp, kick' (Rowe-Rowe 1990a). Neck bites are the most common killing technique, although bites to the throat have also been recorded when killing large prey. Small mammals are eaten head first, and usually entirely consumed (Rowe-Rowe 1978b). Birds are killed by a bite on the head without the use of the forefeet to hold the bird down, and are always eaten head first (Rowe-Rowe 1978b). After killing, prey was always carried or dragged to shelter. A single animal can consume 3–4 mice in a night, but surplus killing sometimes occurs. Captive animals offered eggs did not break them open and did not eat the contents of broken eggs. Hoarding of surplus prey has been recorded in captivity (Rowe-Rowe 1972a, 1978b).

Social and Reproductive Behaviour Normally solitary, but sightings of pairs and groups of up to four individuals are not unusual (typically a ♀ and her young). Individuals in these groups follow very close behind each other, giving the impression of a moving snake (Rowe-Rowe 1978b).

From observations in captivity it appears that the African Striped Weasel is strongly territorial but a ♂ and ♀ will share a burrow or shelter. In arranged encounters between ♂♂, three phases of intensity were recognized: immediate submission by one individual; a challenge followed by wrestling terminating when one released its hold uttering a release call; and high-intensity encounters with ritualized fighting and biting, inflicting no injury, and vocalization again important in termination (Rowe-Rowe 1996).

Marking with the faeces probably plays a territorial role, and according to Kingdon (1977) faeces are mainly situated around the den sites. Faeces may be used for scent-marking, as they are often deposited on vertical, or near vertical, surfaces and not infrequently spread during defecation (Ansell 1960b). In the wild, termitaries and the bases of trees are often used as marking locations with the faeces (Kingdon 1977). Apparently, this weasel does not mark objects with the anal gland secretions, but these are used purely as a self-defence mechanism (Rowe-Rowe 1972a). No information is available on home-range size but this will in large measure be dictated by prey abundance and availability.

Channing & Rowe-Rowe (1977) recognized a total of six different vocalizations by adults (three for threat, two for defence and one for greeting) and three by blind young. Threat calls include a warning call (very similar to that of the Zorilla) and an aggression call, while defence calls include submission and release calls. Males emit a greeting call to ♀♀, usually prior to mating. In both defensive and offensive threats, the short hair along the back is raised, also the tail hairs, with the effect amplified by bark-screaming and feigned attack. As a last resort the animal may spray the product of the anal glands at an attacker (Ansell 1960b).

African Striped Weasel *Poecilogale albinucha*.

African Striped Weasel *Poecilogale albinucha*.

Reproductive behaviour has not been recorded in the wild but captive observations showed that copulation only took place in the den or shelter (Rowe-Rowe 1978a). As African Striped Weasels may copulate for extended periods (62–78 minutes), the advantage of first retreating to shelter is that they would not be vulnerable to potential predators. Females tolerate ♂♂ when they are sexually receptive, and copulation may be preceded by a relatively lengthy courtship involving 'dancing' around each other, bouncing on the front feet, play wrestling, usually with tail erect and fluffed out (Rowe-Rowe 1975b). Females rear young without the help of ♂♂ (Rowe-Rowe 1996).

Reproduction and Population Structure In southern Africa most births are recorded from Nov to Mar, but nothing is recorded from elsewhere within its range. It seems likely that births will coincide with the wet season/s when their rodent prey is most abundant. Litters, normally with 2–3 young, are born after a gestation period of 31–33 days, the shortest of any carnivore without delayed implantation (Rowe-Rowe 1978a). In captivity ♀♀ that successfully raise a litter will not raise a second during the same season. Young are born in an altricial state, hairless, blind and deaf. Birth-weight is some 4 g (n = 6), with a total length averaging 70 mm. Canine teeth erupt at about 35 days, which is when young first eat solid food; eyes open at between 51 and 54 days after birth, and they make their first rodent kill at 13 weeks. Maturity is reached by Week 20 (Rowe-Rowe 1978c). Longevity is around 4–6 years (Rowe-Rowe 1992a, Weigl 2005).

Predators, Parasites and Diseases Little recorded on mortality, but probably vulnerable to predation by certain owls and other carnivores. A dead weasel found in the Drakensberg in South Africa appeared to have been killed, but not eaten, by a raptor. Perhaps the aposematic colouring also warns that they are distasteful (D. T. Rowe-Rowe pers. comm.). Over much of their range, they coexist with the Zorilla. Although the African Striped Weasel appears less common where their ranges overlap (Kingdon 1977), competition between the two species is likely avoided due to the Zorilla being more of a generalist predator, whereas the African Striped Weasel is a rodent specialist.

The only endoparasite recorded is the tapeworm *Taenia brachyacantha* (Round 1968). Some captive weasels have been recorded as dying from tuberculosis of the spleen (Ansell 1960b).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although thinly distributed and occurring at apparently low densities, the African Striped Weasel faces no known major threats, is present in several protected areas and does not require any special conservation action. However, Cunningham & Zondi (1991) found that pressure on weasel numbers had increased, and that they were becoming more scarce in E South Africa. They regarded the African Striped Weasel as highly threatened, being one of the most-used animals in traditional medicine. Indeed, in parts of its range the skins of this mustelid are commonly used by traditional healers and sangomas as a good luck charm. Rowe-Rowe (1990a, 1992a, 1996) stated that human population growth, predation by dogs, and loss of habitat owing to conversion of grasslands to monocultures, e.g. timber plantations, maize, sugarcane (KwaZulu–Natal), pineapples (Eastern Cape), as well as overgrazing with loss of suitable rodent habitat, is having an impact on weasel populations.

 KwaZulu–Natal, South Africa (Rowe-Rowe 1978a)
 Skull measurements: South Africa (Roberts 1951)
 In the former Cape Province, Stuart (1981) recorded HB as 314 mm (306–327 mm) for ♂♂ (n = 3) and 315 mm (280–350 mm) for ♀♀ (n = 2); and T as 176 mm (171–180 mm) for ♂♂ and 148 mm (145–150 mm) for ♀♀. In a series of seven ♂♂ from L. Kivu, body weight ranged from 255 to 390 g (with one animal apparently weighing 610 g), and in a series of eight ♀♀, from 214 to 350 g (Rahm & Christiaensen 1963)

Subfamily LUTRINAE – Otters

Lutrinae Bonaparte, 1838. Nuovi Ann. Sci. Nat. 2: 111.

Spotted-necked Otter *Hydrictis maculicollis* facial myology.

Spotted-necked Otter *Hydrictis maculicollis* skeleton.

The subfamily Lutrinae contains the Otters, with three genera (*Lutra*, *Hydrictis* and *Aonyx*) represented by four species in Africa. Worldwide, around 13 species are recognized in this subfamily, although there is some debate as to the validity of the Japanese Otter *Lutra nippon*, which has been considered a subspecies of the more widespread Common Otter *L. lutra*. Likewise, Wozencraft (2005) synonymized the two African forms of *Aonyx*, a view that has not been generally supported (see genus account). There is also uncertainty as regards the status of *Amblonyx* (for the Oriental Small-clawed Otter, *A. cinerea*), which is sometimes treated as congeneric with *Aonyx* (Ellerman & Morrison-Scott 1951, Koepfli & Wayne 1998, Wozencraft 2005), the separation of the New World otters (with the exception of *Pteronura*) in the genus *Lontra* (Van Zyll de Jong 1972, 1987, Koepfli & Wayne 1998, Wozencraft 2005), and the status of the Spotted-necked Otter *Hydrictis maculicollis*, which has variably been included in *Lutra* or in its own genus (e.g. Wozencraft 2005; and see genus account).

Otters are medium-sized, all rather similar in appearance, with an overall length of 1.0–1.5 m and a weight of 3.0–16.0 kg (up to 45 kg in the extralimital Northern Pacific Sea Otter *Enhydra lutra*); ♂♂ are up to 30% heavier than ♀♀. Their elongated body shape suggests adaptation to aquatic habitat, but this is probably incorrect, as such form is also found in related, non-aquatic mustelids. Thus, it is more likely that otters could take to an aquatic existence because of their overall shape, and this in itself is not an adaptation to water. Colour dark brown above, lighter underneath; guard hairs over very dense underfur provides insulation in water by holding air close to the skin. Otters differ from many other mammals by having little (<3%) body fat, and little of that is subcutaneous (to prevent buoyancy; Kruuk 1995, 2006). They are remarkably streamlined, and have a rather flat head with equally broad neck, short legs, small eyes and ears, and large prominent vibrissae. The thick tapering tail (dorso-ventrally flattened in some species) serves as a rudder, and is important especially to provide counterbalance when swimming: otters propel themselves underwater by kicking with both hindlegs simultaneously, whilst holding the frontlegs back along the body. For this mode of swimming, the centre of gravity needs to be close to the hindlegs. The heavy tail also helps with diving, and when swimming along the surface: otters flip forwards and down whilst lifting the tail out of water. Hindlegs with fully webbed digits, front legs partly webbed.

There are five upper cheekteeth, the upper first molar much enlarged, more or less square, as large or larger than the adjoining carnassial.

In *Aonyx*, the feet have rudimentary webs, nails are absent or small and blunt, the mastoid process projects prominently behind ear opening, the postorbital process is clearly developed, and the greatest skull length in adults is usually more than 115 mm. In *Lutra* and *Hydrictis* the feet are clearly webbed, with well-developed claws; the mastoid process is weak while the postorbital process is vestigial, and the skull is normally less than 110 mm (Coetzee 1977, Meester *et al.* 1986).

Otters are semi-aquatic carnivores, being highly dependent on water for feeding, with Common Otter and African Clawless Otter found along coastal areas as well as in freshwater habitat, while the others occur only in freshwater. Their movement on land is somewhat clumsy, though fast, and they cover long distances between water-courses. Feeding habits of different species vary widely, especially where two species co-occur: *Lutra* and *Hydrictis* specialize on fish and frogs, the African Clawless Otter specializes mostly on crustaceans (Rowe-Rowe & Somers 1998). Generally, all otters are nocturnal, but they are highly flexible and exceptions occur, particularly related to the availability of their main prey (Kruuk & Goudswaard 1990, Kruuk 1995, 2006, Perrin & d’Inzillo Carranza 2000). All species scent-mark frequently, with faeces (‘spraints’), urine and rubbing. Spraints have a strong, fishy smell detectable over long distances. All species are territorial, with single-sex territories; in some species, a territory may be inhabited by several individuals.

GENUS *Aonyx* Clawless Otters

Aonyx Lesson, 1827. Manual de Mammalogie, p. 157.

Palatal views of skulls of African Clawless Otter *Aonyx capensis* (top) and Congo Clawless Otter *A. congicus* (bottom).

This genus includes two species: the African Clawless Otter *A. capensis*, widely distributed in sub-Saharan Africa, except for the Congo basin, where it is replaced by the Congo Clawless Otter *A. congicus*. Allen (1924) and Davis (1978) stated that apparent differences in colour and molar size between the two species represent only geographic variations and that the Congo Clawless Otter does not represent a valid species. However, most authors have treated the two as separate species (e.g. Van Zyll de Jong 1972, Rosevear 1974, Coetzee 1977, Wozencraft 1993), although Wozencraft (2005) regarded them as conspecific.

Some authors, such as Ellerman & Morrison-Scott (1951), Coetzee (1977), Anderson & Jones (1984) and Koepfli & Wayne (1998), have considered the Asian Small-clawed Otter *Amblonyx cinerea* as congeneric, while Harris (1968), Medway (1978), and Van Zyll de Jong (1972, 1987) regarded it as a distinct genus (and see Bininda-Emonds *et al.* 1999). Marmi *et al.* (2004) suggested that all *Aonyx* and *Amblonyx* species could be included in the genus *Lutra*. Koepfli & Wayne (1998) found that although *Aonyx* (including *Amblonyx*) are linked to *Lutra* in a well-supported clade, these two genera last shared a common ancestor 8.0–6.3 mya. The Congo Clawless Otter also has been included in its own genus *Paraonyx* (Hinton 1921).

Characteristics of the genus include the unwebbed forefeet (unlike Spotted-necked Otter *Hydrictis maculicollis*), with blunt fingers lacking any nails or claws. Hindfeet are webbed to the second digit, but toes either lack nails or claws or have rudimentary nails. Postorbital bar present as a distinct process, and mastoid process projects behind the ear opening; rostrum short and broad. The dental formula is $I^{3/3}, C^{1/1}, P^{4/3}, M^{1/2} = 36$. The first upper premolar is sometimes

Congo Clawless Otter *Aonyx congicus* hands and feet.

absent, or present only on one side. Cheek teeth, especially P^4 and M^1 , as well as M_1 , are very robust and greatly enlarged, low cusped for a crushing function (rather less so in Congo Clawless Otter); those of the African Clawless Otter ca. 30% larger than in the Congo Clawless Otter (Jacques *et al.* 2004, 2009). Second lower molars occlude with upper molar for at least half their surface, and so assist with crushing function. Canines long and well developed; lower canines recurved. Outer upper incisors are enlarged.

Aonyx are specialized crab eaters, but they also include other items in their diet, including fish, small mammals, frogs and some invertebrate prey (Rowe-Rowe & Somers 1998). Otters of the genus *Aonyx* (meaning 'without nails') are well adapted to foraging with their fingers. The lack of webbing between the digits of their forepaws allows for considerable dexterity of individual fingers when feeling for prey in mud and murky water. Unlike other otter species, *Aonyx* use their forepaws to catch prey rather than their mouth (Duplaix 1982). They have larger somatic sensorial areas in their brain corresponding with increased forepaw use (Radinsky 1968). Both species are primarily solitary, although they may occur in small groups (Rowe-Rowe & Somers 1998).

Jan A. J. Nel & Michael J. Somers

Aonyx capensis AFRICAN CLAWLESS OTTER

Fr. Loutre à joues blanches; Ger. Fingerotter

Aonyx capensis (Schinz, 1821). In: G. Cuvier, Das Thierreich 1: 211. 'Capischer otter ... Afrika'
 ['Cape of Good Hope', Western Cape Province, South Africa].

African Clawless Otter *Aonyx capensis*.

Taxonomy Three subspecies have been recognized (Coetzee 1977): *A. c. capensis* (including *coombi* and *angolae*), from southern Africa, W Zambia, Angola, Gabon, Nigeria and throughout West Africa; *A. c. hindei* (including *helios*), from Uganda to E DR Congo as far south as N Zambia; and *A. c. meneleki*, from Ethiopia. Meester *et al.* (1986) only considered the nominate form to extend as far north as Angola and Zambia, noting that the case for including West African forms is unproven. Rosevear (1974) remarked that it was not possible to determine whether any forms might constitute valid West African races based on the study material available to him. Since variations in pelage are apparent from across the range of the species, subspecific delineation appears tenuous at best and no subspecies are recognized here. Synonyms: *angolae*, *calaboricus*, *coombi*, *delalandi*, *gambianus*, *helios*, *hindei*, *inunguis*, *lenoiri*, *meneleki*. Chromosome number: $2n = 38$ (Van Zyll de Jong 1987).

Description Medium-sized species, with streamlined body covered in short, dense fur. Head very broad at back, especially in ♂♂, narrowing to short, broad muzzle. Ears small, uniformly brown and adpressed to head. Top border of rhinarium rounded or lightly V-shaped. Colour varies from dark brown dorsally to creamy off-white on upper lips, side of face, throat, belly, edge of ears and neck. In some specimens, hair on forehead, across top of head and extending onto shoulders has silvery tips, giving the appearance of a mantle, somewhat like that found in the Congo Clawless Otter *A. congicus* (Skinner & Chimimba 2005). Coat has dense covering of guard hairs, from 10 mm in length on head and tail to 25 mm on mid-back (Skinner & Chimimba 2005). Underfur much finer, slightly shorter and white or off-white in colour, although it is obscured by the dense guard coat. Skin is thick. Vibrissae are white to grey (or sometimes with dark bases and white tips) and occur on both upper and lower jaws (Tayler 1970). Tail stout, long and dorsoventrally flattened. Legs short with hindfeet webbed for half their length while webs of the front feet are hardly noticeable. There are five digits. Forefeet clawless but rudimentary nails found on hindfeet (Skinner & Chimimba 2005). Both sexes have paired anal glands (Kingdon 1977). Females have two pairs of abdominal nipples.

Skull large and heavily built as brain size is large relative to body size (Sheppey & Bernard 1984). Eye orbits and ear bullae relatively

Lateral, palatal and dorsal views of skull of African Clawless Otter *Aonyx capensis*.

small compared with the size of the skull. Rostrum short and broad, the length from the front of the eye orbit to the incisors around one-fifth the total length of the skull. The zygomatic arch is thin and lightly built, as compared with the robust construction of the skull. This is a common feature in the mustelids, and reflects the development of the temporalis muscles at the expense of the masseters. The supra-occipital crest appears well developed. The lower jaw is thick and massive. Molars are broad and bunodont (Skinner & Chimimba 2005), highly suited for crushing crustaceans. The upper canines are formidable, round and sharp, the lower markedly recurved. The first upper premolar is not always present or, in some specimens, is present only on one side (Skinner & Chimimba 2005).

Geographic Variation See Taxonomy.

Similar Species

Aonyx congicus. Degree of sympatry with African Clawless Otter unknown. Similar size, but with posterior cheekteeth reduced in size (see Measurements and *Aonyx congicus* species profile) and more slender, especially in the head and neck region (Kingdon 1977); upper border of the rhinarium straight; head and neck extensively frosted, and throat, chin, side of head, nose and ears

creamy-white, with a prominent black patch between eyes and nostril (see species profile *Aonyx congicus*).

Hydricis maculicollis. See species profile for notes on sympatry.

Smaller in size with throat and neck with pale cream or white mottling, or the same colour as the rest of the body; webbed feet.

Distribution The African Clawless Otter is the most widely distributed otter species in Africa, occurring throughout most of the tropical and sub-tropical regions of sub-Saharan Africa, where there is permanent freshwater (Nel & Somers 2002). The range stretches from Senegal and Mali throughout most of West Africa to Sudan and Ethiopia then southwards throughout East Africa to the Western Cape of South Africa, being absent from the Congo basin (where they are replaced by the Congo Clawless Otter).

African Clawless Otters occur widely in seasonal rivers in arid and semi-arid areas of southern Africa, such as the Fish and Löwe Rivers in SC Namibia, and many seasonal or episodic rivers in the Karoo, such as the Sak, Vis, Riet and Gamka Rivers, as long as suitable-sized pools persist (Nel & Somers 2007). This suggests that this species could inhabit similar areas further north in Africa, albeit at probably lower densities than in more productive habitats. Skinner & Chimimba (2005) noted a tendency for the species to occur in the tributaries of some major rivers and not in the main rivers themselves, giving an example in Zimbabwe where they occur in the Mazoe R., which drains into the Zambezi R., from which they are absent downstream of the Victoria Falls. On the other hand, Somers & Nel (2004a) found that in the Western Cape they do often use main rivers and seldom use tributaries.

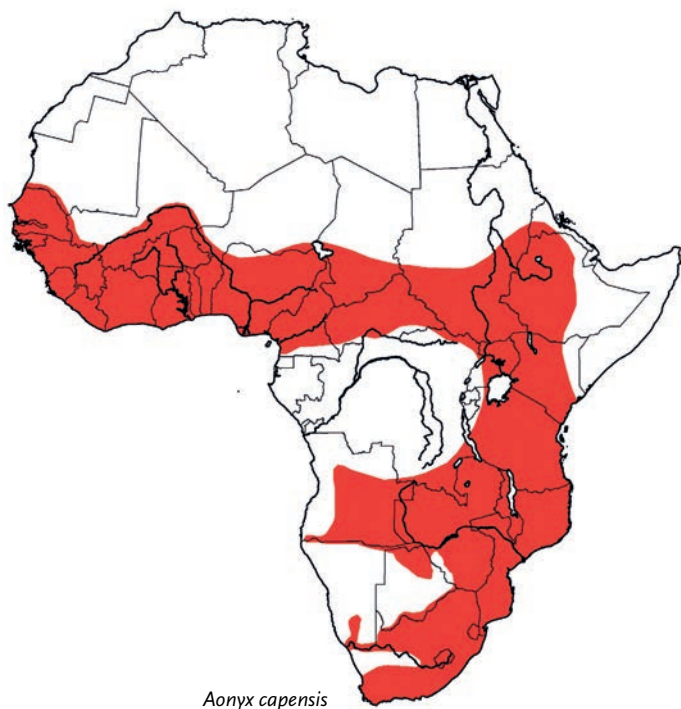

Habitat African Clawless Otters are predominantly aquatic and consequently are seldom found far from water. Freshwater is the essential habitat requirement (Van Niekerk *et al.* 1998), but they also occur in marine habitats provided there is access to freshwater (presumably to wash salt off coat and for drinking). In riparian habitats

the best habitats appear to be those with boulders and reed-beds (Somers & Nel 2004a). In marine habitats, rocky shores are preferred (Van Niekerk *et al.* 1998). Elsewhere, found in diverse habitats, from impoundments, estuaries, mangroves (Nel & Somers 2007, M.J. Somers pers. obs.) to the desert conditions of the upper Doring R. in the Western Cape and the Fish R. in S Namibia (Nel & Somers 2007). In general, their occurrence would appear to be independent of the surrounding terrain, providing the aquatic conditions are suitable and there is adequate cover. They have been recorded up to 2400 m in montane streams in the Drakensberg and Maluti Mts in South Africa and Lesotho (D.T. Rowe-Rowe & N. L. Avenant pers. comm.) and to 3000 m in Ethiopia (Yalden *et al.* 1996). African Clawless Otters have been found in towns (e.g. Stellenbosch) and cities (e.g. Port Elizabeth, Cape Town) (M. J. Somers & J. A. J. Nel pers. obs.), and can occupy rivers with high pollution and eutrophication levels (Heath & Claassen 1999, Somers 2001).

Abundance Throughout their range, African Clawless Otters are fairly common to rare, with populations thought to be stable in 29 of the 35 countries from which they have been recorded (Rowe-Rowe 1990b, 1995, Nel & Somers 2002). Abundance appears to be dependent on the availability of crabs (Rowe-Rowe & Somers 1998). For example, this species is the more abundant of the two otters in most of southern Africa, as crabs constitute the highest macro-invertebrate biomass in many rivers in the region (Hill & O’Keeffe 1992). Further north, however, where fishes are plentiful, the piscivorous Spotted-necked Otter is more abundant (Rowe-Rowe & Somers 1998).

Density estimates in Tsitsikamma Coastal N. P. in the Eastern Cape, South Africa, have been given as one otter per 1.9–2 km of coast (Van der Zee 1979, 1982, Arden-Clarke 1983, 1986). Verwoerd (1987) estimated one otter per 2 km of coast at Betty’s Bay in the Western Cape. As the otters rarely ventured further than 100 m from shore (Arden-Clarke 1983, 1986), these densities are equivalent to one per 20, 19 and 20 ha of water for the three studies, respectively. Using signs such as spoor, estimates of density in freshwater habitats are one otter per 1.25–2.5 km (Carugati 1995, Perrin & Carugati 2000b), one otter per 3–4 km (Rowe-Rowe 1992b) and one otter per 8–10 km of river (Butler & du Toit 1994). Somers (2001), using recovery of radioactive scats ($n = 55$), gives an estimate of 1.53 otters per km of river. Assuming there are two otters per km of river the estimate for the total population in South Africa alone is around 21,500 animals (M. J. Somers pers. obs.).

Adaptations The African Clawless Otter is highly adapted for an aquatic way of life. As with other otters, the guard hair and underfur are particularly dense to insulate the body when swimming. The hindfeet are webbed for half their length providing the main means of propulsion, while the tail serves as a rudder. Their many long vibrissae possibly assist in locating prey such as crabs (Rowe-Rowe 1977b). The front feet have no claws, the digits rather being adapted to feeling and grasping. The third and fourth, and in some cases the second, digits on the back feet have rudimentary nails. The undersides of the digits are rough to assist in holding slippery objects. The nasal apertures are set in slits in the rhinarium, which is small when compared with the size of the head; the edges of these slits can be brought together to close the nasal apertures when the individual is swimming under water (Skinner & Chimimba 2005).

Aonyx capensis

In an investigation of relative brain size (cranial volume in relation to body weight) among 30 South African carnivores, Sheppey & Bernard (1984) found that African Clawless Otters had the largest brain: 2.08 times the expected. These authors hypothesized that this accounted for their advanced dexterity. As in the Spotted-necked Otter, the structure of the glenoid cavity and glenoid processes is such that side-to-side movement of the lower mandible is limited. The dentition appears to be developed primarily for crushing. The development of P^4 and M^1 and M_1 is pronounced, being very heavy and broad; the outer edges can be used for cutting, but their main function is crushing hard-shelled prey such as crustaceans. The second lower molars, for at least half their surface, occlude on the first upper molars, and assist in this function (Skinner & Chimimba 2005).

In freshwater, otters are typically active from dawn for 2.6 h and from sunset for a mean of 2.3 h (Somers & Nel 2004b). In the coastal waters main periods of activity are from 20:00 to 22:00h (Arden-Clarke 1983). During the heat of the day they rest in dry places, in holes in the ground, under rocks, in sheltered places in erosion gullies or in dense reed-beds and shrubs adjacent to their habitat. Rowe-Rowe (1992b) found that they often excavate holts (dens) in river banks, the openings of which are elliptical (mean width, 361 ± 85 mm; mean height, 246 ± 32 mm; $n = 8$). The otters modify these resting places by lining them with vegetation, and indeed dense riparian vegetation (long grass, reeds, bushes) is essential to provide cover for holts and resting places (Rowe-Rowe 1992a, b). Some burrows have more than one entrance and tunnel lengths vary between 2 and 3 metres.

Foraging and Food African Clawless Otters are specialized crab eaters, but also feed on fish, frogs, insects and occasionally birds (waterfowl) and small mammals, such as shrews and rodents (Rowe-Rowe 1977a, Smithers & Wilson 1979, Kruuk & Goudswaard 1990, Butler & du Toit 1994, Ligthart *et al.* 1994, Purves *et al.* 1994, Carugati 1995, Somers & Purves 1996). The importance of different secondary items is probably related to local prey-availability (Rowe-Rowe & Somers 1998). For example, the highest percentage of crab and the lowest percentage of fish have been recorded from KwaZulu-Natal (South Africa). This study was done at mid-altitude (1060–1650 m) where fish faunas are poor and crabs abundant (Rowe-Rowe 1977a). It was at this wetland-rich locality, too, that the frog component was highest (23% relative occurrence) and constituted the most important supplement to crabs (65% relative occurrence). In Zimbabwe, where mountain catfish and eels were abundant, the percentage of fish was highest (23% relative occurrence; Butler & du Toit 1994; and see also Smithers & Wilson 1979). Purely aquatic prey comprised 87–97% relative occurrence at all localities (Rowe-Rowe & Somers 1998). In Groenvlei Lake, Western Cape, where freshwater crabs are absent, fish make up 69% of the diet, illustrating how otters adapt to local food abundance (Watson & Lang 2003).

In marine habitats they eat mostly fish followed first by crab, then by octopus or lobster (Van der Zee 1979, 1981, Arden-Clarke 1983, Verwoerd 1987, Somers 2000a, b). In Tsitsikamma N. P., Van der Zee (1979, 1981) recorded over 35 species of crabs, fish and octopus. Calculated on a relative frequency basis the Red Rock Crab *Plagusia chabrus* had the highest frequency at 28%, followed by Rocksucker *Chorisochismus dentex* at 17% and the Brown Rock Crab *Cyclograpsus punctatus* at 10%. At Betty's Bay, Verwoerd (1987) found that fish

constituted 59% of the biomass of the food, followed by octopus (15%), Red Rock Crab (13%) and rock lobster (10%).

Rowe-Rowe & Somers (1998) state that although African Clawless Otters may occur in groups, they usually forage singly. In shallow, stony bottomed water they walk, submerging the head occasionally, feeling with the forefeet under and between stones for prey (Rowe-Rowe 1977b, Somers 2000a). In deeper water the otter dives to the bottom and forages on the substrate, once again using the forefeet (Rowe-Rowe 1977b, Purves *et al.* 1994). In freshwater 1.5 m deep, dives had a mean duration of 17.4 sec (range 8–26 sec; Rowe-Rowe 1977b). Somers (2000a) found a mean dive time of 21 sec in the sea.

Somers (2000a) found they moved along the coast, while feeding, at a mean speed of 21.4 m per min. Almost all prey is captured using the forefeet (sometimes with the mouth), then bitten. Where larger prey is involved, such as large fish and frogs, the killing bite is directed at the head. Barbel *Barbus* spp., for example, are pinned to the bottom of the pool with the front feet and bitten behind the head. In experiments (Rowe-Rowe 1977c) it was found that slow-swimming fishes were more easily captured than fast-swimming species, as was the case with small fish versus larger specimens of the same species. Smaller fish and crabs may be consumed while treading water but are typically taken to the shallows (prey is usually carried in the forefeet, but sometimes in the mouth) and eaten there (Rowe-Rowe 1977b). Prey is fed into the mouth using the forefeet. Frogs and fish, except large *Clarias* spp. (which have a bony head structure), are eaten from the head first (in contrast to the Spotted-necked Otter *Hydricis maculicollis*, which eats fish from the tail first). Crabs of all sizes are consumed entirely (Rowe-Rowe 1977b), which is in contrast with the Marsh Mongoose *Atilax paludinosus*, which will leave the shell of the carapace in the case of crabs larger than about 40 mm across carapace (although the shells of smaller crabs [<30 mm] may be consumed; D. T. Rowe-Rowe pers. comm.). Rowe-Rowe (1977b) found that with large crabs, the otter usually ate the chelae and limbs first. No particular order was obvious with smaller crabs. In the case of frogs, the legs of the frog were grasped in a forefoot and pieces of the body torn off with the mouth by pulling the frog downwards and moving the head backwards, or by chewing pieces off with the cheekteeth (Rowe-Rowe 1977b).

In KwaZulu-Natal, most freshwater fishes eaten are small (less than 200 mm) (Rowe-Rowe 1977a). In the Okavango R., Botswana, much larger fish (up to 2 kg) were freely taken (Smithers 1983). Somers & Purves (1996) recorded that the mean carapace width of crabs eaten by African Clawless Otters in the Bushmans R., Eastern Cape, was 23.5 mm (range 3.1–65.5 mm; $n = 1365$) while a mean of 28.5 mm (range 4.3–61.0) was determined for the Olifants R., Western Cape (Purves *et al.* 1994). Nevertheless, African Clawless Otters will consume freshwater crabs of all sizes and capably handle even the largest crabs (D. T. Rowe-Rowe pers. comm.).

There is some trophic overlap between the African Clawless Otter, Spotted-necked Otter and Marsh Mongoose (Rowe-Rowe 1977a, Somers & Purves 1996, Rowe-Rowe & Somers 1998). Freshwater crabs feature prominently as shared food in the diets of the three species (Rowe-Rowe & Somers 1998). However, the diets of the two otters reflect a much greater dependence on aquatic prey than does that of the Marsh Mongoose. Comparisons of the diets of the two otters (Rowe-Rowe 1977a, Somers & Purves 1996) reflected a greater dependence on crabs by African Clawless Otters, and a higher amount of fish in the diet of Spotted-necked Otters (Rowe-Rowe & Somers 1998).

Social and Reproductive Behaviour African Clawless Otters are mainly solitary in all habitats, though occasionally they occur in pairs or small family parties (Arden-Clarke 1983, Somers 2000a, Somers & Nel 2004b). In KwaZulu–Natal, group size varied from one to five, with solitary individuals or pairs the most common (Rowe-Rowe 1978a), while in Tsitsikamma N. P., of 56 observations, 35 were of solitary individuals, five of two, eight of three, three of four and one group of five (Arden-Clarke 1986).

The pattern of female home-ranges is suggestive of territoriality. Males have overlapping home-ranges, both with other ♂♂ and ♀♀ (Somers & Nel 2004b). In freshwater, total home-range length varies from 4.9 to 54.1 km. The total area of water used ranges from 4.9 to 1063 ha (Somers & Nel 2004b).

Rowe-Rowe (1992b) found that latrines are usually in grass above river banks or oxbow lake shores or dams, on earth ledges in river banks, or on islands or rocks. African Clawless Otter defecated close to water (mean 4.2 m from water; range 1–15 m; $n = 135$), with most faeces (85%) found between 1 and 7 metres from water. There were between 1.4 and 2.6 faeces per km of river, with most found in spring. Latrines contain a large amount of crab shell remains and fish scales. Rowe-Rowe (1992b) found that, during late autumn, winter and early spring, when there was little rain, spraints remained intact, retaining their shape for 4–5 weeks. Spraints containing crab material bleached, changing colour from dark brown to cream. During summer, when rainfall was higher, spraints broke up after 15–21 days, although some remains were still visible. The spraints of African Clawless Otter can be distinguished from those of the Marsh Mongoose, because the latter contain rodent fur and other items normally not eaten by otters (although where both are feeding extensively on crabs alone, identification may be difficult).

The most common vocalizations of African Clawless Otters are squeaks but they also growl, whine, chirp and hiss. When alarmed they give a sudden *Hah!* sound after which they usually disappear underwater not to be seen again. They are very playful, especially after meals and even more so when kept as pets (Maxwell 1960, Eyre 1963). In the wild they often chase one another and slide down muddy banks, seemingly in a playful manner. When alone they may play with inanimate objects or play ‘cat and mouse’ with prey.

African Clawless Otter *Aonyx capensis*.

Reproduction and Population Structure One to three (though Rosevear [1974] suggests a possible five) young are born at widely divergent times throughout the year. At Betty's Bay, Verwoerd (1987) recorded five litters that he estimated were born between Apr and Jun. At Die Kelders in Walker Bay, ca. 100 km south-east of Cape Town, a ♀ suckled two very small cubs on land in late Dec; another ♀ and small cub was seen swimming at Scarborough on the Cape Peninsula beginning Jan (C. Boucher pers. comm.). The natal den at Die Kelders was situated in weathered calcrete and sandstone, near a freshwater seepage. Stuart (1981), also in the former Cape Province, recorded a foetus taken from a ♀ in Jul and a juvenile with its eyes still closed taken in Apr. In KwaZulu–Natal, Rowe-Rowe (1978a) recorded two one-week-old juveniles in the last week of Aug, and a single juvenile estimated to have been born in Nov. In Zimbabwe, Smithers (1971) recorded juveniles in Mar and Apr, while, in Zambia, Ansell (1960a) estimated births to occur in about Jul/Aug. Rosevear (1974) remarks on a very young animal that was probably still being suckled taken in early Oct in Sierra Leone.

Gestation is 60–64 days (Ewer 1973). Two young otters less than one week old weighed 260 g each (Rowe-Rowe 1978a) and the young are weaned at eight weeks (Verwoerd 1987). Kingdon (1977) noted that during the first months of life the young are hidden, opening their eyes at about four weeks, and then venturing out with the mother. Longevity in captivity is on the order of 14 years (Nowak 1999, Weigl 2005).

Predators, Parasites and Diseases No data available on natural predators. However, sharks are thought to be a possible predator in the sea (Somers 2000a) and Nile Crocodiles *Crocodylus niloticus* and birds of prey in freshwater (Kruuk & Goudswaard 1990). Endoparasites recorded from African Clawless Otters include trematodes (*Baschkirovitrema incrassatum*, *Clinostomum pyriforme* and *Prudhoella rhodesiensis*) and the nematode *Cloeoascaris spinicollis* (Round 1968). No information is available on possible diseases.

Conservation IUCN Category: Least Concern. CITES: Appendix II.

A rapidly increasing human population has been identified as the greatest threat to this species' existence (Rowe-Rowe 1990b, 1995), although the African Clawless Otter does not appear to have reduced its range (Nel & Somers 2002). Alteration of freshwater habitats and riparian vegetation, loss of habitat as a consequence of increased agricultural activity, unsound agricultural practices, overgrazing by livestock in rural areas, or lack of natural resource conservation are among the other main threats. They are sometimes killed when they prey upon waterfowl on farms, and as a competitor for a common food source, fish. Fisheries managers of the Kairezi River Protected Area in Zimbabwe blamed trout declines on otter predation and competition with trout for food, even though scat analysis revealed that only 1% of faeces ($n = 255$) contained the remains of trout and diets overlapped only 17% (Butler 1994, Butler & Marshall 1996). Occasionally, they are accidentally caught and drowned in gill nets and fish traps (Rowe-Rowe 1990b) and in peri-urban areas road kills can be significant (Verwoerd 1987). Although seldom killed for food, skins and other body parts are sought after for use in traditional medicine in various parts of

their range, including KwaZulu–Natal (Cunningham & Zondi 1991, White 2001), Lesotho (N. L. Avenant pers. comm.) and the Udzungwas (De Luca & Mpunga 2005). They are present in a number of protected areas across their range.

Measurements

Aonyx capensis

HB (♂♂): 1265 (1130–1380) mm, n = 13

HB (♀♀): 1233 (1140–1330) mm, n = 7

T (♂♂): 505 (445–570) mm, n = 13

T (♀♀): 483 (450–495) mm, n = 7

HF c.u. (♂♂): 159 (150–170) mm, n = 13

HF c.u. (♀♀): 147 (145–160) mm, n = 7

E (♂♂): 32 (30–36) mm, n = 7

E (♀♀): 30 (31–33) mm, n = 4

WT (♂♂): 14.1 (10.0–18.0) kg, n = 16

WT (♀♀): 11.7 (10.0–13.8) kg, n = 9

South Africa (Van der Zee 1979, Stuart 1981 [♀♀ only; excluding WT], Arden-Clarke 1983, Somers & Nel 2004)

Stuart (1981) recorded an average weight of 15.1 kg for ♂♂ in

the former Cape provinces of South Africa (11.5–21.0; n = 7) and 12.9 for ♀♀ (10.6–14.2; n = 3). The maximum weight recorded (34 kg) was a ♂ kept as a pet (Eyre 1963)

P⁺ (L × W): 12.9 × 14.1 mm, n = 26*

M¹ (L × W): 17.8 × 14.2 mm, n = 28*

Aonyx congicus CONGO CLAWLESS OTTER

Fr. Loutre à joues blanches du Congo; Ger. Kongootter (Kleinzahn Fingerotter)

Aonyx congicus Lönnerberg, 1910. Ark. Zool. 7 (9): 1. Lower Congo, Zaïre.

Congo Clawless Otter *Aonyx congicus*.

Taxonomy Originally described as, and sometimes included as, a subspecies of African Clawless Otter *Aonyx capensis* (see, most recently, Wozencraft 2005). Three subspecies have been recognized (Hinton 1921, Harris 1968, Coetzee 1977): *A. c. congicus*, from Gabon and Congo (DR Congo, except eastern highlands); *A. c. microdon*, from Cameroon and Nigerian border along the upper Cross R.; and *A. c. philippii*, from Rwanda, Burundi, the eastern highlands of DR Congo and SW Uganda. Kingdon (1997) added a fourth subspecies, *A. c. poensis*, known from a single specimen described by Waterhouse (1838) from Bioko I. This taxon has had a contentious past, including being considered as a synonym of *Aonyx capensis* (Wozencraft 1993) and as a subspecies of Spotted-necked Otter *Hydrictis maculicollis* (Rosevear 1974, Wozencraft 2005, and herein). Most authorities now consider *A. congicus* to be monotypic (e.g. Rosevear 1974, Larivière 2001), which is also the preferred

view followed here. Note that *Aonyx*, being of Greek origin and of masculine gender, requires the specific name to concur (Van Bree *et al.* 1999). Therefore, the correct name is *Aonyx congicus*, although *A. congica* is still often incorrectly used. Synonyms: *hindei*, *microdon*, *philippii*. Chromosome number: 2n = 38 (Van Zyll de Jong 1987).

Description A very large otter, similar in size to the African Clawless Otter. The species is characterized by a conspicuous dark patch between the eyes and the nostrils contrasting sharply with the surrounding whitish fur (Kingdon 1997, Jacques *et al.* 2002). Upper lips, top of the nose to the eyebrows white or yellowish-white. Head and shoulders conspicuously frosted (more so than in African Clawless Otter) by the silvery tips of most of the longer guard hairs, which are numerous on the head and shoulders, becoming rare on the back. Small round ears with a distinct white margin on

the border. Upper border of the rhinarium straight (rounded or V-shaped in African Clawless Otter). Sometimes a dusky cross-band behind the chin (Allen 1924, H. Jacques pers. obs.). Dorsal pelage dark chocolate to pale grey. Ventral pelage of a similar colour, except the cheeks, chin, throat and upper chest, which are white or light cream. Front digits naked, claws and webbing absent, toes webbed to the base of the second phalanx, rudiments of claws on the second, third and fourth toes only (rarely on the thumb and fifth). Tail long and heavily muscled, tapering towards the tip. There is little or no sexual dimorphism. Females have two pairs of abdominal nipples.

The skull of the Congo Clawless Otter resembles that of the African Clawless Otter in most respects. However, the cheekteeth (P^4 , M^1 , M_1 , M_2) are conspicuously smaller when compared with those of the African Clawless Otter (30% smaller; Rosevear 1974, Jacques *et al.* 2004, 2009) (see Measurements). Apart from the dentition, no important features distinguish mature skulls of the two species (Rosevear 1974, Jacques *et al.* 2004, 2009) (see Measurements).

Geographic Variation Both regional and individual variation appears to be minimal.

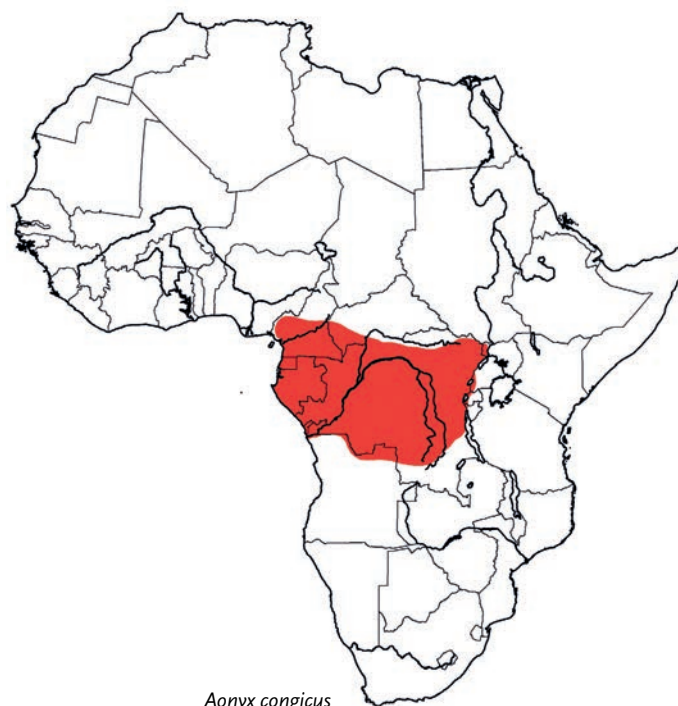

Similar Species

Aonyx capensis. Patch between eye and nostril is less conspicuous and blends with the colour of the darker upperparts; ears uniformly brown or may have a thin white edge; frosting reduced or absent on the head and shoulders (these differences are less conspicuous when the fur is wet); top border of rhinarium rounded or lightly V-shaped. Some individuals show intermediate patterns between Congo Clawless and African Clawless Otters. These intermediate forms seem to come from the limits of the distribution range of the former species (De Barros Machado 1969, H. Jacques pers. obs.). It is not yet known whether, or to what degree, the two species are sympatric.

Hydrictis maculicollis. See species profile for notes on sympatry. Smaller in size; throat and neck with pale cream or white mottling, or the same colour as the rest of the body; webbed feet.

Distribution Endemic to Africa, this species occurs in the rainforests of the Congo basin including Equatorial Guinea, Gabon, Congo, DR Congo, as well as S Cameroon, S Central African Republic, N Angola and extending eastward to the forests and the wetlands of Rwanda, Burundi and Uganda (Rowe-Rowe 1990b, Larivière 2001). The exact limits of the species' distribution range are still unclear (including the range east of the Rift), particularly due to the species' possible confusion with the African Clawless Otter. Older recorded localities of Congo Clawless Otter from Nigeria are now located in Cameroon due to international boundary changes (Harris 1968, relocated by Rosevear 1974). The African Clawless Otter is recorded in SE Nigeria (Eniang & Luiselli 2002), but Congo Clawless Otter probably are absent (L. Luiselli pers. comm.). Neither Happold (1987) nor Van Rompaey & Powell (1999) mention the species as occurring in Nigeria.

The 32 skins of Congo Clawless Otter examined in the Tervuren Royal Museum come mainly from the north and west of DR Congo. Due to hunting pressure the species is no longer found in the east of the country (J. P. Van de Weghe pers. comm.). In Angola, the species occurs only in the northern part of the Lunda district, north of the 10° parallel (De Barros Machado 1969, Crawford-Cabral 1989a), though interestingly Hayman (1963) does not mention the species.

Aonyx congicus

Habitat The prime habitat of this species is the tropical rainforest of the Congo basin. There is no evidence to suggest that they use shoreline habitats (as the African Clawless Otter does), although its presence further inland in coastal freshwater lagoons and mangrove swamps was reported in Gabon and Congo (Jacques 2002). Congo Clawless Otter can be readily observed in large and small rivers, and not only in swamps as one of its common names suggests. It is frequently observed in swampy forest clearings (bais) (e.g. Langoué Bai in C Gabon, and Mbeli Bai in Nouabalé-Ndoki N. P. in N Congo). Spotted-necked Otters are sympatric in parts of their range, such as at Mbeli, and both species have been observed feeding in proximity without conflict. Bai-use by Congo Clawless or Spotted-necked Otters seems to vary according to changes in aquatic vegetation, with the latter favouring more open water than the former (R. Parnell & E. Stokes pers. obs.). Recorded to 2200 m on the Kahuzi Massif (Rahm & Christiaensen 1963).

Abundance This is a very poorly known species, and there is limited information available. It may be common in certain undisturbed rainforest locations, though it is thought to be otherwise rare and perhaps even extirpated in parts of some countries. However, from 1998 to 2001 otters were observed in Mbeli Bai between 10 and 40% of days per month and appeared to be common (R. Parnell & E. Stokes pers. obs.).

Adaptations General adaptations are shared with African Clawless Otter. The smaller molars of the Congo Clawless Otter, compared with African Clawless Otter, probably reflect their selection of generally softer prey items (see Foraging and Food). Besides the Spotted-necked Otter, *A. congicus* is also sympatric with the Marsh Mongoose *Atilax paludinosus* and African Clawless Otter; segregation in diet presumably allows these species to co-exist (Rowe-Rowe & Somers 1998).

Foraging and Food Carnivorous. Food items include earthworms, molluscs, fish, frogs, crabs and other small vertebrates and invertebrates (see Jacques *et al.* 2009 and references therein). At Mbeli Bai, almost all observed feeding is on worms, though fish are sometimes caught (R. Parnell pers. obs.). Worms are located by pushing the forepaws deep into soft mud banks, and feeling through the mud with the fingers, gaze averted. After several seconds the forepaws are withdrawn and the worm transferred from the digits to the mouth. An average of three worms per minute are obtained in this manner. Parent otters have been observed feeding immatures, with worms passed from mouth to mouth. After feeding, otters at Mbeli were observed rolling in grass, self-grooming and further drying their fur by resting in the sun (R. Parnell pers. obs.). Defecation at rolling sites is common.

Social and Reproductive Behaviour Unknown, although 'family parties' have been observed in rivers in Cameroon (Kingdon 1997). At Mbeli Bai, up to four individuals have been seen together although most are seen alone or in pairs (frequently mother/offspring) (R. Parnell pers. obs.). Vocalizations, which are common when individuals meet, include barks, growls, snorts, hah!, coos, hums and whistles (Duplaix 1982). Serious fights are rare but squabbles and play fighting are frequently observed.

Reproduction and Population Structure Unknown. In DR Congo, there are records of cubs being born in Feb (R. Chapman pers. comm.) and Aug (J. Thompson pers. comm.) and three cubs were born in the beginning of Jan in SE Gabon (O. Bourry pers. comm.). At Mbeli Bai, subadults have been seen in most months of the year and cubs seen in Feb (R. Parnell pers. obs.). These meagre observations suggest that breeding may occur throughout the year. Other reproductive parameters are probably as for African Clawless Otter. Newborn cubs are pure white (J. Thompson & P. Charles-Dominique pers. comm.), although two-month-old cubs have the same colouration as adults.

Congo Clawless Otter *Aonyx congicus* face.

Predators, Parasites and Diseases Uncertain, but crocodiles, pythons, large raptors and Leopards *Panthera pardus* are likely predators, particularly of cubs. A single parasite has been reported, the nematode *Microfilaria aonycis* (van den Berghe *et al.* 1963); due to their aquatic way of life, otters in general have few ectoparasites. Distemper, parvovirus and leptospirosis have been reported in other otter species when in contact with infected domestic dogs.

Conservation IUCN Category: Least Concern. CITES: Appendix I (Cameroon, Nigeria); Appendix II (other populations).

Localized threats to the Congo Clawless Otter include hunting for bushmeat and skins, habitat loss and degradation, and overfishing. As with African Clawless Otters, this species is present in several protected areas across its range. Recent confirmed records include: Dja reserve in Cameroon (F. Alary pers. obs.); Dzanga-Sangha N. P. in Central African Republic (A. Turkalo, J. Ray pers. comm.); Ivindo N. P. (L. Davenport pers. comm.), Lopé N. P. (L. White pers. comm.) and Langoué Bai (WCS team pers. obs.) in Gabon; and Nouabalé-Ndoki (R. Parnell, H. Jaques, F. Alary pers. obs.) and Odzala (J.M. Froment pers. comm.) National Parks in Congo.

Measurements

T (♀ ♀): 454 mm, n = 6

HF c.u. (♂ ♂): 147 mm, n = 3

HF c.u. (♀ ♀): 138 mm, n = 6

E (♂ ♂): 35 mm, n = 3

E (♀ ♀): 33 mm, n = 6

Allen 1924 (ranges not given)

Note that although Allen identifies his specimens as African Clawless Otter, the molar measurements given as well as the description and the locality of Faradje in DR Congo refer to Congo Clawless Otter instead (Schouteden 1942). Further, skins and skulls of the Lang & Chaplin expedition (examined in AMNH by the authors) are indeed Congo Clawless Otter. Lönnberg (1910) recorded weights of 13.6–18.1 kg from lower Congo, though Kingdon (1977, 1997) gives a range to 34 kg

P⁺ (L × W): 10.2 × 10.7 mm, n = 43*

M¹ (L × W): 13.0 × 10.0 mm, n = 44*

M₁ (L × W): 13.4 × 7.6 mm, n = 40*

GLS (♂ ♂): 129.9 (108.4–145.0) mm, n = 44

GWS: 89.7 (70.8–109.0) mm, n = 39

Throughout range (Jacques *et al.* 2009)

*L = longest length, W = greatest width, at right-angles to the main longitudinal axis of the skull

GENUS *Lutra*

Common Otter

Lutra Brisson, 1762. Regnum Animale, Ed. 2.

The content of the genus is dependent upon whether the genera *Lontra* (four species of New World Otters, except the Giant Otter *Pteronura brasiliensis*) and *Hydrictis* (including the Spotted-necked Otter *H. maculicollis*) are considered distinct or synonymous with *Lutra*. Separation of New World Otters in *Lontra* appears well supported (Van Zyll de Jong 1972, 1987, Koepfli & Wayne 1998, Bininda-Emonds *et al.* 1999). However, whereas the genus *Hydrictis* has been recognized as distinct by some (e.g. Pocock 1921, Davis 1978, Davis *et al.* 1979, Grubb *et al.* 1998), it was not recognized as such by Harris (1968) or Van Zyll de Jong (1987) on morphological grounds. The molecular data of Marmi *et al.* (2004) also supported inclusion of all otters in the genus *Lutra*. None the less, inclusion of the Spotted-necked Otter in a separate genus appears warranted as the genus *Lutra* is paraphyletic, and the Spotted-necked Otter diverges before the clade that includes Common or Eurasian Otter *Lutra lutra* and the two clawless otter species, African Clawless Otter *Aonyx capensis* and Congo Clawless Otter *A. congicus* (Koepfli & Wayne 1998; and

see Bininda-Emonds *et al.* 1999). Consequently, Wozencraft (2005) recognized *Hydrictis* as distinct from *Lutra*, which now appears well supported (Koepfli *et al.* 2008, Sato *et al.* 2012).

Worldwide, then, three species of *Lutra* are recognized, of which one occurs in Africa: the Common or Eurasian Otter, which is found in North Africa and then extraliminally throughout much of Eurasia. The two extralimital *Lutra* species are the Japanese Otter *L. nippon* (which some authors consider synonymous with the Common Otter), and the Hairy-nosed Otter *L. sumatrana*, from South-East Asia. The Common Otter is considerably smaller than the two *Aonyx* species, and yet about twice the mass of the Spotted-necked Otter (which is the smallest of the African otters), though similar in appearance. In contrast to *Aonyx*, the Common Otter has webbed forefeet, strong claws on all feet and the tail is cylindrical, not flattened.

Hans Kruuk

Lutra lutra COMMON OTTER

Fr. Loutre; Ger. Fisch-Otter

Lutra lutra (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 45. 'Euopae aquis dulcibus fluviis, flagnis, piscinis,' subsequently restricted by Thomas (1911) to 'Uppsala' [Sweden].

Common Otter *Lutra lutra*.

Taxonomy In North Africa originally described as a new species *Lutra angustifrons* Lataste, 1885, although the same author subsequently considered the species conspecific with European otters. Indeed, although African populations have been treated subspecifically as *L. l. angustifrons* (e.g. Allen 1939, Ellerman & Morrison-Scott 1951), Van Bree (1968) showed that otters from North Africa and the European populations are inseparable, Lataste having originally compared the skull of an adult otter from Algeria with that of a juvenile from France (Coetzee 1977). Synonyms (Africa only): *angustifrons*, *spendida*, *vulgaris*. Chromosome number: $2n = 38$ (Günter & Gebauer 1982).

Description Medium-sized, with streamlined and elongated body, muzzle rather blunt with large whiskers, head somewhat flattened, short round ears, small eyes. Vibrissae can be rotated downward during diving, to create larger contact area when fishing. Head tapering into body, with head and neck of equal width. Pelage fairly short and extremely dense, hair length even over entire body, guard hairs overlying very compact undercoat (about 500 hairs per mm^2 , Kruuk 1995, 2006). Overall colour evenly dark brown, lighter underneath, throat usually the lightest part. Occasionally individuals have small, clear white patches on throat, but generally there is little variation in colour. Legs short, especially forelegs; also equipped with small vibrissae at the elbow. All feet have five toes and clear claws, not very sharp. Hindfeet fully webbed, forefeet partially so. Long, round tail, thick at base and tapering to end. Males are about one-third heavier than ♀♀. Two or three pairs abdominal nipples.

In the skull the postorbital constriction is uniquely narrow. Dental formula is $I^{3/3}, C^{1/1}, P^{4/3}, M^{1/2} = 36$; some incisors are often missing.

Geographic Variation None recorded within Africa.

Similar Species

Hydrictis maculicollis. Sub-Saharan Africa only. Darker brown and darker coloured underneath, with striking irregular white blotches on throat. Usually occurs in small groups and can be highly gregarious (e.g. in L. Victoria; Procter 1963).

Lateral, palatal and dorsal views of skull of Common Otter *Lutra lutra*.

Distribution The Common Otter is a Eurasian species, with the largest geographical distribution of all otters, ranging throughout much of the Palearctic (except the Siberian tundra), including the British Isles, Sri Lanka, Taiwan and Sumatra (Corbet 1978). Only a very small part of the range extends into North Africa, where it is found in rivers in the plains and in the Atlas Mts, in originally contiguous but now more fragmented populations. Widespread in the foothills of the Middle and High Atlas of N Morocco, where it seems to be limited by available water and rivers with suitable cover (Macdonald & Mason 1984, Broyer *et al.* 1988, Aulagnier 1990, Cuzin 1996, 2003, Delibes *et al.* 2012). In Algeria, Common Otters formerly inhabited larger rivers and lakes in the coastal region and Tell Atlas, and in W Algeria they were sporadically observed in seasonal rivers on the border of the Saharan Atlas and the desert (Kowalski & Rzebik-Kowalska 1991). Today, the Common Otter is limited to the Sebaou R. in Kabylie and the coastal eastern parts (Macdonald *et al.* 1985, Kowalski & Rzebik-Kowalska 1991), ranging into wetlands in N Tunisia, where they are common in and around L. Ichkeul, with the Oued Medjerde representing a southern limit for the species in the country (as rivers further south offer little shelter) (Macdonald & Mason 1983).

Habitat Totally dependent on water: edges of lakes, dams and rivers, extending into swamps and up the smallest of streams, including irrigation channels (Cuzin 2003). Forages in shallow water, mostly less than 2 m deep, but spends most of the time resting inside cover of reeds, shrubs and other dense vegetation. In Tunisia, otters would lie up in dense bankside cover, primarily provided by *Nerium oleander* (Macdonald & Mason 1983); the latter plant is evergreen and, being poisonous, is not grazed by livestock. In Africa, found up to 2295 m in Morocco (Cuzin 2003). Crosses watersheds overland, and dens may be used up to 1 km from water. May occur close to settlement and in tree plantations. In Europe, also occurs along rocky seashores, but only where freshwater is available (for otters to wash salt out of fur as well as for drinking; Kruuk

Lutra lutra

1995, 2006); in North Africa, they only very rarely are found in the sea (Piquet 1961) and in coastal lagoons (Cuzin 2003). In S Morocco, otters are found until the southern limit of permanent freshwater, reaching the northern Sahara. Habitat selection differs between ♂♂ and ♀♀: ♀♀ more often in small streams and lakes, ♂♂ in the larger rivers.

Abundance Locally relatively common, though declining throughout their African range. Rarely seen, so evidence for their presence is derived from field signs such as droppings ('spraints') and tracks (e.g. Macdonald *et al.* 1985, Delibes *et al.* 2012). Such evidence is not reliable for assessment of densities. Even in the best habitats, otters rarely reach densities of more than one animal per 10 km of bank, but spraints may be found in many places. There is a good correlation between fish biomass and otter density, suggesting that otter density in any area is limited by availability of prey (Kruuk 1995, 2006).

Adaptations Common Otters have remarkably sharp teeth (used for catching fish). Their eyesight is moderate, and used under and above water; hearing is not very acute, but their sense of smell is excellent, with an ability to detect other otters over hundreds of metres.

Foraging and Food Highly specialized fish eaters, but also taking amphibians, crustaceans and occasionally birds (as large as geese) and small mammals. They prefer slow, bottom-dwelling fish, preferably with a high fat content (e.g. eels, salmonids, silurids), and take fish upwards of about 4 cm in length, usually 12–20 cm long, and occasionally much larger. In Morocco, fish (*Salmo trutta* or *Barbus* spp.) predominate in the diet, but amphibians are the secondary main prey. Occasionally, birds, snakes and crustaceans are preyed upon; important seasonal variations have been observed, with predominance of amphibians and crustaceans (Broyer *et al.* 1988).

Common Otters forage for 4–6 hours per day. They rarely pursue their prey, but surprise it, often when the prey is non-active. Mostly nocturnal in areas where the main prey is diurnally active, and vice

versa. They often find underwater prey by touch (feet, vibrissae), but also use vision when there is sufficient light. In lakes they dive from the surface, remaining underwater for 10–25 sec (depending on water depth; rarely up to 60 sec), surfacing for 5–10 sec. When successful, they feed on small prey on the surface, but move to land with large prey. In streams, the amount of time spent underwater is much shorter. Because of heat loss in water, foraging is energetically very demanding and animals need to be highly successful. On average, Common Otters eat 1.2–1.5 kg per day (Kruuk 1995).

Social and Reproductive Behaviour Solitary, although cubs may accompany the ♀♀ for a year or more, even when fully grown. Females defend a territory against other ♀♀, though often there are large overlaps, and there may be several (related) ♀♀ in one territory, who avoid but tolerate each other. Males fight over territories larger than those of ♀♀, and overlap with several ♀♀. In Europe, individual home-ranges average about 21 km for ♀♀, and 40 km for ♂♂ (but up to 80 km; Kruuk 1995, 2006). Faeces ('spraints') are used for scent-marking, in small but strong fish-smelling quantities. There is no system of boundary-marking, but they spraint close to foraging sites and other resources, and more often when there is competition for food, so sprainting is often seasonal.

Cubs are born in dens, often far from water, or in a covered nest of reeds. After two months the mother forcefully carries the cubs into water, and they accompany the ♀ when foraging. In the first week outside the den ♀♀ may deliberately abandon one or more of the cubs, perhaps related to food availability (Kruuk 1995, 2006). Weaning takes place at 4–6 months, when cubs start to catch their own prey (usually close alongside the mother), but remain dependent on the mother for prey for another year. Cubs and mother keep in contact using a whistling call; when play-fighting they emit a high-pitched rattling call ('wickerling') or loud screams. Foraging and diving efficiency of cubs increases up to at least 18 months of age (Watt 1993). The ♂ is not involved in any aspect of rearing or defence.

Reproduction and Population Structure Most information available on breeding comes from the European part of its range. Females are polyoestrus, the cycle lasting 4–6 weeks, and with first litter at the age of 2–3 years. Young are born at any time of the year after a gestation period of about eight weeks (Wayre 1979). Litter-size is 1–4 and there is no delayed implantation. Longevity in captivity is around 18–20 years (Nowak 1999, Weigl 2005); in the wild average age at death is 4–5 years, and, with long cub dependence on mother, lifetime reproductive output is small (Kruuk 1995, 2006). Mortality rate increases with age, related to high rate of metabolism, and the main cause is probably food shortage.

Predators, Parasites and Diseases There are no known natural predators for this species in North Africa, with the exception of large raptors preying on cubs. Common Otters are susceptible to distemper and rabies, but the effects of these on populations is unknown.

Conservation IUCN Category: Near Threatened. CITES: Appendix I.

Legally fully protected in Morocco, Algeria and Tunisia. Common Otters are vulnerable to loss of habitat, especially in riparian vegetation. Their aquatic habitat is susceptible to pollution by organochlorines, such as DDT, dieldrin and heavy metals (Foster-Turley *et al.* 1990), and preferred prey species accumulate such pollutants. A large 1960s population crash in Europe was probably caused by dieldrin. Present-day effects on populations are often unclear (and probably over-rated). Macdonald *et al.* (1985) attributed a decline in Algeria to changing water levels in rivers (due to the destruction of forest), the disappearance of suitable habitat along water-banks and pollution (pollution of inland rivers in Algeria seems to contrast markedly with the situation elsewhere in parts of North Africa). In Morocco, pollution, mainly domestic but sometimes industrial, has increased dramatically in the major rivers, especially in the north, where otters have apparently disappeared from rivers in the lowland plains, and the use of domestic detergents has led to eutrophication, especially in the south, where water resources are scarce; dam building has also reduced available habitat and led to the fragmentation of populations. Compliance with international treaties, such as the Stockholm Convention, could see otters recolonize the plains from source populations in mountainous areas (Delibes *et al.* 2012). Usually, numbers are limited by fish biomass (Kruuk 1995, 2006), and the best way to promote otter numbers is to manage for high densities of fish. Illegal hunting is a problem in some areas, as otters are sometimes eaten and their pelts sold (F. Cuzin pers. comm.).

Measurements

Lutra lutra

GENUS *Hydricis* Spotted-necked Otter

Hydricis Pocock, 1921. Proc. Zool. Soc. Lond, 1921: 543.

The genus *Hydricis* includes the Spotted-necked Otter, which occurs throughout most tropical and sub-tropical regions of sub-Saharan Africa. The species is often included in the genus *Lutra*; the classification here follows Wozencraft (2005), since inclusion in

Lutra would render *Lutra* paraphyletic (Bininda-Emonds *et al.* 1999, Koepfli *et al.* 2008, Sato *et al.* 2012).

Hydriactis maculicollis (Lichtenstein, 1835). Archiv Naturgesch. 1 (1): 'Kafferlandes am ostlichen Abhange der Bambusberge' (Bamboesberge 31° 30' S 26° 20' E, near Sterkstroom, Eastern Cape Province, South Africa).

Spotted-necked Otter *Hydriactis maculicollis*.

Lateral, palatal and dorsal views of skull of Spotted-necked Otter *Hydriactis maculicollis*.

Taxonomy Nine forms have been described from Africa, mainly on the basis of size, colour or markings, with six subspecies listed by Allen (1939) and five by Coetzee (1977). The validity of these subspecies is questionable, and the listing of five subspecies here is provisional and follows Coetzee (1977) and Meester *et al.* (1986). Synonyms: *chobiensis*, *concolor*, *grayii*, *kivuana*, *malculicollis*, *matschiei*,

mutandae, *nilotica*, *poensis*, *tenuis*. Chromosome number: $2n = 40$, the only otter species with more than 38 chromosomes. Fundamental number is 66; X chromosome is submetacentric and Y chromosome is metacentric (Davis *et al.* 1979, Van Zyll de Jong 1987).

Description Spotted-necked Otters are the smallest of African otters. Medium-sized, with a streamlined body covered in short, dense fur (guard hairs 15–20 mm long) varying from chocolate brown to dark reddish in colour; underfur slightly shorter and white or off-white. Throat and neck with pale cream or white mottling, or, less commonly, same colour as rest of body. Underparts generally same colour as back and sides. Albinos or partial albinos have been recorded (Procter 1963). Head broad at back, narrows at short, broad muzzle. Ears small. Upper lips and area under nostrils pale pink. Tail long and dorsoventrally flattened. Legs short with five toes webbed to their tips, each possessing a creamy-white claw about 10 mm long. Anal glands present. Two pairs abdominal nipples.

The skull conforms to the typical mustelid shape but is lightly built, with rostrum short and broad. The postorbital bar is represented by a small knob-like process behind and above the eye and a slightly better developed process on the zygomatic arch. The eye sockets are proportionally larger than in the African Clawless Otter *Aonyx capensis* (Skinner & Chimimba 2005). Dental formula is $I^{3/3}, C^{1/1}, P^{4/3}, M^{1/2} = 36$.

Geographic Variation

H. m. maculicollis: South Africa, Mozambique, S Malawi.

H. m. chobiensis: N Botswana, Caprivi Strip, Cunene and Okavango Rivers of Namibia, Angola, W Zambia and lowland Congo basin.

H. m. kivuana (including *mutandae* and *tenuis*): L. Kivu area (DR Congo), Burundi, Rwanda, SW Uganda, L. Victoria, NW Tanzania and adjacent parts of Kenya.

H. m. matschiei: Gabon, Cameroon, Nigeria, S Niger. Western limit unclear.

H. m. nilotica: S Sudan and Ethiopia.

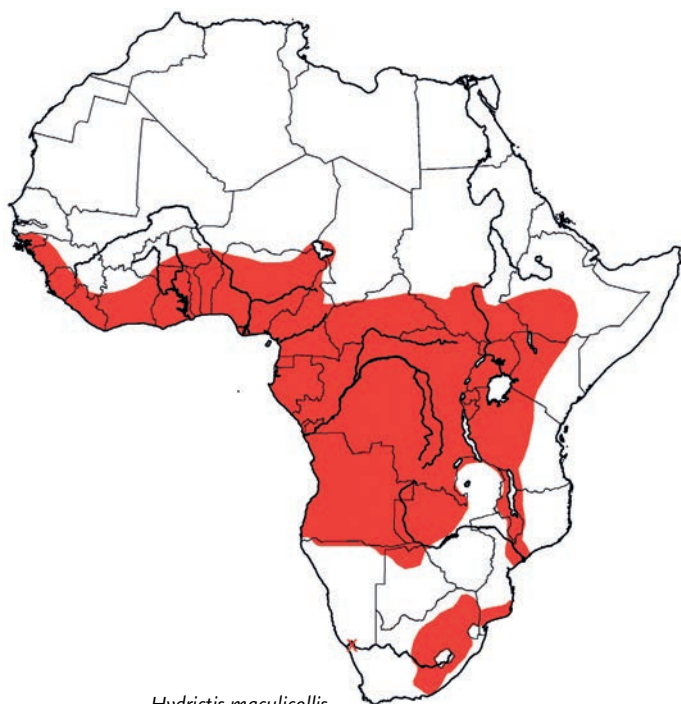

The subspecies status of *Hydrictis maculicollis* in West Africa is not clear, and none are currently named (see Rosevear 1977, Grubb *et al.* 1998). H.-J. Kuhn (in Coetzee 1977) thought that specimens from Liberia allied closely with the nominate form, even though he supported differentiating between *maculicollis* and *matschiei*, the form that might occur.

Similar Species

Lutra lutra. North Africa only and then extraliminally. Lacks white mottling on throat. Usually solitary.

Aonyx capensis and *A. congicus*. Both larger in size with unspotted off-white chin, throat, and upper chest; toes clawless and forefeet unwebbed; molars broad and robust for crushing crustaceans. The three species coexist in the Congo basin, SW Central African Republic and possibly in Rwanda, Burundi and W Uganda. The Congo Clawless Otter and the Spotted-necked Otter are both also found in Gabon. Clawless otters and Spotted-necked Otters coexist throughout most of the eastern and southern part of their range of distribution. Owing to behavioural and morphological differences and specific habitat use there does not appear to be competition between Spotted-necked Otters and the two clawless species (Rowe-Rowe 1977, Somers & Purves 1996, Rowe-Rowe & Somers 1998).

Distribution An African endemic, occurring throughout most of tropical and sub-tropical sub-Saharan Africa where there is permanent water containing small fishes. The range is given by Rowe-Rowe & Somers (1998) as Sierra Leone eastwards to L. Chad, then from S Central African Republic to SW Ethiopia. In the west, they range southwards to rivers forming the northern border of Namibia and swamps and rivers of NW Botswana. In the east,

Hydrictis maculicollis

they range southwards through W Kenya and Tanzania, Malawi, part of Mozambique, to E South Africa. Power & Slater-Jones (2010) recorded a sighting of a Spotted-necked Otter on the lower Orange R. at Senderling's Drift in the Ais/Ais Richtersveld Transfrontier Park, some 1200 km downstream from their known distribution.

Although usually reported as absent from Zimbabwe (Smithers & Wilson 1979), the species has recently been recorded from Zambezi N. P. and Matetsi Unit 7 in the far north-west (Purchase *et al.* 2007). They are otherwise absent from most of Zimbabwe, E Zambia and Swaziland, and apparently locally extinct in Burundi, Ghana, Togo and Lesotho (although it is not clear if they ever occurred in this country). That their range formerly extended further north at least along the Egyptian Nile is proven by the discovery of skeletal remains at late Palaeolithic fishing sites (Van Neer 2002).

In West Africa, the exact distribution range is unclear. According to Grubb *et al.* (1998) the farthest west the species has been reliably recorded is Guinea in the Kounounkan Massif (Barnett *et al.* 1996). Distribution is not continuous eastwards from Sierra Leone, and Grubb *et al.* (1998) state that 'west of Nigeria Harris (1968) recorded only Liberia, overlooking Sierra Leone and Côte d'Ivoire. But there is no confirmed record between the western part of Côte d'Ivoire and SW Niger where Poché (1976) listed it from 'W' N. P. (though this was not based on collected material) and Nigeria (Happold 1987). There is a real, though unexplained, absence of this species from many parts of eastern and southern Africa, as well as much of West Africa.' Their presence in the WAP Complex of protected areas at the confluence of the Benin, Niger and Burkina Faso borders is discussed by Lamarque (2004). The recent catch of a specimen, and findings from a field survey, have confirmed the presence of this species in Guinea-Bissau, moving its western boundary further west (Reuther *et al.* 2003).

Whether this species ever occurred on Bioko I. is unclear. Waterhouse (1838) described the form *poensis* (in the past also based on a single specimen) apparently collected from Bioko. However, Eisentraut (1973), reviewing earlier opinions on the matter, and who himself failed to record the species, contested the presence of the species on Bioko concluding that Waterhouse's specimen had mainland origins. The only other observations of an otter on Bioko are those reported by Kingsley (1897), who remarked on 'a very pretty otter (*Lutra poensis*) with yellow brown fur often quite golden underneath'. These observations provide some evidence that otters may once have existed on Bioko, although there is little doubt that the species is now extinct on the island (Harrington *et al.* 2002).

Habitat The Spotted-necked Otter inhabits freshwater habitats where water is unsilted, unpolluted and rich in small fishes; it does not occur in marine or estuarine waters. Most suitable habitat appears to be the large lakes of central and East Africa and open waters of areas such as the Okavango Delta (Rowe-Rowe & Somers 1998). Elsewhere, it is found in streams, rivers and impoundments up to altitudes of 2500 m (Yalden *et al.* 1996). Wherever it occurs, the Spotted-necked Otter prefers shallow to deep waters (Larivière 2002c). Adequate riparian vegetation in the form of long grass, reeds, or bushes is essential to provide cover during periods of inactivity. Resting places and dens are generally on stream or river banks, on ledges in banks, rock ledges, islands, or lake shores, wherever dense vegetation cover is present (Rowe-Rowe 1992b, Perrin & Carugati 2000b). A telemetry study conducted in KwaZulu-Natal, South Africa, revealed core areas

included a highland river and tributaries, natural oxbow lakes and some man-made lakes artificially stocked with alien trout (Perrin *et al.* 2000).

Abundance Common or fairly common in the fish-rich central African lakes. Throughout the rest of Africa, where fish faunas tend to be poor, the species is generally uncommon or rare (Rowe-Rowe 1990b, 1995). Abundance and density appear to be strictly dependent on the availability of fish. In the central and East African lakes, density was estimated at between one and two otters per kilometre of shoreline (Procter 1963, Kruuk & Goudswaard 1990, Lejeune & Frank 1990). In an area that included a highland stream and man-made lakes in South Africa, Perrin *et al.* (2000) estimated 1 otter/1–2 km of stream, while in less suitable habitat Rowe-Rowe (1992b) estimated 1 otter/6–11 km. In a survey conducted on four 5 km sections on three different rivers in Ukhahlamba-Drakensberg Park, Carugati (1995) estimated that the number of otters using each of the different sections ranged between one and five, depending on habitat suitability. In Sierra Leone, the species was found to be much rarer than the African Clawless Otter, and out of some 30 skins examined over a period of 15 years, only two were Spotted-necked Otters (Rosevear 1974, Grubb *et al.* 1998).

Adaptations The feet are fully webbed and clawed, unlike the clawless otters. This represents a substantial difference in the nature of the interface between otter and environment and, in spite of this species being quite dextrous with its forefeet, it can be described as ‘mouth-oriented’, rather than ‘finger-oriented’, as the clawless species are (Kingdon 1977). When swimming, all four feet are used for the initial thrust, and the hindfeet propel the otter onward. The forefeet steer the animal through water in combination with the very slightly flattened tail, which serves as a rudder and balancing organ (Mortimer 1963, Rowe-Rowe 1975b). The guard hair and underfur are particularly dense to insulate the body when swimming.

In the skull, the long glenoid process on the lower jaw fits into the groove of the upper part of the skull, inhibiting all sideways movement, unnecessary in an animal such as the Spotted-necked Otter where food does not need to be masticated thoroughly. The condyle is broad and high, allowing for a firm attachment of the temporalis muscles. However, the zygomatic arches are weak, the bone being broad and thin, suggesting that the function of the masseter muscles is reduced in favour of the temporalis (Skinner & Chimimba 2005). The upper canines are sharp and straight, lower canines recurved for holding prey. PM^4 and M_1 form carnassial shear for eating fish (Rowe-Rowe & Somers 1998). The perianal glands produce a secretion with a typical musty odour. The secretion appears as a gelatinous mass and it is always associated with spraints.

Dens are occasionally excavated by the otters where there is suitable alluvial soil (Rowe-Rowe 1992b). These excavated ‘holts’ have elliptical openings roughly 200 mm wide by 130 mm high ($n = 6$), with tunnel lengths between 0.9 and 1.0 m. Rowe-Rowe (1992b) noted that on a section of the Mooi R. in Ukhahlamba Drakensberg Park, the use of both dens and resting sites varied seasonally and ranged from 1 per 2 km to 1 per 3.5 km per season for dens and 1 per km to 1 per 1.7 km per season for resting sites. On three different rivers in the same park, Carugati (1995) found den density to be one den every 1–5 km.

Spotted-necked Otters have been described as diurnal, with activity peaks during early morning and late afternoon (Mortimer

1963, Procter 1963, Rowe-Rowe 1978a, Lejeune 1989). Using telemetry, d’Inzillo Carranza (1997) confirmed that they are most active between 06:00 and 09:00h, and then again between 15:00 and 18:00h. On bright moonlight nights activity was also recorded between 18:00 and 21:00h, occasionally continuing to 24:00h.

Foraging and Food The Spotted-necked Otter is a specialized fish eater, also feeding on crabs, frogs, insects and occasionally birds. In L. Muhazi (Rwanda) and L. Victoria (Tanzania) diet consists almost entirely of fish of the genus *Haplochromis*, followed by fish of the genus *Tilapia* (Procter 1963, Kruuk & Goudswaard 1990, Lejeune 1990). Kingdon (1977) in L. Bunyoni (Uganda/Rwanda) reported that the main prey before the introduction of *Tilapia* sp. was the clawed toad *Xenopus laevis*, and the otter population at that time was thriving.

In South Africa, where fish faunas of inland rivers are poor, Spotted-necked Otters appear to forage on almost equal amounts of fish, crabs and frogs, supplemented by small amounts of dragonfly (Odonata) larvae (Rowe-Rowe 1977a, Somers & Purves 1996, Perrin & Carugati 2000a). Where otters lived almost entirely on fish, no seasonal variation was obvious. In South Africa, the fish component was highest during autumn and winter while the crab component was highest during spring and summer (Rowe-Rowe 1977a, Perrin & Carugati 2000a). This could be related to the effects of water temperature on the prey: during the cold season crabs retreat into inaccessible places and at the same time the efficiency of locomotion of fishes is reduced by cold water (Rowe-Rowe 1977a).

In all studies to date, Spotted-necked Otters fed mainly on small fish, 80–90% being smaller than 100–150 mm fork length (Rowe-Rowe & Somers 1998). When preying on crabs, specimens with a carapace width <45 mm appear to be selected (Rowe-Rowe & Somers 1998) and Rowe-Rowe (1977b) found that most crabs with a carapace width >50 mm were avoided. Somers & Purves (1996) in the Bushman R. also found fish of the genus *Tilapia* to be the main component of its diet, and they did not find remains of any other species of fish. Rowe-Rowe (1977b) and Perrin & d’Inzillo Carranza (2000) suggested that they hunt mainly by sight. However, in the lakes where both small fishes and Spotted-necked Otters are most abundant, the water is very turbid (Lejeune & Frank 1990, H. Kruuk pers. comm.), suggesting that senses additional to sight are used. Foraging occurs mainly within 2–10 m of the shore (Procter 1963, Lejeune 1989, Kruuk & Goudswaard 1990). Foraging dives generally have a duration of 16–25 sec in deep water (Lejeune 1989) and shorter (5–20 sec) in shallower water (Rowe-Rowe 1977b). Surfacing periods between unsuccessful dives are brief (6–10 sec) as are those when small fish are caught and eaten in the water (11–16 sec) (Lejeune 1989). Larger prey is taken to the shore and eaten out of the water (Procter 1963, Rowe-Rowe 1977b). Prey appears to be always captured in the mouth. Very small fish (<60 mm) are eaten from the head, but all larger fish and frogs are eaten tail first, with the heads sometimes being discarded (Rowe-Rowe 1977b, Power & Slater-Jones 2010).

Foraging is mostly solitary, except in lakes where the otters fish in large groups (Procter 1963, Kruuk & Goudswaard 1990). In an impoundment stocked with alien trout, d’Inzillo Carranza (1997) occasionally observed groups of two or three individuals hunting together with synchronized dives, and on two occasions subsequently sharing the prey on the shore.

Social and Reproductive Behaviour Although territorial behaviour has never been observed, intra-specific relationships appear to vary in relation to food availability. In the fish-rich central African lakes Spotted-necked Otters generally occur in small groups, on average three, sometimes up to 10–20 individuals (Procter 1963, Lejeune 1989, Kruuk & Goudswaard 1990). In South Africa, where

fish faunas are poor, they are mainly solitary or in groups of up to five individuals (Rowe-Rowe 1978a, 1992a). As Rowe-Rowe & Somers (1998) hypothesized, larger aggregations seem to be associated with abundance of its favourite prey, such as small fishes. In the KwaZulu–Natal highlands a radio-telemetry study on six adult Spotted-necked Otters (three ♂♂ and three ♀♀) revealed a strict interrelation

Spotted-necked Otter *Hydrictis maculicollis*.

between social behaviour, group size and food availability: in an area that included several impoundments stocked with alien trout, 70% of all groups recorded ($n = 64$) comprised three otters or more, while in a nearby area comprising a natural stream and a few oxbow lakes, 77% ($n = 31$) of all groups seen consisted of two otters. No indication of territoriality was noted in either area (Perrin *et al.* 2000). Allo-grooming was often observed among individuals living around the impoundments, and activity and resting periods were mainly synchronized. Average sizes of home-range core areas were 8.7 km^2 for ♂♂ and 3.4 km^2 for ♀♀. Mean length of the river within the home-ranges was 14.8 km (Perrin *et al.* 2000).

Spraints are believed to be used for scent-marking as a means of communication. These latrines are similar to those of clawless otters (and sometimes even at the same site), and are located in grass above river banks or lake shores, on earth ledges in the river banks, on islands and less frequently on rocks (Rowe-Rowe 1992b). Most sites are found beside water at least 0.5–1 m deep, or in dense cover if water is very shallow. Distance from water was 1–6 m, mainly 2 m (Rowe-Rowe 1992b). Faeces have an average diameter of 15 mm (range 12–18 mm). If they contain a high proportion of crab remains they resemble clawless otter faeces in colour (dark brown when fresh fading gradually to cream). If mainly fish has been eaten they are dark grey and fade to light grey (Rowe-Rowe 1992b). Spraint sites are sometimes associated with rolling places, and spraint sites are spaced between 200 and 1000 m apart (Rowe-Rowe 1992b, Carugati 1995).

Vocalization as a form of communication among individuals was frequently noted (Procter 1963, d'Inzillo Carranza 1997). They occur mainly in the form of a high-pitched squeak. When alarmed, they emit a kind of a snort (Procter 1963, I. d'Inzillo Carranza pers. obs.). Mortimer (1963) observed in a captive specimen that a shrill trilling noise combined with neck stretching or lying on the back implies submission to another individual. Reliable information on other forms of communication is not available, neither is information on reproductive behaviour.

Reproduction and Population Structure In KwaZulu–Natal mating appears to take place during the dry season (May–Aug) (d'Inzillo Carranza 1997). On L. Victoria, Procter (1963) estimated that births occurred about Sep, while in Zambia Ansell (1960a) estimated Nov or Dec. Gestation is assumed to be 60–63 days (Rowe-Rowe 1992a), so young are born at the end of the dry season or early in the wet season. Delayed implantation likely does not occur (Procter 1963). Mean litter-size is not known, but adults with one or two young have been recorded (Rowe-Rowe 1978a, d'Inzillo Carranza 1997). Young may remain with the mother for up to one year (Kingdon 1997). No reliable information is available about where young are born and on growth. Davis (1978) suggested that longevity in the wild could reach eight years; in captivity, one animal lived to nearly 23 years (Weigl 2005).

Predators, Parasites and Diseases No meaningful data are available on natural predators, although crocodiles and pythons have been suggested (Lejeune & Frank 1990, Skinner & Chimimba 2005) and the young may be taken by African Fish-eagles *Haliaeetus vocifer* (Kruuk & Goudswaard 1990). Endoparasites recorded from Spotted-necked Otters include trematodes, such as *Baschkirovitrema incrasatum*, *Cynodiplostomum namrui* and *Prudhoella rhodesiensis* (Round

1968), and nematodes (Lejeune 1990). No information is available on possible diseases.

Conservation IUCN Category: Least Concern. CITES: Appendix II.

The Spotted-necked Otter is decreasing throughout its range. Rapidly increasing human populations are leading to the adverse alteration of freshwater habitats and riparian vegetation, exacerbated by the loss of habitat as a consequence of increased agricultural activity. Near urban areas expansion and industrialization have been responsible for both loss of habitat and pollution and sedimentation of streams and rivers, as too has acid pollution from coal mining (Stuart 1985, Rowe-Rowe 1990b, 1992a, 1995). Bioaccumulation of organochlorines and other biocontaminants has been recorded in Spotted-necked Otters: Mason & Rowe-Rowe (1992) examined four scats collected in KwaZulu–Natal and detected concentrations (mg/kg of extractable fat) of 0.02 for dieldrin (range 0.02–0.03), 0.04 for *O,p*-DDE (range 0.03–0.08) and 0.12 for total PCB (range 0.05–0.24).

Spotted-necked Otters are also killed for food or skins (see, for example, Lejeune & Frank 1990), as a perceived threat to poultry, or as a competitor for fish (Rowe-Rowe 1990b). Occasionally, they are accidentally caught and drowned in gill nets and fish traps (Stuart 1985, Rowe-Rowe 1990b). Introduction of alien fish species that out-compete the smaller indigenous fish was identified as a main threat for the L. Victoria population (Kruuk & Goudswaard 1990). Otter products are used in traditional medicine in KwaZulu–Natal (Cunningham & Zondi 1991). They are present in a number of protected areas across their range (in at least 28 of the 33 countries from which they have been recorded), though quality of protection obviously is not the same in all instances (Rowe-Rowe 1990b, 1995).

Measurements

Hydrictis maculicollis

HB (♂♂): 698 (650–760) mm, $n = 5$

Subfamily MELLIVORINAE – Ratel

Mellivorinae Gray, 1865. Proc. Zool. Soc. London 1865: 103.

The Mellivorinae is a monogeneric subfamily. Recognition of the Mellivorinae here follows McKenna & Bell (1997), in line with recent molecular evidence (Koepfli *et al.* 2008, Wolsan & Sato 2010, Sato *et al.* 2012). Wozencraft (2005) provisionally retained *Mellivora* in the Mustelinae.

Mieczyslaw Wolsan & Michael Hoffmann

GENUS *Mellivora*

Ratel

Mellivora Storr 1780. Prodr. Meth. Mamm., p. 34, Tabl. A.

Mellivora is a monospecific genus, containing the single extant species, the Ratel *Mellivora capensis*, which is widely distributed in Africa and also in SW Asia. The oldest fossil *Mellivora* is from the earliest Pliocene of Langebaanweg, South Africa. The genus is also known from other sites of Plio-Pleistocene age in Africa and from the lower Pleistocene of the Indian sub-continent (Petter 1987). A possibly ancestral genus, *Erokomellivora*, is known from the late Miocene of Kenya (Werdelin 2003a).

Colleen Begg & Keith Begg Ratel *Mellivora capensis*.

Mellivora capensis RATER (HONEY BADGER)

Fr. Ratel; Ger. Honigdachs

Mellivora capensis (Schreber, 1776). Die Säugethiere 3 (18): pl. 125 [1776] + text in Vol. III (26) 450 [1777].

‘Vorgebirge der guten Hofnung’ [South Africa, Western Cape Prov., Cape of Good Hope].

Ratel *Mellivora capensis*.

Taxonomy Ten subspecies have been described from Africa based primarily on size and pelage (mainly mantle) variation (Coetzee 1977). Since most type specimens appear to represent individual variants of a polymorphic species and the white mantle darkens with age, many (if not all) of these subspecies are of doubtful validity. Baryshnikov (1988,

2000) recognizes a total of ten subspecies from across the entire range of the species (i.e. including its distribution outside of the African continent) in two major subdivisions. The first, ‘*capensis*’ includes all the African subspecies together with *M. c. wilsoni* and *M. c. pumilio* from the Arabian peninsula and SW Asia. The second cluster, ‘*indica*’, comprises the other Asiatic forms. He distinguishes the two groupings on the basis of mantle colour (the presence of a whiter, border colour in the African subspecies) and skull morphometrics (the correlation of palatal length and condylobasal length). Ongoing research aims to determine the phylogeography of the Ratel and to investigate whether there is any genetic evidence to support the current subspecies descriptions. Preliminary analyses suggest a division between East African and southern African groups (J. Rhodes pers. comm.), but, pending the completion of such a revision, no subspecies are listed here (though see Vanderhaar & Hwang 2003). Synonyms (Africa only): *brockmani*, *buchanani*, *concisa*, *cottoni*, *leuconota*, *maxwelli*, *mellivorus*, *ratel*, *sagulata*, *signata*, *typicus*, *vernayi*. Chromosome number: 2n=40 (Wurster-Hill & Centerwall 1982).

Description Medium-sized, stocky, lumbering carnivore with distinctive black and white colouring. Forehead white, back mantle

Lateral, palatal and dorsal views of skull of Ratel *Mellivora capensis*.Ratel *Mellivora capensis* skeleton.Ratel *Mellivora capensis* myology.

greyish-white and underparts black. Some individuals with entire upper side white or near white, in others a white, narrow boundary line separates the greyish-white back from the black underparts. Occasional all-black animals have been recorded in central and West Africa (P. Henschel pers. comm.). Muzzle short, blunt and sparsely haired with rather few, slender vibrissae. Eyes are small and dark brown with black, nearly hairless lids set within dense, rather coarse black hair over the prominent cheek and brow. Cartilaginous pinnae of the ears are enclosed within the overall body sleeve of the skin and there is no obvious external ear. Muscular attachments at the back of the skull are well developed and there is little visible transition between the long head and short neck. Forehead white or off-white, bulbous, broad but elongated and sharply demarcated from the lower part of the head, which is black. The precise tone of the greyish-white mantle is the product of coarse hairs that are dispersed in variable ratios of white or black. The white mantle may extend to varying degrees onto the short, well-haired tail, which usually has a black tip. Pelage mainly composed of coarse guard hairs that are densest on the back and longest on the hindquarters; underside and inner surfaces of the limbs are more sparsely haired and the stomach and area around the genitalia and scent glands are bare. Underfur softer and shorter, individually variable in its density and occurrence (nearly absent in most animals).

In the S Kalahari 86% of adult male Ratels have a prominent scar or callus in the middle of the back (ca. 12×13 cm) that has not been observed in ♀♀ or young ♂♂. The scar develops over time and is thought to be the result of repeated bites in the same area by other Ratels (probably ♂♂). The callus has also been identified in male Ratels from Zimbabwe, Botswana and Namibia. Forelimbs long and flexible, well muscled along their entire length and forefeet robust and armed with sharp claws 3–4 cm in length. Hindlimbs less well developed and bearing conventional nails on small compact digits. Both fore- and hindfeet have five toes and tough dog-like pads. The different claw length and size of fore- and hindfeet show up well in spoor. Well-developed anal glands are under muscular control and can be extruded.

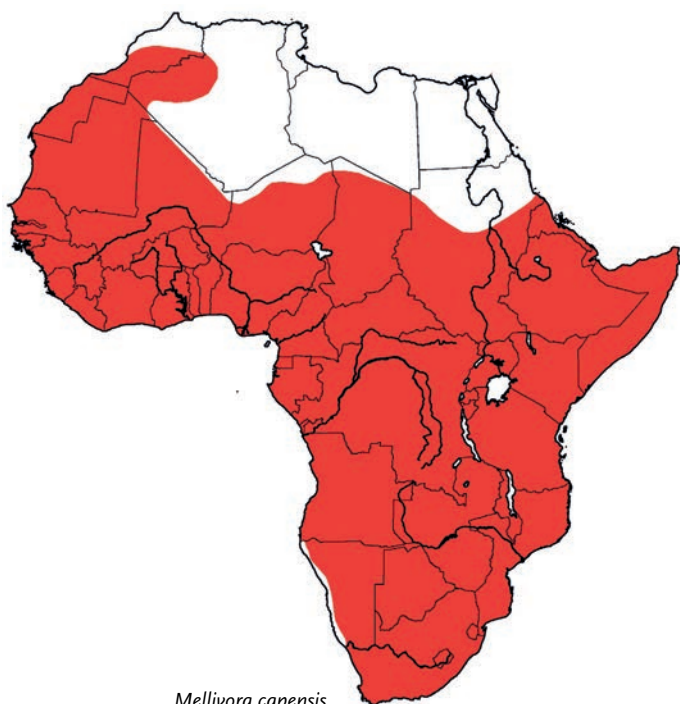

Sexes show marked sexual size dimorphism, with ♂♂ at least one-third heavier than ♀♀. There are no sexual differences in pelage colour. The testes of adult ♂♂ are disproportionately large for the animal's size. Baculum distinctive with the distal end of the shaft angulated sharply upwards, terminally expanded, and hollowed out above (Pocock 1920). Two pairs of inguinal nipples.

Strongly built skull with an undeveloped sagittal crest, broad braincase and well-developed zygomatic arches and mastoids. There is no second lower molar reducing the dental formula to $I^{3/3}, C^{1/1}, P^{3/3}, M^{1/1} = 32$. Teeth are robust but unspecialized; the two outer incisors are larger than the others, curved inwards and resemble canines but wear down rapidly.

Geographic Variation See Taxonomy.

Similar Species

Civettictis civetta. Sympatric through most of sub-Saharan Africa, but absent from parts of South Africa, most of Namibia, Eritrea and drier areas of the Horn where Ratels are present. Similar in size, but distinguished by its mottled pattern, gracile limbs, and long, well-haired tail.

Mellivora capensis

Distribution Widespread through most of the continent, particularly sub-Saharan Africa, but absent from some regions such as the Free State in South Africa, Lesotho, the Namib Desert, central Sahara Desert, Mediterranean littoral and the lower Nile Valley. Range extends outside of Africa through Arabia, Iran and western Asia to Turkmenistan and the Indian peninsula. Little information available on current distribution but it appears patchy due to persecution and habitat transformation.

Habitat Occurs in most habitat types, from sea level to above 4000 m (e.g. Sillero-Zubiri 1996) and can tolerate habitats with annual rainfall varying from 50 to 2000 mm, i.e. from desert to moist rainforest. Absent from the driest and sandiest parts of the Sahara and from the dunes of the Namib.

Abundance Ratels are considered rare or to exist at low densities throughout their range compared with other medium-sized carnivores. Their propensity to raid beehives has advertised their presence in certain areas, particularly *Brachystegia* woodland and the Cape fynbos, and this suggests that they may be more abundant than commonly thought. In some prime honey-producing areas beekeepers report them to be common, while nature conservation authorities suggest they are rare. Ratels are difficult to locate using conventional mammal surveys and, in the S Kalahari and Mana Pools N. P., in Zimbabwe, night counts and day transects were poor indicators of Ratel density due to their relatively small size, small eyes (poor eyeshine) and elusive nocturnal behaviour. Bearing this in mind, densities based on night counts have been estimated variously as 0.1 individuals/km² in Serengeti N. P., Tanzania (Waser 1980) and 0.07 ind/100 km (Sillero-Zubiri & Marino 1997) in Niokolo-Koba N. P., Senegal. The density of Ratels in the semi-arid Kgalagadi Transfrontier Park, South Africa, estimated from visual observations of marked and unmarked individuals, was 0.03 adults/km² (C. M. Begg 2001).

Adaptations The forelimbs are adapted for digging but their strength and manoeuvrability also serve to make them quite adequate for climbing. The long, massive claws are used to excavate hard termitaries, to dig for buried beetle larvae and to tear open bees' nests in tree trunks. In the latter activity the exceptionally robust jaws and teeth may also assist. The power of the claws may be augmented by leverage from muscular shoulders, neck and back, which are employed to dislodge hives or budge rocks that conceal prey. Indian Ratels have been filmed shifting rocks in this way to provide a platform from which to reach a previously inaccessible source of food. The thick but also loose skin around the neck area serves as some protection against the bites of larger carnivores and possibly the venom of snakes and bee stings. Enclosure of the external ear within the thickened body skin may also be an adaptation against bites, especially those of social insects. While the absence of external ears may attenuate longer-distance air-borne sounds, the Ratel is very sensitive to vibrations and sound within trees or underground.

The sense of smell is well developed and, while animals see well within their immediate vicinity, they appear not to register much from further afield. The anal glands are unusual among mustelids in being eversible (Pocock 1920). These glands are used for scent-marking and as a defence against predators. They also emit an aerosol that is repellant to humans and other predators and has been reported to deter or immobilize bees (Kingdon 1977). This behaviour and the chemistry of secretions needs further research.

Foraging and Food Opportunistic, generalized carnivores, which eat a wide variety of prey varying in size from small insect larvae to the young of ungulates. In the S Kalahari, 80% of their prey was caught through digging and their diet comprised more than 70 different species including insects, scorpions, reptiles, including the highly venomous Cape Cobra *Naja nivea* and Puff Adder *Bitis arietans*, rodents, particularly Paeba Hair-footed Gerbil *Gerbillurus paeba* and Highveld Gerbil *Gerbilliscus brantsii*, and the young of Cape Foxes *Vulpes chama*, Black-backed Jackals *Canis mesomelas*, Bat-eared Foxes *Otocyon megalotis* and Wildcats *Felis silvestris* (Begg *et al.* 2003a). In addition, Ratels climb up to Sociable Weaver *Philetairus socius* nests to feed on chicks, and remove raptor chicks from their nests (Marlow 1983).

In seven stomachs collected in Zimbabwe and Botswana scorpions had the highest occurrence (five stomachs), followed by spiders (4), murid rodents (4), lizards (3), insects (2), myriapods (2), birds (1), snakes (1), bee larvae and honey (1) (Skinner & Chimimba 2005). Ratels also eat young crocodiles (D. English pers. comm.), Mozambique Rain Frogs *Breviceps mossambicus* (Smithers & Lobão Tello 1976) and raid sea turtle nests (R. Penn Sawyers pers. comm.). They have been implicated in predation upon the Tent Tortoise *Psammobates tentorius* in a case in which more than 30 shells were found to be cleanly broken open and the body removed after forcibly pulling back the anterior projecting section of the plastron (Lloyd & Stadler 1998).

On the opposite side of the continent, in Aïr (Niger), the diet of Ratels includes small rodents (*Meriones* spp., *Gerbillus* spp.), Desert Hedgehogs *Hemiechinus aethiopicus*, terrestrial birds (hunted by night) and their clutches, African Spurred Tortoises *Geochelone sulcata*, lizards, skinks (Peters' Banded Skink *Scincopus fasciatus*), toads, human excrement and plants such as wild fruits (*Hyphaene thebaïca*, *Balanites aegyptiaca*, *Salvadora persica*, *Grewia tenax*, *Cordia rothii*), bark (*Maerua crassifolia*, *Boscia senegalensis*) and the grass Indian Sandbir *Cenchrus*

biflorus (Dragesco-Joffé 1993). In Western Sahara, they are well known for digging lizards (*Uromastix acanthinura*) out of their burrows, and eating roots of *Launaea arborescens* bushes (Valverde 1957). In S Morocco, they were seen actively digging out small rodents *Meriones* spp., searching for insects and small lizards under rocks, and eating dead animals; remains of *Uromastix* insects, and goat hairs were commonly found in their scats (F. Cuzin pers. comm.).

On occasion Ratels may pirate food from other carnivores (Kruuk & Mills 1983) and will also scavenge from the kills of larger animals although they are primarily hunters of their own food. Caching of food, notably honeycombs and dead animals, has been observed, with the animal returning to the cache during the next few days. Water does not appear to be essential and Ratels probably obtain sufficient moisture from their food. In the S Kalahari, the flesh of Tsama Melons *Citrullus lanatus* is regularly eaten, seemingly for its high water content.

There are strong regional, seasonal and individual differences in diet. For example, while small mammals (<100 g) and small reptiles (<100 g) were the most common prey items in all seasons in the S Kalahari, large snakes were particularly important in the hot-wet season and the cubs of jackals and foxes and raptor chicks were important prey items during their respective breeding seasons.

In areas where hives are uncommon, such as the S Kalahari, honey and bee larvae do not form a major part of the diet but are taken when available. In areas where beekeeping and hives are common, Ratels frequently break into traditional, commercial and natural hives. Dung examined in July in C Tanzania showed a very high incidence of bee remains (Kingdon 1977). Reports from beekeepers in Tanzania and the Western Cape of South Africa indicate a strong seasonality of attacks on hives (K. S. Begg 2001). In Tanzania attacks are negligible during the wet season (Dec–May) but numerous during the dry season, with a peak between Jul and Oct. The fact that attacks coincide with principal honey harvests suggests that Ratels respond opportunistically to the abundance of honey at that time.

While the buzzing of bees may be the Ratels' principal guide to hives during the day, there are fewer clues for nocturnal honey-hunting. The Ratel's legendary association with a small bird, the Greater Honeyguide *Indicator indicator*, was first reported in 1629, and has been extensively discussed but is still disputed. The Ratel is 'guided' by the bird to a bee's nest whereupon it tears open the nest in an untidy manner so that bees, larvae, wax and honey are available for the bird. Because the association is completely dependent upon diurnal foraging by the Ratel and has to be learned by both 'partners' it is fragile; none the less, once learned, it would seem to offer substantial rewards to both bird and mammal. Some ornithologists appear to have misrepresented the known and various interactions between honeyguides and Ratels as a 'co-evolved mutualistic behaviour' (Dean *et al.* 1990). That the interactions are likely to be opportunistic and learnt has been recognized by most observers of honeyguide, Ratel and human interactive behaviour (Kingdon 1977).

Foraging associations between the Pale Chanting-goshawk *Melierax canorus* and Ratels, and between Black-backed Jackals *Canis mesomelas* and Ratels are regularly seen in the arid, open areas of southern Africa (C. M. Begg 2001) and East Africa. In both cases, goshawks and jackals follow the badgers and catch rodents that escape while the Ratel is digging and this appears to be facultative commensalism with no benefits and few costs to the Ratel (C. M. Begg 2001). Other observations of Wildcats *Felis silvestris*, Barn Owls *Tyto alba*, Marsh

Owls *Asio capensis*, Spotted Eagle-owls *Bubo africanus*, Crimson-breasted Gonoleks *Laniarius atrococcineus* and the Southern Anteater-chat *Myrmecocichla formicivora* following foraging Ratels in the S Kalahari suggest that these inter-specific foraging associations may be common (Begg & Begg 2005). In other areas, a Dark Chanting-goshawk *Melierax metabates* has been observed following a Ratel in the lowveld of South Africa (Roche 2004, P. Chadwick pers. comm.), and a subadult male Ethiopian Wolf *Canis simensis* was observed following a Ratel in the Bale Mts of Ethiopia (Sillero-Zubiri 1996).

Both sexes are solitary foragers and foraging behaviour is characterized by a slow winding walk with systematic examination of holes and crevices. Foraging activity is primarily driven by scent; for example, individuals often stop to smell with their heads turned upwind and then change their foraging direction towards a prey item, but hearing is also important. On average, ♀♀ moved 8 km actual distance (2.4 km straight line) and ♂♂ moved 14 km actual distance (6.2 km straight line) during a single period of activity in the S Kalahari (C. M. Begg 2001). Males are capable of moving 40 km in a single day. In Air (Niger), tracks were followed for distances between 8 and 14 km from the burrow (Dragesco-Joffé 1993).

In the S Kalahari, activity patterns shift from being nocturnal in the hot-wet season, to primarily diurnal in the cold-dry season and seem to be driven primarily by temperature (C. M. Begg 2001). Ratels show a two-peaked activity pattern with two active periods of 2–8 hours during a 24-hour period and prolonged resting in burrows, or under bushes.

Social and Reproductive Behaviour Essentially solitary (no male involvement in parental care), with a non-territorial polygynous or promiscuous mating system. Detailed information on social and reproductive behaviour is available only from the S Kalahari (Begg *et al.* 2005a).

In the S Kalahari, adult male Ratels have average home-ranges of 541 km² (range 229–698 km²), which overlap extensively with other ♂♂ and encompass the smaller home-ranges of young ♂♂ (151 km²) and ♀♀ (126 km²; range 85–194 km²; Begg *et al.* 2005b). One adult ♂ had access to at least 12 ♀♀. The home-ranges of Ratels in more mesic environments are likely to be smaller although minimum home-range sizes of 150 km² and 480 km² have been recorded for young male Ratels on the Zambezi flood-plain and in Niassa Reserve, N Mozambique (primarily miombo woodland) (C. M. Begg & K. S. Begg pers. obs.).

Ratels do not have a fixed home site and rest in a different place each day. Females with cubs younger than three months old change dens every 2–5 days until, at three months old, they revert to the typical pattern of using a different hole each day. While Ratels usually dig their own resting burrows in the sandy Kalahari, they also used the burrows of Aardvark *Orycteropus afer* or Southern African Springhares *Pedetes capensis*. In the flood-plain habitat of Mana Pools N. P., Zimbabwe, they were not observed to dig their own burrows and utilized Aardvark and Cape Porcupine *Hystrix africae australis* burrows. Ratels in Niassa Reserve generally rest in hollow tree trunks, rocky caves, under bushes and in holes in termite mounds (C. M. Begg & K. S. Begg pers. obs.).

Males do not defend territories; rather adult ♂♂ adopt a roaming tactic to search the home-ranges of ♀♀ for receptive mates. Males compete with other ♂♂ for mating opportunities through a dominance hierarchy, which is maintained by direct interactions and scent-marking.

Ratel *Mellivora capensis*.

The dominance hierarchy is loosely correlated with age (older ♂♂ dominant over younger ♂♂), body weight and testes size. The hierarchy system is no guarantee that only the dominant ♂♂ will reproduce, as genetic analysis in the S Kalahari has revealed that the dominant ♂ was the most likely father of only 50% of the cubs within his home-range (Verwey *et al.* 2004). Most direct interactions are ritualized, being expressed through attack and retreat postures and through vocalizations. Overt aggression is rare but involves tumbling, biting and chasing.

In the Kalahari, ♂♂ of varying ages sometimes travel in groups of 2–5 individuals, searching for ♀♀ and scent-marking together. These ♂♂ have been seen in groups for up to 21 hours. Similar groups of five individuals have been seen in Zimbabwe. Of 34 Tanzanian beekeepers (who have extensive experience of Ratels), 23 had never seen more than two animals together while seven had only seen them singly and the remaining four observers had reported seeing 4, 6, 8 and 12, respectively (Kingdon 1977).

Scent-marking is the main form of communication in Ratels and both sexes have well-developed anal scent glands. Male Ratels regularly patrol latrines within their home-ranges and scent-marking behaviour at latrines involves anal dragging (Ratels assume a squatting position with the pelvis depressed so that the anus touches the ground and walk forward with the forelegs, dragging the anus along the substrate), squat-marking (repeatedly pressing anus to the ground on the same place whilst in a squatting position) and belly and neck rubbing on the ground as well as the deposition of faeces and urine. Latrines are commonly placed near prominent landmarks such as trees but are also located near productive food patches. Female Ratels only visit latrines when in oestrus but they routinely token-urinate in holes along their foraging path (Begg *et al.* 2003b). Token urination in ♀♀ is thought to mediate the spatio-temporal separation of neighbours because adult ♀♀ were never observed to interact although their home-ranges showed an average overlap of 13%.

Mating appears to occur in a burrow over the course of 2–4 days. During this period the ♂ physically restrains the ♀ from leaving the burrow and repeated matings are thought to occur. Once mating is complete, the pair separates. Young are born in a burrow, and for the first three months the cub does not accompany the mother foraging but remains in the den. Every 3–8 days the ♀ moves the cub to a new den with an average distance of 2.1 km recorded between dens in the Kalahari. At 2–3 months of age, ♀♀ begin to take prey to the den and it is assumed that weaning occurs during this period. Juveniles remain with their mothers for at least 12–18 months and are entirely dependent on their mothers for food during this first year, with a gradual increase in the proficiency of hunting, digging and climbing. In the S Kalahari, ♀♀ dispersed immediately on independence, while ♂♂ remained within their natal home-range for up to a year after independence before a sudden increase in home-range size occurs (Begg *et al.* 2005b). A female cub in the S Kalahari was located 53 km away from her natal home-range five months after dispersal. A similar dispersal of a young female Ratel was recorded in the Niassa Reserve.

During social interactions, vocalizations are common. Sikes (1964) described how the tongue modulated the common rasping call to generate a variety of calls at different frequencies and pitch in a captive Ratel. In free-living individuals vocalizations can be broadly divided into four types: a low, short rattle grunt used only by adult ♂♂ when interacting with ♀♀ and young ♂♂ accompanied by piloerection, head high, tail up and a stiff-legged posture; a high-pitched squeal-rattle

accompanied by a smacking or teeth-clapping sound used by young ♂♂ and ♀♀ when interacting with adult ♂♂ (accompanied by a side-on posture, with the head and tail held low); a short, high-pitched purr used as a contact call between mother and cub; and the threatening rattle-roar used in the anti-predator display (described later).

Reproduction and Population Structure There is no evidence for a distinct breeding season in South Africa (Fairall 1968, C. M. Begg 2001). Matings might be timed to coincide with the maximum availability of honey in Nigeria (Hancox 1992). Three litters were found after the summer rains between mid-Aug and Oct in Aïr, Niger (Dragesco-Joffé 1993).

Data from free-living Ratels in the S Kalahari (Begg *et al.* 2005a) and captive individuals in Israel (Mendelssohn & Yom-Tov 1999) suggest a gestation of 50–70 days and 62–72 days, respectively. In contrast, gestations of 153 and 162 days were recorded for two captive-bred individuals in Howletts Zoo, England (Johnstone-Scott 1981). This suggests that under some circumstances Ratels may show some form of delayed implantation or slowed foetal development, but this remains to be verified.

On all occasions only a single cub emerged from dens in the Kalahari ($n = 20$; Begg *et al.* 2005a). In captivity a litter of two was recorded on one occasion at Howletts Zoo, England (17%; $n = 6$ litters), but both died within a few days (Johnstone-Scott 1981), and once in Israel (20%; $n = 5$ litters; Y. Yom-Tov pers. comm.). An average birth-weight of 182 g was recorded for four female cubs in captivity (Johnstone-Scott 1981), but no data from wild individuals are available. Development is slow. Initially cubs are almost hairless and only attain the characteristic black and white pelage at 3–5 weeks old (Mendelssohn & Yom-Tov 1987). At the age of 6–8 months, male and female cubs already show marked sexual size dimorphism. As a result, adult ♀♀ are at least 2 kg lighter and noticeably smaller than male cubs during the final months of dependency. It seems likely that it is these mother–son pairs that have been confused with adult male–female pairs in the past, leading to the incorrect suggestion that Ratels are monogamous. The age of sexual maturity is unknown.

Cub mortality in the S Kalahari is at least 47% and the causes of death included starvation, infanticide (killed by adult ♂♂) and predation (Begg *et al.* 2003a). Ratels have been recorded to live for more than 30 years in captivity (Weigl 2005), although it is predicted that they do not live much longer than 6–8 years in the Kalahari (C. M. Begg & K. S. Begg pers. obs.).

Predators, Parasites and Diseases Adult Ratels are sometimes killed by Lions *Panthera leo* and Leopards *P. pardus*, though usually not without a fight; in one instance, it took six Lions some 15 minutes to kill a Ratel (Lautenbach & Vorster 2003). There is a record of an attempted predation by a Cheetah *Acinonyx jubatus* on a subadult from the Limpopo Province in South Africa (Retallack 2005). One cub was killed by two Golden Jackals *Canis aureus* in N Niger (Dragesco-Joffé 1993) and young are probably vulnerable to other large predators.

The conspicuousness of the Ratel's colouring is thought to provide a warning to predators of their strength and tenacity. Their impressive predator display consists of a rattling-roar vocalization, piloerection and the emission of a strong smelling evacuate from the anal scent glands, and is accompanied by rushing movements towards the predator. This display, aided by the Ratel's formidable strength,

powerful bite, loose skin and long claws, is well designed to intimidate and is frequently successful in driving predators away. Ratels do appear to have some immunity to snake and scorpion venom; for example, a male Ratel bitten on the face by the highly cytotoxic Puff Adder showed signs of severe pain, but recovered fully within five hours (C. M. Begg & K. S. Begg pers. obs.). Ratels are occasionally stung to death by bees, especially in commercial apiaries.

Srivastava (1964) recorded the trematode *Strongyloides akbari* and the nematode *Artyfechinostomum* in the intestine of an Indian Ratel. In South Africa, ixodid ticks of the species *Haemaphysalis aciculifer*, *H. zumpti*, *Rhipicephalus thelieri*, *R. appendiculatus*, *R. evertsi*, *R. simus*, *Boophilus decoloratus*, *Hyalomma truncatum* and *Amblyomma hebraeum* have been found on Ratels with old individuals particularly heavily infested (Horak *et al.* 2000). Horak *et al.* (2004) recovered the fleas *Ctenocephalides damarensis*, *Echidnophaga gallinacea* and *Synosternus caffer* from Ratels in South Africa, all likely infesting prey species. In addition, the biting louse *Trichodectes vosseleri* has been identified on Ratels from South Africa and Kenya (I. Horak pers. comm.).

Canine distemper has been implicated in Ratel deaths (A. Root pers. comm.), and while they are known to be carriers of rabies they do not appear to be vectors (J. Bingham pers. comm.). Ratels carrying rabies are usually associated with rabies outbreaks amongst Black-backed Jackals *Canis mesomelas*. A faecal sample from the Kalahari indicated infection with feline panleukopenia virus, a subgroup of feline parvovirus (Steinel *et al.* 2000).

Conservation IUCN Category: Least Concern. Appendix III: CITES (Botswana, Ghana).

Ratels are directly persecuted (through the use of, among others, steel-jawed traps and poisons) by apiculturists and small livestock farmers throughout their range, and are also indirectly killed by non-selective control programmes targeting other species (Stuart 1981, Dragesco-Joffé 1993, F. Cuzin pers. comm.). In the Western Cape of South Africa, where a permit is now required to move or kill a Ratel, half of 82 commercial beekeepers surveyed in 2001 admitted to killing Ratels despite their protected status; surveyed beekeepers destroyed a minimum of 248 Ratels, with 231 removals occurring within the previous 15 years (K. S. Begg 2001). Commercial hive damage can be simply and effectively reduced (26% to 1%) by securing the hive a metre or more above the ground on a stand or trestle (Begg & Begg 2002). Persecution of Ratels continues both due to ignorance of suitable hive protection measures and because of entrenched hostility towards Ratels and carnivores in general. Ratel body parts (particularly paws, skin and organs) are commonly used in traditional medicine because of the animals' reputation for fearlessness and tenacity. In some areas (W Zambia, Guinea), Ratels appear in the bushmeat trade due to the decline in other more favoured bushmeat species (C. M. Begg & K. S. Begg pers. obs., Colyn *et al.* 2004). As modern apiculture displaces the more fatalistic and tolerant practices of traditional beekeepers in East and central Africa, it is likely that the Ratel will suffer increasing persecution.

Since Ratels range over unusually large areas, many protected areas may be inadequate in conserving viable populations. Little information is available on their status, particularly from central and West Africa, but the number of areas in which Ratels are rare or absent appears to be increasing and populations may be becoming increasingly fragmented throughout their range. Their small litter-size

and long birth interval (14–16 months), and therefore slow recruitment to the population, may also make them particularly vulnerable to persecution. As Ratels are seldom seen, their populations could easily reach critically low levels without conservation authorities being aware of the problem. More information on the biology and status of Ratels is crucially needed, particularly in the northern and western parts of their range.

Measurements

Mellivora capensis

HB (♂ ♂): 686 (580–790) mm, n = 15
 HB (♀ ♀): 637 (580–690) mm, n = 12
 T (♂ ♂): 197 (160–230) mm, n = 19
 T (♀ ♀): 187 (180–220) mm, n = 14
 Sh. ht (♂ ♂): 394 (350–430) mm, n = 19
 Sh. ht (♀ ♀): 327 (320–370) mm, n = 14
 WT (♂ ♂): 9.3 (8.0–11.2) kg, n = 19
 WT (♀ ♀): 6.1 (5.2–7.1) kg, n = 14
 S Kalahari, South Africa (C. M. Begg 2001)

HB (♂ ♂): 715 (680–770) mm, n = 4
 HB (♀ ♀): 675 (630–720) mm, n = 2
 T (♂ ♂): 215 (160–220) mm, n = 4
 T (♀ ♀): 217 (190–245) mm, n = 2
 Namibia (Shortridge 1934)

TL (♂ ♂): 954 (902–1020) mm, n = 8
 TL (♀ ♀): 950, 960 mm, n = 2
 T (♂ ♂): 219 (200–240) mm, n = 8
 T (♀ ♀): 195, 220 mm, n = 2
 HF c.u. (♂ ♂): 133 (123–145) mm, n = 8
 HF c.u. (♀ ♀): 115, 120 mm, n = 2
 E (♂ ♂): 43 (40–48) mm, n = 8
 E (♀ ♀): 35, 47 mm, n = 2
 WT (♂ ♂): 11.7 (7.9–14.5) kg, n = 8
 WT (♀ ♀): 9.5, 13.6 kg, n = 2
 Zimbabwe (Smithers 1983)

Superfamily PINNIPEDIA

SEALS

Pinnipedia Illiger, 1811. Prodr. Syst. Mamm. Avium., p. 138.

The name pinniped is derived from the Latin *pinnipes*, for wing- or fin-footed, referring to the group’s modified fin-like appendages. The name refers to those mammals that are adapted to both terrestrial and aquatic conditions, have a fusiform body shape adapted to reduce turbulence and resistance (drag) while swimming and diving, possess a subcutaneous layer of fat (blubber) that provides stored energy, insulation and buoyancy, a coarse pelage of guard hairs, and relatively short, stout limbs (with limb bones enclosed inside the body) that are modified to form paddle-like flippers (Nowak 1999).

Members of this group range in size from, for example, small lake seals in Asia, the Baikal Seal *Pusa sibirica*, which reaches 1.5 m in length and 70 kg in weight, to the mammoth Southern Elephant Seals *Mirounga leonina*, bulls of which can reach masses of four tonnes and lengths of 4 m (Martin & Reeves 2002). Pinnipeds spend the majority of their lives at sea where they feed almost exclusively, but they are constrained by the need to return to land or stable ice substrates to give birth, to lactate and in some instances, to moult.

Pinnipeds are now thought to represent a monophyletic group, diagnosed by a suite of shared derived morphological characters (synapomorphies), including: enlarged orbits; large infraorbital foramen; a maxilla that uniquely contributes to the orbital wall; a lacrimal (absent or fused) that does not contact the jugal; enlarged humeral tuberosities and deltopectoral crest; short and robust humerus; and emphasized Digit I on both hand and foot, and Digit V on foot (Berta & Sumich 1999). Historically classified under a separate mammalian order, Pinnipedia, they are now contained within the order Carnivora, but still embrace the families Otariidae (sea lions and fur seals), Phocidae (‘true’ seals, or earless seals) and Odobenidae (walruses). Of the three extant families, only Odobenidae are not represented in African waters, with the single extant species, the Walrus *Odobenus rosmarus*, having a disjunct circumpolar Arctic distribution.

Pinnipeds have been believed to be most closely related to the bears (family Ursidae), although a possible diphyletic pinniped origin, with Phocidae arising from a mustelid ancestor instead, has caused some argument (see Heyning & Lento 2002, Flynn *et al.* 2005). Further controversy exists on the evolutionary relationships within the group, revolving around whether Odobenids are more closely related to the Otariidae (as historically proposed and

suggested by molecular evidence) or to the Phocidae (as suggested by morphological evidence) (see Berta & Sumich 1999, Deméré *et al.* 2003 for a discussion and suggestions for further reading). Recent molecular evidence not only strongly supports the monophyly of Pinnipedia, but also places Pinnipedia as the sister-group to the Musteloidea, a clade that includes Mustelidae + Procyonidae + Mephitidae + Ailuridae (i.e. leaving Ursidae as the most basal arctoid lineage) (Sato *et al.* 2009, Eizirik *et al.* 2010; although see Agnarrson *et al.* [2010] who found strong support for the traditional sister relationship between Ursidae and Pinnipedia). The latter study also strongly supports a sister-group relationship between Otariidae and Odobenidae (and see Arnason *et al.* 2006, Higdon *et al.* 2007).

Pinnipeds are believed to have had a northern Pacific centre of origin, evolving from a basal pinnipedimorph *Enaliarctos* sometime during the late Oligocene (27–25 million years ago), ‘true’ pinnipeds arising from this line some time before 18 mya, during the early Miocene (Berta & Sumich 1999, Deméré *et al.* 2003).

Phocids are the most widespread of the pinniped families, represented at most latitudes in both hemispheres, including both polar regions. Phocids consist of 19 species (one, the Caribbean Monk Seal *Monachus tropicalis* recently extinct) in 13 genera (Rice 1998, Wozencraft 2005). Originating in the North Pacific some time during the early Miocene, they are postulated to have dispersed to the North Atlantic some time before 16 mya, where they diverged into a northern group, the Phocinae, which includes temperate region, sub-Arctic and Arctic species, and a southern group, Monachinae, which embraces the warm-water monk seals, the Antarctic ice seals, as well as the wide-ranging elephant seals of the genus *Mirounga* (Heyning & Lento 2002, Deméré *et al.* 2003).

Otariids originated in the eastern North Pacific during the late Miocene, some time before 11 mya, migrated to the South Pacific during the Pliocene, around 6–5 mya, and from there radiated to most of the circum-Antarctic islands in association with the prevailing west wind drift (Berta & Sumich 1999, Deméré *et al.* 2003). Modern otariids are absent in the North Atlantic, but are widespread in the southern oceans, and occur in the Pacific as far north as the Bering Strait.

Family OTARIIDAE

FUR SEALS

Otariidae Gray, 1825. Ann. Philos., n.s., 10: 340.

| | | |
|----------------------------------|-----------|-------|
| <i>Arctocephalus</i> (1 species) | Fur Seals | p.127 |
|----------------------------------|-----------|-------|

Worldwide, the family Otariidae has customarily been classified into seven genera and 16 species (Rice 1998, Wozencraft 2005), although various lines of evidence (Brunner 2000, 2003, Wynen *et al.* 2001), as well as observations of inter-specific, even inter-generic, hybridization

(see Brunner 2000, and references therein) have highlighted the taxonomic confusion present in this family. The otariids have been subdivided into two subfamilies, the Otariinae (sea lions – five genera and seven species: *Eumetopias*, *Neophoca*, *Otaria*, *Zalophus* and *Phocarctos*) and the Arctocephalinae (fur or eared seals – two genera and nine species: *Arctocephalus* and *Callorhinus*) (Berta & Sumich 1999). Sea lions

are characterized and readily distinguished from fur seals by their sparser pelage (fur seals have abundant underfur) and a tendency towards larger body size, and the separation is often maintained as a division of convenience. However, the validity of the subfamilial separation has long been questioned (Repenning & Tedford 1977). The monophyly of the Arctocephalinae, in particular, is not supported by fossil evidence, which suggests that *Callorhinus* diverged from the main line, *Arctocephalus* about 6 mya, about 3 million years before the divergence of sea lions (Bininda-Emonds *et al.* 1999). This is supported by recent morphological and molecular evidence (Brunner 2000, 2003, Wynen *et al.* 2001), and it has been argued that there should be no subdivision above the generic level within Otariidae (Bonner 1994, Bininda-Emonds *et al.* 1999, Higdon *et al.* 2007).

Sea lions do not occur on African coasts, the only otariid being the South African (Cape) Fur Seal *Arctocephalus pusillus pusillus* (conspecific with the Australian Fur Seal *A. pusillus doriferus*). One other species, the Subantarctic Fur Seal *A. tropicalis*, occasionally turns up on the southern African coastline as a vagrant.

Otariidae can be diagnosed as a monophyletic group by several osteological and soft anatomical characters that separate the family from the phocids (true, or earless seals) and odobenids (walruses). They have external ear pinnae, smooth vibrissae, a light coloured skin, a double layer of fur, partially hairless fore- and hind flippers, four nipples in females, and scrotal testes. Claws on the fore-flippers are vestigial or absent. Otariids swim primarily with fore-flipper strokes, the hindlimbs being used in steering when swimming. They can rotate the hindlimbs under the body and move on all fours on land. Eyes of otariids (as with the phocids) are relatively large and modified to focus underwater by means of greater corneal curvature and spherical eye lenses, and see effectively under conditions of reduced light. Physiological processes for diving are pronounced (see family Phocidae), but depths of dives are shallower for most otariids. Cranially they have large and shelf-like supra-orbital processes, their frontal bones penetrate between the nasals on the mid-line, a secondary spine subdivides the supraspinous fossa of the scapula, the trachea has an anterior bifurcation of the bronchi closer to the larynx, and they have uniformly spaced pelage units (Berta & Sumich 1999). As carnivores they typically have differentiated teeth, including incisors, canines and postcanines. Premolars and molars are not differentiated, neither are carnassial teeth. The characteristic dental formula is $I^{3/2}, C^{1/1}, PC^{5-6/5} = 34-36$. Some variation is

found in upper postcanine numbers especially (sea lions generally have five upper postcanines, and fur seals six, although sometimes one more or fewer is present). Their first two upper incisors are transversally grooved (Jefferson *et al.* 1993).

Pronounced sexual dimorphism in size is the rule in the otariids, ♂♂ being larger than ♀♀ roughly by a factor of five. Adult male fur seals reach masses of 60–350 kg and standard body lengths of 1.5–2.3 m, while the ♀♀ reach masses of approximately 22–80 kg and standard body lengths of 1.1–1.8 m (from Jefferson *et al.* 1993). They are all polygynous, ♂♂ using their large size and powerful forequarters for establishing and maintaining dominance on land during the breeding season (Boness *et al.* 2002). Mating generally takes place on land. Males defend onshore territories against other ♂♂, which results in access by relatively few dominant ♂♂ to numerous ♀♀. This social system represents rapid selection for very large, powerful ♂♂. Otariid ♂♂ gain condition at sea and then remain on land without feeding for the duration of the summer breeding season. The ♀♀, instead, alternate between periods of foraging at sea and suckling their pups on land. Male numbers ashore peak during the breeding season in spring and summer when ♀♀ give birth to single pups and become impregnated during a brief perinatal period. Otariids wean their pups after extended periods, from four months (as in the Antarctic Fur Seal *Arctocephalus gazella*) to ten months or sometimes longer. All otariids have an annual, gradual moult when the hairs fall out individually over periods of weeks or months, and hauling out is not a prerequisite for the gradual moult.

In general, while dives to 500 m are not uncommon, otariids are less capable divers and breath-holders than phocids. They feed variously on penguins (sometimes taking them also on land), fish, cephalopods, crustaceans, gastropods, jellyfish and occasionally on other marine birds, while sea lions take fur seal and elephant seal pups on occasion.

Several extinct otariids are known, the earliest being from the late Miocene (11 mya) of California. Amongst the southern fur seal genus *Arctocephalus*, the earliest known taxa are *A. pusillus* (South Africa) and *A. townsendi* (California) from the late Pleistocene. The widely accepted hypothesis is that primitive otariids entered the Southern Ocean from the North Pacific around 6–5 mya and radiated to most of the circum-Antarctic islands in association with the prevailing west wind drift (Berta & Sumich 1999, Deméré *et al.* 2003).

Marthán N. Bester & Paul N. Odendaal

GENUS *Arctocephalus*

Fur Seals

Arctocephalus E. Geoffroy Saint-Hilaire & F. Cuvier, 1826. In: F. Cuvier, Dict. Sci. Nat. 39: 554 [1826].

The genus *Arctocephalus* (from the Greek expression meaning ‘bear-headed’) is represented by eight species of fur seal, occurring from tropical to polar latitudes. The Cape Fur Seal *A. pusillus pusillus* and the Australian Fur Seal *A. p. doriferus* share subspecies status. The remaining seven species include: the South American Fur Seal *A. australis*; the Juan Fernández Fur Seal *A. philippii*; the Galapagos Fur Seal *A. galapagoensis*; the Guadalupe Fur Seal *A. townsendi*; the New Zealand or Australasian Fur Seal *A. forsteri*; the Subantarctic Fur Seal *A. tropicalis*; and the Antarctic Fur Seal *A. gazella*. With the exception

of *A. townsendi*, all occur in the southern hemisphere, hence the vernacular term ‘southern fur seals’ (Bonner 1981). Molecular studies show that *Arctocephalus* is not monophyletic (e.g. Arnason *et al.* 2006, Higdon *et al.* 2007), and the genus is in need of revision.

Arctocephalus and the only other genus of fur seal, the monotypic *Callorhinus* from the Northern Hemisphere, are distinguished on the basis of a few morphological traits, the most obvious of which are: the snout angle of *Arctocephalus* is more pointed than that of *Callorhinus*, which have a shorter, downwards curved rostrum;

and hair growth occurs on the dorsal surface of the fore-flipper of *Arctocephalus*, whereas hair growth terminates abruptly at the wrist of the fore-flipper in the case of *Callorhinus* (Bonner 1994).

In terms of appearance, social behaviour, reproduction and ecological role, *Arctocephalus* species are remarkably similar to each other (Gentry & Kooyman 1986). All are top carnivores, gregarious, sexually dimorphic in body size (σ σ outweigh φ φ by 2–4 times, depending on species), and have a polygynous mating system characterized by aggressive territoriality on the part of adult σ σ . Breeding is synchronous and φ φ give birth to a single pup (twin births are extremely rare). After birth, mothers alternate between foraging at sea and suckling on shore,

until weaning. Females are capable of producing a pup every year of their lives after first parturition. The natal fur of pups is nearly always black or very dark brown. Adults are typically coloured a grizzled dark-grey brown dorsally, shading to lighter beneath, with only the male *A. tropicalis* being clearly bi-coloured. Despite the similarities between *Arctocephalus* species, there are considerable underlying differences between them in details of their biology and ecology, including adult size, the duration of neonatal dependence and diet (Gentry *et al.* 1986, Wickens & York 1997).

Steve Kirkman & Herman Oosthuizen

Arctocephalus pusillus CAPE FUR SEAL

Fr. Phoque du Cap; Ger. Kapseehund

Arctocephalus pusillus (Schreber, 1776). Die Säugethiere 2 (13): pl. 85 [1775]; text, 3 (17): 314 [1776]. Unknown. 'Diese Gattung findet sich in den levantischen, und nach dem Herrn Grafen von Büffon, im indischen Meere'; see Allen (1880), Scheffer (1958).

Cape Fur Seal *Arctocephalus pusillus*.

Taxonomy Two subspecies are recognized, the Cape Fur Seal *A. p. pusillus* and the Australian Fur Seal *A. p. doriferus*, which occurs on the south-east coast of Australia and Tasmania (Repenning *et al.* 1971, Shaughnessy 1979, Warneke 1979, King 1983). The specific name *pusillus* means small, due to the fact that the type specimen was a pup. The information in this account relates only to the Cape Fur Seal. Synonyms (*A. p. pusillus* only): *antarctica*, *compressa*, *delalandii*, *nivosus*, *parva*, *peronii*, *schist-hyperves*. Chromosome number: $2n = 36$ (Arnason 1981).

Description The Cape Fur Seal is the only seal endemic to southern African waters. Cape Fur Seals look very similar to sea lions, to which they are closely related, the two major differences being the thick underfur of the fur seals, compared to very sparse underfur in sea lions, and the blunter nose of the latter (King 1983). At first glance the animals in a fur seal colony appear to be all dark grey, but closer inspection reveals variations in size and appearance between different age and sex classes. Coat colour in adults of both sexes is variable, but is mainly different shades of brown or grey, from light to very dark. Adult bulls are mostly dark grey, but φ φ can be lighter in colour and an occasional φ appears almost white. All seals appear black when they are wet. Pups are born with a jet-black velvety coat that changes to olive-grey during its first moult that takes place after about four months in Mar/Apr, and which then darkens noticeably towards the

end of the first year. A yellow strip round the jaws is prominent in yearlings. Juvenile σ σ are difficult to distinguish from φ φ as they are of similar size, but their neck, head and front flippers are proportionally larger than those of φ φ . Adult bulls are a conspicuous class, especially in summer during the breeding season, when their large size and noisy courting of φ φ set them apart. They have a prominent heavy mantle or wig of long hair on the nape of the neck and shoulders, which is an adaptation for protection during territorial disputes. Forelimbs have five rudimentary nails; hindlimbs are directed forwards and incised into flipper-like digits, the first without a claw, the three middle digits with large claws, and the fifth with a rudimentary claw (King 1983, Skinner & Chimimba 2005). Females have two pairs of inguinal nipples. Age determination in the Cape Fur Seal has been discussed in detail by Oosthuizen (1997) and Oosthuizen & Bester (1997).

Geographic Variation The Cape Fur Seal population is homogeneous (Matthee *et al.* 2006) and there is no discernible variation in colour or size of individuals throughout the subspecies' range. This is to be expected as there is continuous mingling of animals from different colonies as they move along the coast while foraging. Recaptures of tagged animals have demonstrated that even juveniles in their first year are capable of swimming from Seal I. in False Bay (near Cape Town) as far north as Cape Cross in Namibia, a distance of over 1500 km (David 1989, Oosthuizen 1991).

Similar Species All the fur seal species tend to be very similar in appearance and, with the exception of the Northern Fur Seal *Callorhinus ursinus*, which has a characteristic head shape, and the Subantarctic Fur Seal *Arctocephalus tropicalis*, which has a white chest and face, they are difficult to tell apart in the field (King 1983). In the skull, at least, *A. pusillus* is characterized by post-canine teeth with a small accessory cusp, and the ventral edge of the jugal arch lying dorsal to the dentary part of the maxilla (Coetzee 1977).

Distribution The Cape Fur Seal is widely distributed over the continental shelf. It is spread along over 3000 km of coastline and ranges from Baía dos Tigres in S Angola (16° S, 11° E) to about East London in SE South Africa (33° S, 27° E). It has been seen up to

220 km (120 nautical miles) from the coast (Rand 1959, Shaughnessy 1982, David 1987a). About 90% of the seal population occurs on the west coast of South Africa and Namibia, because of the high productivity of the Benguela Current marine ecosystem, which characterizes the region (Nelson & Hutchings 1983, Shannon 1985, 1989, David 1989). Cape Fur Seals do not undertake regular migrations, but there is a great deal of movement between the breeding colonies, particularly among juveniles (Rand 1956, Oosthuizen 1991). There are three confirmed records of vagrant Cape Fur Seals sighted outside southern African waters, two from West Africa, in Ghana (Thibault 1999) and Côte d'Ivoire (Marine and Coastal Management pers. comm.) (5°N) and one from Marion I. (46°S) (Kerley 1983).

Habitat The species occurs coastally in three marine zones, the highly productive cool Benguela system of southern Africa's west coast, the near-shore mixing area between warmer Agulhas water and cooler Atlantic water off South Africa's south coast, and the south-east coast inshore of the warm Agulhas system.

Breeding takes place at 25 colonies and there are another ten haul-out sites, classed as non-breeding colonies, where a few pups may be born annually (David 1987a, 1989, Oosthuizen & David 1988). Eighteen breeding colonies are on islands and seven are on the mainland. By preference, seals choose rocky near-shore islands for breeding, because they are cooler than the mainland and are free of terrestrial predators. It is thought that none of the mainland colonies, with the exception of Cape Cross in Namibia, existed before about 1940. The possible reasons for the establishment of mainland colonies include the fact that most of the islands are small, so that breeding space was limited and the disturbance caused by the annual seal harvests (see Conservation) would have caused some animals to flee to the nearby mainland. During the twentieth century the mainland became more suitable for colonization by seals, as all large land predators were eradicated and, in addition, large tracts of the west coast of South Africa and Namibia were declared security zones for diamond mining, thus prohibiting public access. Hence, the seals could breed undisturbed, with no space limitations. This has resulted in the development of some extremely large colonies (e.g. Kleinsee colony in South Africa, where over 70,000 pups are born per annum), so that currently over 75% of the population breeds on the mainland.

Abundance The Cape Fur Seal is possibly the most abundant of the fur seals worldwide, with a current population estimated to be about 1.5–2 million animals, based on regular aerial censuses of newly born black pups at all breeding colonies (Butterworth *et al.* 1995). The surveys are timed for the end of the breeding season (normally the period 18–23 December), when the black pups are on average about 2–4 weeks old, and cannot yet swim. The pups are counted on large monochrome or colour prints and the total population is then calculated from age-structured models (Butterworth *et al.* 1988, 1995). Some of the counts made are verified using tag-recapture estimates of pup population size at selected colonies.

Adaptations Cape Fur Seals are adapted for diving to catch prey, and while the majority of dives are shallow dives of no more than 50 m, results from the deployment of time-depth-recorders show that adult bulls can reach depths of 500 m and ♀♀ can dive to over 400 m (Marine and Coastal Management, pers. comm.). In addition,

the seals breed during summer (Nov/Dec) on the exposed coast of southern Africa where high day-time temperatures are common. Little shade is available at the colonies and adults are adapted to endure prolonged direct insolation. When body temperatures rise beyond a tolerable level, they retreat into the water to cool off. However, the young pups do not possess the same degree of heat tolerance and it is noticeable that on very hot days at mainland colonies pups less than about a month old may suffer heavy mortality due to heat stress, especially amongst pups occupying the sandy parts of the colonies.

Foraging and Food Cape Fur Seals are opportunistic feeders and prey on at least 34 species of fish, 18 species of cephalopods and a number of crustaceans such as swimming decapods, amphipods and isopods (Rand 1959, Lipinski & David 1990, Punt *et al.* 1995). The main prey of seals older than one year is teleost fish. Analysis of undigested stomach contents of seals collected at sea on the west coast of southern Africa, by reconstituting the mass of fish prey from measurement of the otoliths, shows that overall about 80–90% of the diet is teleost fish, with a range from about 50–100% depending on season and area, and that the next most important item is cephalopods (David 1987b, Punt *et al.* 1995). Crustacea constitute a minor fraction of the diet.

The importance of individual teleost species was determined from the otoliths occurring in seal stomachs. In South African waters anchovies (*Engraulis japonicus*), sardines (*Sardinops ocellatus*) and two species of hake (*Merluccius capensis* and *M. paradoxus*) are dominant, whereas in Namibia the Bearded Goby *Sufflogobius bibarbatus* and Horse Mackerel *Trachurus trachurus* are the most important fish prey. Castley *et al.* (1991), who analysed the stomach contents of 49 seals stranded on the south-east coast (mainly in the Algoa Bay area), concluded that regional differences in seal prey were worthy of further study.

Six time-depth-recorders were fitted to lactating ♀♀ at Kleinsee colony in 1977. Only two instruments with dive records were recovered, but analysis of these indicated that the animals dived much

of the time they were at sea, which was presumed to reflect feeding activity (Kooyman & Gentry 1986). Feeding occurred in two peaks daily, but the timing of these peaks could not be determined. On average there were 12 bouts of diving of three hours' duration each during a feeding trip to sea. The dive rate was 16.5 dives per hour, but rates as great as 40 dives per hour were recorded. Most dives were of the continuous descent and ascent type, although on some dives seals spent some 1.5 minutes at the greatest depth reached. They descended rapidly, but the ascent was much slower, which would have facilitated searching for prey from below. It is suggested that seals were taking different prey at different times and depths. Dives lasted on average 2.1 minutes with a maximum of 7.5 minutes. The mean depth of all dives was 45 m and the maximum depth was 204 m. The most frequently attained depth was 50 m or less, but dives to 100 m were common (Kooyman & Gentry 1986).

The recovery of tagged animals at sea and the deployment of satellite-linked time-depth-recorders has also enabled some assessments to be made of the preferred foraging areas of seals from different colonies. Analysis of results indicates that seals from different coastal regions generally do not share the same feeding grounds, though there is some overlap. Tracking of seals fitted with satellite transmitters indicated that northern Namibian colonies feed north of Walvis Bay, the central Namibian colonies feed between Walvis Bay and Luderitz, the colonies south of Luderitz between just north of the Orange R. and Cape Agulhas and the Mossel Bay and Port Elizabeth colonies between Stilbaai and Cape St Frances (Marine and Coastal Management pers. comm.).

Lactating ♀♀ are likely to feed closer to their natal colonies immediately after pupping. They are thus more vulnerable to local fluctuations in food supply than seals with no ties to their colonies, which are free to forage more widely. The close proximity of colonies to abundant food sources is therefore a prerequisite for the colonies to function successfully as breeding units. Immature seals forage close inshore and progressively start to feed further offshore as they mature. Some juvenile and mature ♂♂ (but very few ♀♀) have learned to associate fishing vessels with easily obtainable food and will feed on the offal and trash fish discarded behind trawlers (David 1987b, 1989, Wickens *et al.* 1992, Punt *et al.* 1995, Miller *et al.* 1996).

Social and Reproductive Behaviour Most seals tend to return to their natal colony to breed and in many cases they occupy the same spot year after year. However, some seals do move between colonies and, in a growing population, new breeding colonies may be formed from time to time (e.g. Cape Frio in Namibia, which had been a non-breeding colony for years, became a breeding colony in 1994). Evidence for the movement of ♀♀ is provided by the results of aerial surveys, which sometimes show that there has been a sudden large increase in pup numbers at a particular colony. This can be attributed to the immigration of pregnant ♀♀.

Large bulls haul out and establish territories at the end of Oct and in early Nov, which they defend against all other ♂♂ including juveniles. This is achieved mainly through noisy ritualized displays at the common border between adjacent territories and seldom by actual fighting, although there are reports of bulls that have perished during severe skirmishes or as a result of wounds received (Rand 1956). If an interloping ♂ does not flee at the approach of the territory holder, he will be unceremoniously ousted through chest-

Lateral, palatal and dorsal views of skull of Cape Fur Seal *Arctocephalus pusillus*.

to-chest pushing by the dominant bull. Cows may fight over pups and there are frequent squabbles amongst themselves using a repertoire of threats and lunges. Territorial bulls usually prevent serious quarrels amongst ♀♀ by interposing themselves between the quarrelling pair. Juvenile and subordinate ♂♂ are scattered through the colony, and remain alert for an opportunity to mate with unattended ♀♀.

Females are gregarious and lie in close proximity to each other, except for ♀♀ with newly born pups, which are usually highly aggressive and defend the space around them against other ♀♀ and even pups. Females do not form groups of specific size, but form variable clumps with animals constantly joining or leaving throughout the day (David 1989).

Most ♀♀ arrive at the colonies from mid-Nov to mid-Dec, hauling out one or two days before they give birth to a single pup. After parturition, ♀♀ remain on average 4.3 days (range 0–13 days) with their pup, before they go to sea to feed, leaving the pup alone on the colony (David & Rand 1986). Pups older than about a week tend to congregate in large clumps or crèches for mutual warmth, comfort and protection. The mean duration of the feeding trips varied, but the average absence was 2.8 days during the first month, which increased progressively to 4 days by the third month. Females without pups spent approximately half as much time ashore as did mothers (David & Rand 1986). The mean interval from parturition to copulation was 6 days. At Van Reenen Bay colony in Namibia, 90% of births occurred from 22 Nov to 17 Dec, with a median pupping date of 4 Dec (David 1987a; and see Shaughnessy 1979).

On return to the colony, the ♀ finds her pup by going first to the precise spot where she left it. She recognizes her pup first by its call and when she reaches the pup she smells it carefully to confirm that

Sexual dimorphism in *Arctocephalus pusillus*.

it is indeed her own. If the pup wanders to a different part of the colony the mother may not be able to reunite with it and, because cows will only feed their own pups, lost pups will die of starvation.

Colonies of Cape Fur Seals are occupied all year round, but numbers fluctuate seasonally. The population peaks from mid-Nov to mid-Dec at the height of the breeding season and then declines slowly thereafter, as all bulls vacate the colony by early Jan. During the remainder of the year, the colonies are occupied by ♀♀ with dependent young, and by juveniles of both sexes. Bulls make sporadic brief visits throughout the year. The time of lowest numbers is during Oct, when most animals are at sea feeding in preparation for the coming breeding season.

A Cape Fur Seal colony is generally a noisy place, but this is especially true during the breeding season. The dominant noises are from the high-pitched bleating of the young pups, sounding much like domestic lambs, and the deeper, lowing calls of the ♀♀. The territorial bulls add their contribution through the staccato 'honking' or barking calls when courting ♀♀, and through explosive snorts when engaged in regular ritualized encounters with neighbouring ♂♂.

Reproduction and Population Structure Females give birth to a single pup after an apparent gestation period of almost a year. However, as implantation is delayed for about four months (taking place between Mar and Apr), the true gestation is about eight months. Females enter oestrus within a week of the birth of the pup (Rand 1955). Pups have a length of 0.6–0.7 m and a weight of 4.5–7.0 kg. Females suckle their pups for 8–10 months, though some continue to suckle into the second year. During this period the lactating ♀♀ make regular trips between the feeding grounds and the breeding colonies. Weaning is a gradual process, which starts in Jul and is normally complete by the end of Sep (with pups slowly supplementing their milk requirements with limited foraging bouts 3–4 months before weaning), so that the ♀ is free to spend Oct in foraging in preparation for the new birth (David 1987a).

Males reach puberty at the age of three years when most ♂♂ first exhibit spermatogenesis (De Villiers *et al.* 1997, Stewardson *et al.* 1998), but they are not socially mature until 8–10 years old, which coincides with a spurt in body and bacular growth (Oosthuizen & Miller 2000). At this age they may have attained a size large enough to challenge successfully for a territory during the breeding season (David 1989). Some ♀♀ become sexually mature at three years old, and give birth to their first pup at the age of four years, but most ♀♀ mature at the age of four or five, giving birth at age five or six (Shaughnessy 1982, David 1987a).

The sex ratio of full-term foetuses *in utero* is 1 : 1 ($n = 477$), but 57♂ : 43♀ for pups at an age of six weeks ($n = 68,980$). This ratio (57% male) was also found in a sample of adults and juveniles collected at sea ($n = 243$) (Oosthuizen 1991). This indicates that the initial natural mortality rate of ♀♀ is higher than for ♂♂ from birth to six weeks, but thereafter it is the same for both sexes. Males have a life expectancy of at least 20 years (Wickens 1993); one captive specimen lived to 32 years (Weigl 2005).

Predators, Parasites and Diseases Black-backed Jackals *Canis mesomelas* and Brown Hyenas *Hyaena brunnea* are the main terrestrial predators, preying mainly on pups at the Namibian mainland colonies. A study at Van Reenen Bay in S Namibia found that up to 36% of the pups born were preyed on by Black-backed Jackals (Oosthuizen *et al.* 1997). Marine predators include sharks and killer whales. White Sharks *Carcharodon carcharias* are common in the vicinity of seal colonies on the South African south and west coasts and many cases of predation on seals have been reported (see Stewardson & Brett 2000). Seal remains have been identified in the stomachs of seven-gill sharks in the vicinity of the Luderitz seal colonies.

Adult seals are sometimes infested with internal parasites, though generally the parasite load is quite moderate. Younger seals usually carry few parasites. Many animals have small numbers of mites in the nasal cavity (*Orthohalarachne attenuata*) and in the respiratory tract (*O. diminuta*) (Till 1955). Nematodes occur in the stomach (*Contracaecum osculatum* and *Anisakis simplex*), a cestode (*Diphyllobothrium atlanticum*) in the small and large intestine and an acanthocephalan (*Corynosoma australe*) in the small intestine (Rand 1956, Pansegrouw 1990). Larval cestodes (*Phyllobothrium tumidum*) are frequently found embedded in the abdominal blubber, especially of adult ♀♀ (Pansegrouw 1990), and a louse (*Proechinophthirus*), invisible to the naked eye, is a common ectoparasite (Rand 1956).

At the colonies one seldom sees sick animals. Known incidents of mass mortality, such as occurred in Namibia in 1994–95, were found to be due to starvation, not to disease (Roux 1998).

Conservation IUCN Category: Least Concern. CITES: Appendix II.

Uncontrolled exploitation by man over more than four centuries for meat, skins and oil has resulted in Cape Fur Seals disappearing from at least 23 island colonies around the South African and Namibian coastline, since sealing began late in the sixteenth century (Raven-Hart 1967, Shaughnessy 1984, David 1987a, 1989). The colonies were invaded at all times of year, even during the breeding season, and all age classes were taken, including pups and pregnant ♀♀, thus causing large-scale disturbance, and consequent abandonment of the colonies. As a result the seal population was reduced to very low levels by the end of the nineteenth century, which motivated the government of the Cape Colony to enact the first legislation protecting seals in 1893.

The proclamation of the Cape Fish Protection Act of 1893 stipulated that no seals might be harvested without a government permit. This was amended in 1909 and again in 1936 to prevent sealing during the breeding season. Sealing in Namibia (formerly the German colony of South West Africa, taken over by South Africa in 1920) was not controlled until 1922, when the Union Government passed the Sealing and Fisheries Proclamation. In 1949, this was replaced by the Sealing

and Fisheries Ordinance (Shaughnessy 1984, David 1989). All these measures were replaced by the Sea Birds and Seals Protection Act of 1973, which fully protected seals and sea birds in both countries until 1990, when Namibia gained its independence. The 1973 Act is still in force in South Africa, but is in process of being revised.

Despite the seal population being much reduced during the early years of the twentieth century, commercial harvesting of pups and bulls continued under government control in both countries up to 1990, when it was banned in South Africa for political reasons by the Minister of Environmental Affairs. However, seal harvesting in Namibia still continues under government licence at three mainland colonies. From 1900 to 1990 the total known harvest of pups in both countries was over 2.5 million and of bulls was over 200,000 (Wickens *et al.* 1991).

Despite this continuation of commercial exploitation, the Cape Fur Seal population has recovered in spectacular fashion, to stand currently at the previously mentioned total figure of 1.5–2 million animals. This is perhaps one of the outstanding success stories of conservation in the twentieth century. It is interesting that many of the extinct island seal colonies destroyed by the sealers were subsequently colonized by breeding sea birds. Only four extinct island colonies (three in Namibia and one in South Africa) are known to have been permanently recolonized by seals (Shaughnessy 1984).

Conflicts between the seal population and commercial fishing interests have led to the illegal shooting of seals at sea (Shaughnessy 1985, Wickens *et al.* 1992) and remain unresolved. Seals can be a nuisance around fishing vessels and may consume the catch and damage or become entangled in nets or lines. This is especially the case in the hand-line industry for the migratory Snoek *Thyrsites atun*, where the annual estimate of such damage is South African Rand 0.5–1 million (3.3–7% of the total landed annual value of Snoek; Wickens 1996). The conclusion that the seal population consumes roughly 2 million tonnes of food annually (Butterworth *et al.* 1995) has tended to confirm the fears of the fishing industry that seals are a major competitor for commercially important fish species. Close to sea bird breeding colonies there is concern that seals may kill and eat substantial numbers of fledgling and adult sea birds of threatened species such as Cape Gannets *Morus capensis* and African Penguins *Spheniscus demersus*

Cape Fur Seal *Arctocephalus pusillus*.

(Marks *et al.* 1997, David *et al.* 2003). However, the conclusion by Wickens *et al.* (1992) was that the overall losses to the fishing industry due to interference by seals in fishing operations, damage to gear and consumption of catch were minor compared with the wholesale value of the catches.

Measurements

Arctocephalus pusillus pusillus

TL (♂): 1900–2300 mm

TL (♀): 1200–1700 mm

WT (♂♂): 247.0 (200.0–350.0) kg, n = 53

WT (♀♀): 57.4 (40.0–80.0) kg, n = 206

Southern Africa (David 1987a)

Note: The weight of 700 kg given for ♂♂ in Shaughnessy (1979) is an error, as the weight in pounds was incorrectly published as kilograms, while the figures of TL 1800 mm and WT 122.0 kg for ♀♀, in the same publication, were undocumented estimates from Rand (1956).

Family PHOCIDAE
TRUE SEALS

Phocidae Gray, 1821. London Med. Repos. 15: 297.

| | | |
|-----------------------------|------------|-------|
| <i>Monachus</i> (1 species) | Monk Seals | p.133 |
|-----------------------------|------------|-------|

The Phocidae (true seals or earless seals) form a monophyletic group, consisting of 19 species (one, the Caribbean Monk Seal *Monachus tropicalis* recently extinct) in 13 genera (Rice 1998, Wozencraft 2005). These are generally divided into two subgroupings, a northern group, Phocinae (containing, but not exclusively comprising, the tribe Phocini), which includes temperate region, sub-Arctic and Arctic species, and a southern group, Monachinae, which embraces the warm-water monk seals (tribe Monachini), the Antarctic ice seals (tribe Lobodontini), as well as the wide-ranging elephant seals of the genus *Mirounga* (Heyning & Lento 2002, Deméré *et al.* 2003, Fulton & Strobeck 2010).

Phocid seals can be recognized by the absence of external ear pinnae, a short muzzle, beaded vibrissae, a dark coloured skin, short fur, furred fore- and hind flippers, five claws on each fore-flipper, generally two nipples in ♀♀, internal testes, as well as a generally larger body size in comparison to otariids. Monophyly is supported by a pachyostic mastoid region, a greatly inflated entotympanic bone, the complete absence of supra-orbital processes, and strongly everted ilia (Berta & Sumich 1999). Also characteristic are the nasal bones that do not penetrate between the frontals on the mid-line and incisors that are not transversally grooved. Phocids typically have teeth differentiated into incisors, canines and postcanines. Premolars and molars are not differentiated, neither are carnassial teeth. The characteristic dental

formula is $I^{3/2}$, $C^{1/1}$, $PC^{5/5} = 34$, but with variations in both upper incisor ($I^{2/2}$ in *Monachus* and Antarctic phocids) and lower incisor ($I^{2/1}$ in hooded and elephant seals), but rarely in postcanine numbers (from Jefferson *et al.* 1993). Postcanine teeth may have multiple cusps in specialist krill feeders, and large canines and postcanines that allow some to hold and rend warm-blooded prey.

Sexual dimorphism in phocids is much less pronounced than in otariids, and may even be reversed, with ♀♀ being slightly larger than ♂♂, as in the lobodontine seals. An exception to this is found in elephant seals, the largest species of seal, which display the greatest disparity in size of all mammals. Southern Elephant Seal *Mirounga leonina* bulls reach masses of 2000–4000 kg, while ♀♀ only reach masses of 400–900 kg.

The earliest known fossil phocid is from the late Oligocene (29–25 mya) of South Carolina, the remainder from the middle Miocene (15 mya) when both phocine and monachine seals became distinct lineages in the North Atlantic. A fossil phocine seal from the late Miocene and early Pliocene has been discovered in South Africa (Hendey & Repenning 1972). Extant phocids are represented in Africa by only one genus and one species: the Mediterranean Monk Seal *Monachus monachus*. Three others, the Southern Elephant Seal, the Crabeater Seal *Lobodon carcinophaga* and the Leopard Seal *Hydrurga leptonyx*, turn up on the African coastline only as vagrants.

Phocids are adept swimmers, and, with the exception of the Leopard Seal (which swims with fore-flipper strokes like the otariids), propulsion is provided by the hindlegs. However, phocids are ungainly on land, moving with a characteristic humping locomotion on land or ice. Unlike otariids they are unable to rotate the hind flippers under the body because of a massively developed astragalar process and greatly reduced calcaneal tuber. Elephant seals and monk seals experience an annual catastrophic moult, with the skin sloughing away in large patches rather than the hairs falling out individually, as in all other species of phocids and all species of otariids.

The eyes are modified to focus underwater and see effectively under conditions of reduced light. Physiological adaptations for diving are especially well developed in several phocids, most remarkably so in the elephant seals and the Weddell Seal *Leptonychotes weddellii*. These include slowing of the heart rate (bradycardia), shunting blood from peripheral

areas to the brain and heart, high tolerance for carbon dioxide levels in the blood, a high concentration of haemoglobin in their red blood cells and myoglobin in their muscle tissue, a relatively large blood volume and the ability to withstand enormous pressures at depth. Upon rapid return to the surface they can avoid developing either nitrogen narcosis (an anaesthetic effect on the nervous system that may lead to unconsciousness and death) or the 'bends' (dissolved nitrogen coming out of solution, forming gas bubbles that may cause embolisms and also result in death). This ability is due to the absence of large gas-filled spaces and the exhalation of their lungs before diving deeply.

Phocids feed on a wide variety of species of open-water and benthic fish, cephalopods, crustaceans, marine birds (primarily penguins) and exceptionally (as in the case of Leopard Seals) other mammals, including otariids and phocids, and scavenging from carcasses of whales. Foraging behaviour depends on the area, season and species and generally takes place at depths of 50–450 m. Consummate divers such as Weddell Seals can make dives to depths of 700 m and of 82 min in duration, while Southern Elephant Seals can make dives to 2150 m (McIntyre *et al.* 2010) and up to 120 min, although foraging is believed to take place primarily between 300 and 400 m during shorter dives.

The breeding season for phocids is spring or summer, and sometimes the boreal autumn. A single pup is born after a gestation period of about one year, which includes a period of delayed implantation. Twinning is extremely rare, and twins have not been recorded to survive in the wild until weaning. Males do not care for the young. The mating systems vary from polygynous (e.g. Weddell Seals, Grey Seals *Halichoerus grypus* and elephant seals to serially monogamous (Crabeater Seals), with mating taking place on land or ice and/or at sea. Females of all phocid species are basically capital breeders, generally storing energy and nutrients in their subcutaneous blubber while foraging before the breeding season haul-out, then come ashore or haul out on ice to fast or feed very little while nursing their pups for between four (Hooded Seal *Cystophora cristata*) and 53 days (Weddell Seal). During the breeding season, polygynous species may haul out in large aggregations and ♀♀ generally come into oestrus from shortly before, to after their pups are weaned (Boness *et al.* 2002).

Marthán N. Bester & Paul N. Odendaal

GENUS *Monachus*

Monk Seals

Monachus Fleming, 1822. Philos. Zool. 2: 187.

The genus *Monachus*, considered to be the most primitive members of all phocids, contains three species: the Mediterranean Monk Seal *Monachus monachus*, the Caribbean Monk Seal *Monachus tropicalis* and the Hawaiian Monk Seal *Monachus schauinslandi* (King 1956, Scheffer 1958, Wozencraft 1993, 2005). With the exception of the California Sea Lion *Zalophus californianus*, monk seals are the only tropical pinnipeds. Unfortunately, the Caribbean Monk Seal is now extinct, with the last reliable observation dating to 1952 (Adam & Garcia 2003).

Differences among the species, which are geographically separated by at least 5000 km, are slight and based on characteristics of the skull and pelage. *Monachus monachus* has upper incisors without a marked cervical constriction; premolars 2–4 with a single cusp posterior to the main

cusp; antorbital process prominent; pterygoid processes poorly defined and not visible in dorsal view; anterior tips of nasals rounded; auditory bulla without distinct oblique ventral sulcus; and adult ♂♂ and pups with a conspicuous ventral white patch (Adam 2004). The structure of the bony parts of the ear indicates that *Monachus* is the least specialized genus of the living Monachinae seals (southern phocids).

It has been suggested that the genus is paraphyletic, with *M. monachus* and *M. tropicalis* more closely related to other phocids than to *M. schauinslandi* (Wyss 1988), but see Bininda-Emonds *et al.* (1999) and Higdon *et al.* (2007).

Luis Mariano González

Monachus monachus MEDITERRANEAN MONK SEAL

Fr. Phoque moine de la Méditerranée; Ger. Mittelmeer-Mönschrobbe

Monachus monachus (Hermann, 1779). Beschäft. Berlin Ges. Naturforsch. Fr. 4: 501, pls. 12, 13. Ossero (now Osor), Cherso island (now Cres island), Croatia.

Mediterranean Monk Seal *Monachus monachus*.

Taxonomy Hermann proposed the specific name from the Greek *monakhos* (monk) because he thought the smooth, round head resembled a human head covered with a hood, and the shoulders and short flippers extended like two elbows beyond a scapular covering a frock. Individuals of the Atlantic were described as a distinct species *Heliophoca atlantica* (Gray 1854). Synonyms: *albiventer*, *atlantica*, *bicolor*, *byronii*, *crinita*, *hermannii*, *isidorei*, *leucogaster*, *mediterraneus*. Chromosome number: $2n = 34$ (Arnason 1974).

Description The Mediterranean Monk Seal is amongst the largest phocid species. Head rounded with a protruding muzzle. Face appears wide because of the flatness of the muzzle and the upper lips. Orbits and eyes large. Nostrils nearly on the dorsal surface of the snout and almost horizontal. Mystacial vibrissae light yellow to brown, oval in cross section and smooth. External ear pinnae absent, with small opening of the ear canal located just behind the eyes. Fusiform bodyshape, dark in colour dorsally and lighter ventrally. The body hair is the shortest of all the pinnipeds, only 5 mm in adults; secondary pelage absent. Unlike any other mammal, members of the tribe Monachini exhibit an unusual moult wherein the hairs are shed along with large sheets of cornified epidermis through which the club hairs penetrate. Moulting ♀♀ can be found throughout the year, with a peak in Mar. Moulting ♂♂ have been found from Apr to Oct, with a peak in Jun (Gazo *et al.* 1999). All individuals, except pups, present obvious marks and scars in the pelage due to the absence of hair pigmentation, caused by interaction between individuals and injuries inflicted by ♂♂ during mating. Adults exhibit marked sexual dimorphism in pelage colour (Samaranch & González 2000; and see below). Fore-flipper short and haired, with a claw on each of five digits. Nails present on both flippers, but very reduced in comparison with other pinnipeds. First digit of the fore-flipper about 25 mm long and the others decrease slightly in size towards the fifth digit. Hind-flippers oriented posteriorly and cannot be rotated forward. Testes not scrotal, but lie separately outside the body cavity in the hypodermal layer of the skin. Tail short and wide. Two pairs of nipples.

Six morphological age-classes have been described, all identifiable in the field (Badosa *et al.* 1998, Samaranch & González 2000):

Newborn/Pup: Pelage woolly. Nape, throat and back uniform black. Belly black interrupted by a yellowish-white patch, squarish in shape in which anterior edge coincides approximately with centre of body and ends caudally between umbilical scar and genital slit. In ♀♀ the caudal margin of the white patch is close to the tail and straight, with the umbilical slit falling within the patch. In contrast, in ♂♂ the caudal margin indents to reach, or almost reach, the umbilical slit. The penile opening falls outside the ventral patch. First moult of this pelage begins nearly 45 days after birth and lasts an average of 25 days.

Youngster: Nape, throat, belly and back light grey. Upper part of head darker, extending to nostrils (hood), leaving 'mask' around eyes that stops above ear. Individuals with these characteristics appear from around 69 days until about nine months old.

Juvenile: Nape, throat, back and belly dark-grey, with hood and mask around eyes. Individuals with these characteristics appear from seven months until 23 months old.

Subadult: Nape, throat, back and belly medium-grey or dark-grey. Hood and 'mask' around eyes extends over outer ear, spreading in sideburn shape. Back interrupted with scars. Individuals with these characteristics appear from 18 months old, but class duration is unknown at present.

Adult female: Similar to subadult class, but with the back interrupted by scars in the form of a patch in the dorsal region.

Adult male: Distinctly black, except the throat is white and the belly presents a white patch similar to male pups'. Back interrupted by

Lateral, palatal and dorsal views of skull of Mediterranean Monk Seal *Monachus monachus*.

scars, without dorsal sash. This pelage appears at approximately four years old. The similarity in pelage pattern and colouring between pups and adult males is striking.

Skull broad in proportion to its length (mastoid width about 1/1.76 condylobasal length). The extension backwards of the zygomatic process of the maxilla is very much greater than in the Phocinae (King 1956).

Geographic Variation None recorded, although Van Bree (1979) reported on differences in skull morphology between Mediterranean Monk Seals from the Atlantic and the western Mediterranean based on a limited sample size.

Distribution Ranges from Cabo Blanco peninsula on the Atlantic Sahara coast (Morocco–Mauritania), at about 20° N, along the Atlantic coast and offshore islands of north-west Africa, and throughout the Mediterranean coasts (with individuals known to wander as far south as Gambia and Senegal) (Marchessaux 1989, Reijnders *et al.* 1997, Grubb *et al.* 1998, López-Jurado *et al.* 1998).

Historical Distribution Until the fourteenth century, this species also occurred on the Azores, Canary and Cape Verde Is., adjacent to the African continent. Present in the Mediterranean until the nineteenth century, and distributed along all the shores of the African coast (Monod 1948).

Current Distribution In the south-eastern North Atlantic, the species is confined to two small areas: Madeira (the main island, Porto Santo,

Monachus monachus

and the Desertas Is.; see Pires *et al.* 2008) and the Cabo Blanco Peninsula. There also are occasional records in the Canary Is. and the front coast of Morocco, the Cabo Barbas-Guerguerat region (Morocco), the Bay of Levrier and in the Banc d'Arguin (Mauritania).

Along the Mediterranean coast of Africa, populations have disappeared from Egypt, the majority of Libya, the western coast of Morocco and recently in E Algeria and Tunisia. The coast between Peñon de Vélez-Bokoyas and Chafarinas Is. (Morocco–Spain), and between Beni Saf and Mostaganem (Algeria), is still occupied by a few monk seals. Also there are sporadic sightings of individuals on La Gallite (Tunisia) and some individuals probably survive in Tolmeythia, along the Cyrenaic coast of Libya (Avellá & González 1984, Bayed & Beabrun 1987, Boutiba *et al.* 1988, Francour *et al.* 1990, Kowalski & Rzebiak-Kowalska 1991, González *et al.* 1997, Reijnders *et al.* 1997).

Otherwise, the stronghold for the species is in the eastern Mediterranean on islands in the Ionian and Aegean Seas, and along the coasts of Greece and W Turkey.

Habitat Predominantly coastal, although they have been observed as far as 80 nautical miles from shore (Maigret *et al.* 1976, Marchessaux 1989). This species prefers coastal waters, with sheltered beaches and caves along inaccessible rocky cliffs. Only two other pinnipeds use this type of habitat on land, the Guadalupe Sea Lion *Arctocephalus townsendi* and certain populations of Grey Seals *Halichoerus grypus* (Sergeant *et al.* 1978, Reijnders *et al.* 1997). Historically, in the Atlantic, Mediterranean Monk Seals also inhabited the beaches of islands and the sand banks and open beaches of the mainland, where there are records of large aggregations of seals (Monod 1948, Marchessaux 1989). Currently, Mediterranean Monk Seals are restricted to cliffs of very remote areas where disturbance by people is slight. Seals disappeared from these habitats due to human persecution, and only those populations that lived in caves or beaches protected by cliffs survived. It has been suggested that this habitat is sub-optimal for the monk seals due to the low survival rate of

pups (Sergeant *et al.* 1978, Francour *et al.* 1990). In the Cabo Blanco peninsula some adult males haul out on open beaches (Marchessaux 1989, González *et al.* 1997); recently, in Desertas, with no human disturbances, immature-size ♀♀ have reoccupied open beaches (abandoned a long time ago) to breed and this has improved the reproductive success of the colony (Costa Neves & Pires 2000).

Abundance The Mediterranean Monk Seal was common along the Atlantic Saharan coast in the Neolithic age, where it was consumed by human coast-dwellers (Marchessaux 1989). It certainly was abundant at least until the fifteenth century. Accounts left by the first Portuguese explorers to arrive on these coasts attest that the seals were sufficiently abundant to justify hunting expeditions for seal oil and skins. In the Mediterranean they also were common along the coast of Egypt, Libya and Algeria in the eighteenth and nineteenth centuries (King 1956, Marchessaux 1989, Kowalski & Rzebik-Kowalska 1991). However, since then, the world population of Mediterranean Monk Seals has undergone rapid decline – up to 80% in the last century – and now is highly fragmented (Reijnders *et al.* 1997). The global population currently is estimated at 300–400 individuals (Reijnders *et al.* 1997).

The largest known population currently occurs on the cliffs of ‘Costa de las Focas’ in the Cabo Blanco peninsula (González *et al.* 1997), with an estimated average population of 317 seals in the mid-1990s (Forcada *et al.* 1999). However, this population was affected by a severe mass mortality in 1997, which reduced its numbers to an estimated 103 individuals in 1998 (Forcada *et al.* 1999). The sub-population in Madeira was composed of about 50 animals in the late 1970s and has been severely reduced to date. Current numbers are around 20–30 animals (Pires *et al.* 2008). Along the Morocco–Algeria coast probably only a few individuals survive (Bayed & Beabrun 1987, Boutiba *et al.* 1988, F. Avella pers. comm.). Some 250–300 individuals survive in the eastern Mediterranean.

Adaptations The genus *Monachus* is considered the most primitive of living seals, due to the possession of some primitive anatomical features (structure of the skull, skeleton and vein system). Monk seals have very poor underwater hearing. The structure of the ear region of the skull offers little resistance to high pressure, and the Mediterranean Monk Seal is, in fact, a littoral species and a shallow diver. Internal temperature ranges between 35.9 and 37.5°C but the species is capable of tolerating solar thermal changes and high prevailing temperatures (36.3°C) without becoming hyperthermic. In this context, dark colouration of the pups could be an adaptive mechanism to intensive solar radiation because it can operate as a dispersant mechanism for the light energy (King 1956, Marchessaux 1989).

It has been suggested that in response to human persecution, the surviving individuals have modified important aspects of their biology and behavioural patterns. Breeding in caves is just one example, with most hauling out and pupping occurring today in caves or grottoes, some of which have underwater entrances. The Cabo Blanco colony occupies an area heavily affected by the action of large oceanic waves and the presence of storms. Individuals haul out and give birth on narrow sandy beaches that disappear during very high tides or when high swells reach the ends of caves. Consequently, pups are fatally injured against rock walls due to the impact of waves (Gazo *et al.* 2000a, Mozetich *et al.* 2002).

Foraging and Food Mediterranean Monk Seals are piscivorous and generally feed on demersal or pelagic fishes, such as those of the families Moronidae, Rynobathidae, Sparidae, Cupleidae, on crustaceans such as *Panulirus regius* and cephalopods of the genera *Octopus*, *Sepia* and *Loligo*. Daily food intake has been estimated at around 5–10% of their total body weight. They are opportunistic feeders, exploiting the resources that are most abundant at the time. Maximum diving depth has been recorded to 90 m (although dives rarely exceed 50 m); the recorded maximum duration of a dive is around eight minutes. They have been observed bringing large fishes (i.e. *Dicentrarchus* sp.) and *Octopus* to the surface, where they shake the prey vigorously before swallowing (Marchessaux 1989, M. Gazo pers. comm., P. Fernández pers. comm.).

Social and Reproductive Behaviour The biology and ecology of this species are not well known. Genetic studies in Cabo Blanco colony suggest that Mediterranean Monk Seals are polygynous, with ♂♂ mating with multiple ♀♀ (Pastor *et al.* 2004). In this colony, up to one hundred individuals have been seen hauled out at the same time. Adult ♂♂ defend aquatic territories at the entrance to their caves and surrounding areas (González *et al.* 1997). Tenure of aquatic territories extends throughout the year and, in some cases, for several years. Females and young regularly are found only in the breeding caves. They probably socialize more frequently in the water than out (Marchessaux 1989, ULPGC 1999).

There is no information regarding mating behaviour, and there are only a few observations that suggest that mating takes place underwater. Prior to parturition, ♀♀ look for isolated spots inside the caves far from other seals and where the beaches will not be covered during high tide and are protected from waves. They dig a hollow in the sand, probably with their fore-flippers and muzzle, and defend the site from any approaching seals (Layna *et al.* 1999). Newborns spend the majority of the time on beaches inside the caves. Pups are highly mobile and have been observed making trips in open waters up to 2.2 km unaccompanied by the mother. Females alternate nursing with feeding trips to open waters. Fostering and milk stealing occurs frequently. Sporadic sightings of juveniles in areas far away from the breeding colonies suggest juvenile dispersal over larger distances can occur (ULPGC 1999, CBD-Habitat pers. comm.).

Reproduction and Population Structure Females are sexually mature at three years of age by which stage they measure from 2.2 to 2.3 m in length (ULPGC 1999). A female at Cabo Blanco became pregnant at 2.5 years and gave birth at 3.7 years, the youngest age known for this species (Gazo *et al.* 2000b). The Mediterranean Monk Seal is the only phocid in which the pupping season extends throughout the whole year (Gazo *et al.* 1999, González *et al.* 2002). The gestation period is unknown, and it is not clear whether there is delayed implantation. Females give birth to a single pup weighing about 15–20 kg. Nursing extends over 120 days, almost doubling the maximum lactation periods observed in other phocids, and appears to end gradually. Average birth interval is about 375 days ($n = 8$) (CBD-Habitat pers. comm.).

In the Cabo Blanco colony, survival rates from known age classes were: 0.52 for pre-weaning pups (0–3 months), similar to rates recorded for pinnipeds breeding in caves, but lower than for those breeding on open beaches; 0.77 for post-weaning juveniles (3 months

Mediterranean Monk Seal *Monachus monachus*.

to 1 year); and 0.8 for juvenile/subadults (1–2.5 year). Only 32% of pups born in this colony reach sexual maturity (Gazo *et al.* 2000a, González *et al.* 2002). Average annual productivity in the Cabo Blanco colony was 60 pups prior to the mass-mortality, and 25–29 thereafter (Gazo *et al.* 1999, González *et al.* 2002). The average number of reproductive ♀♀ in the population that reproduce each year was estimated at 51.9% S. E. = 12.4%). The percentage of adult ♀♀ that successfully reproduce from year to year ranges from 30 to 70%. The massive die-off in 1997 in this colony area reduced the size of the adult ♀♀ population by over 50% (Harwood *et al.* 1998). Maximum recorded age is 44 years for an individual from the Aegean Sea (Reijnders *et al.* 1997).

Predators, Parasites and Diseases The mass-mortality episode in the Cabo Blanco colony was attributed to intoxication through the consumption of prey items contaminated with paralytic shellfish poison saxitoxins (PSPs) (Hernández *et al.* 1998, Reyero *et al.* 1999), caused by a bloom of toxic algae. A virus closely related to the dolphin morbillivirus was isolated from tissues of three individuals and serum antibodies to canine distemper virus were also detected in four individuals in the mass-mortality of 1997 (Osterhaus *et al.* 1997). One ectoparasite has been described, *Lepidophtrirus piriformis*, and eight cestodes and three nematodes, but only *Anisakis pegreffii* is host-specific (King 1956). There is no information regarding predators.

Conservation IUCN Category: Critically Endangered A2abc; C2a(i); E. CITES: Appendix I. CMS: Appendix I.

The Mediterranean Monk Seal is among the rarest and most threatened mammals in the world (Reijnders *et al.* 1993). The decline in population numbers is the result of adverse interactions with man, mostly through direct exploitation in the past, and now deliberate killing to prevent damage to fishing gear, incidental entanglement in fishing nets, destruction or alteration of coastal habitat, reduction of food, pollution, cave collapse and toxic algae blooms. Deliberate or incidental killing of seals by fishermen continues to take place along the Mediterranean shores and represents a significant source of adult mortality. The use of dynamite, driftnets and other illegal gear is frequent and causes sporadic mortality. In Madeira, dangerous

fishing activities have been eliminated from the Nature Reserve of the Desertas Is.; compensation was provided to fishermen forced to change their fishing practices (Costa Neves & Pires 2000).

Genetic studies in the Cabo Blanco colony indicated extremely low allelic variability in comparison with other pinniped populations (Pastor *et al.* 2004). Distances between the two Atlantic populations (some 2000 km between the Desertas and Cabo Blanco colony), and between the Atlantic and the Mediterranean populations, make regular mixing of individuals highly unlikely. Pastor *et al.* (2007) measured levels of nuclear genetic variation at 24 microsatellite loci in 12 seals from the eastern Mediterranean and 98 seals from the Western Sahara (Atlantic) population. The eastern Mediterranean population had 14 unique alleles and the Western Sahara had 18; highly significant differences in allele frequencies between the two populations were found for 14 out of 17 loci. These results suggest that each population may act as a source for introducing additional genetic variation into the other population.

Analysis of the tissues of Mediterranean Monk Seals from the Mediterranean populations has revealed extremely high concentrations of organochlorine compounds (PCBs, DDTs, etc.) and heavy metals (mercury, leads etc.), which may be having negative effects on reproduction and the immune system (Reijnders *et al.* 1993, 1997). This has raised considerable concern over the future of the species and has led to the drawing up of several action plans, including a 'Conservation Guidelines' (Johnson & Lavigne 1995) and two Action Plans, one for the Mediterranean under the Barcelona Convention and the other for the Atlantic under the Bonn Convention (González 2000), that proposed a series of conservation measures, including: (1) reduction in seal mortality; (2) enhancing the level of habitat protection; (3) management plans for protected areas; (4) regulatory measures to minimize the impact of fishing; (5) specific measures to avoid habitat deterioration; (6) reoccupation of beaches as breeding habitat; (7) rescue and rehabilitation of seals; (8) emergency plans for catastrophes; (9) awareness and socio-economic measures for the fishermen and local communities; and (10) research and monitoring of the species. These plans also identified a number of important areas for the protection of these seals, including: along the Mediterranean coasts of Spain and Morocco (the coast of Bokoyas [Peñon de Velez – Al-Hoceima] and Cabo Quilate – Cabo Tres Forcas – Chafarinas Is.); in Algeria (Maddagh – Habibas I. and Cap Ivi – Cap Tarsa – Cap Figalo – Ile Plane); Desertas Is. and Selvagens Is. (Madeira), Cap Tarfaya, Cap Barbas-Guerguerat and Cabo Blanco Peninsula (Morocco–Mauritania), and L'Etoile-Levrier Bay and National Park of Banc d'Arguin (Mauritania).

Measurements

Monachus monachus

HB (♂ ♂): 2520 (2100–2700) mm, n = 39

HB (♀ ♀): 2370 (2100–2620) mm, n = 50

T: 150–190 mm, n = 5

WT (♂): 335.0 kg, n = 1

WT (♀): 300.0 kg, n = 1

Cabo Blanco (ULPGC 1999, CBD-Habitat unpub. rep.).

Suborder FELIFORMIA – Two-spotted Palm Civet, Cats, Viverrids, Hyaenids, Mongooses

Feliformia Kretzoi, 1945. Ann. Hist. Natur. Musei Natn. Hungar. 38: 62.

Suborder Feliformia has traditionally comprised four families (Felidae, Herpestidae, Hyaenidae and Viverridae). However, a much clearer understanding of the relationships within the suborder has developed in the past few decades. The Two-spotted Palm Civet *Nandinia binotata* is a basal feliform, and not included in the Viverridae (Hunt 1987, Flynn & Nedbal 1988). Asian linsangs (genus *Prionodon*) are included in the family Prionodontidae, and constitute the sister-group to felids (Gaubert & Veron 2003). Finally, Malagasy carnivores, once placed in the Herpestidae and Viverridae, form a separate feliform clade, the Eupleridae (Yoder *et al.* 2003). This revised classification of seven major clades now appears well supported (Eizirik *et al.* 2010,

Meredith *et al.* 2011), with Nandiniidae being the most basal lineage, followed by the Felidae + Prionodontidae clade; next to diverge was Viverridae, followed by Hyaenidae, leaving an internal clade composed of Eupleridae + Herpestidae.

In Africa, the Suborder is represented by the Nandiniidae (one genus and one species), Felidae (six genera, 10 species), Viverridae (three genera, 17 species), Hyaenidae (three genera, four species) and Herpestidae (14 genera and 26 species).

Michael Hoffmann

Family NANDINIIDAE TWO-SPOTTED PALM CIVET

Nandiniidae Pocock, 1929. Encyclopaedia Britannica, 14th Ed., IV: 898.

| | | |
|-----------------------------|------------------------|--------|
| <i>Nandinia</i> (1 species) | Two-spotted Palm Civet | p. 139 |
|-----------------------------|------------------------|--------|

The Nandiniidae is a monogeneric family, represented by a single species, the Two-spotted Palm Civet *Nandinia binotata* distributed in the inter-tropical and south-east African forests. The dorsal pelage is greyish-brown with small dark dorsal spots, and there is a pair of whitish-yellow spots on the shoulders. Both upper and lower canines are large, straight and relatively grooved (more so than in *Genetta*). *Nandinia* is the only extant species of Carnivora having the elements that constitute the bulla unfused in adults (although some specimens belonging to the Oriental Palm Civets [genus *Paradoxurus*] have been found with unfused bulla elements; R. M. Hunt pers. comm.). Moreover, the bulla is not divided by a septum, and a cartilaginous caudal entotympanic separates the rostral entotympanic from the tympanic (Hunt 1974). This plesiomorphic structural assembly and the rudimentary state of the cartilaginous caudal entotympanic, ectotympanic and rostral entotympanic are discussed in detail by Hunt (1987). The transpromontorial course of the internal carotid artery is rather small (Chapuis 1966), a characteristic that is supposed to represent the plesiomorphic aeluroid state (Hunt 1989).

There has been much controversy concerning which taxonomic group *Nandinia* should be assigned to. *Nandinia* was traditionally considered either a peculiar member of the Asiatic subfamily Paradoxurinae – it is commonly called the ‘African Palm Civet’ – (Pocock 1915, Simpson 1945, Meester *et al.* 1986) or the single genus constituting the subfamily Nandiniinae (Gregory & Hellman 1939, Coetzee 1977, Wozencraft 1993) in the family Viverridae. However, Gregory & Hellman (1939) themselves admitted that in *Nandinia* ‘carnassials ... are of nearly pure ‘trenchant’ type and directly derivable from those of the upper Eocene Viverrinae’, and assigned the taxon to a primitive branch antedating frugivorous

Two-spotted Palm Civet *Nandinia binotata*.

specializations in Paradoxurinae. Pocock (1929) erected the family Nandiniidae, on the basis of the presence/absence of perineal scent glands and both bullae and paroccipital characters. Important evidence for its very basal affinities within the Feliformia, and for plesiomorphic character states retained by the genus, are mainly based on the structure of the basicranium and auditory bullae. The data have been detailed by Hunt (1974, 1987), who suggested that the bulla of each current family of Feliformia could be derived from the bullar structure of *Nandinia*. Hunt (1989) also noticed that the shape of the petrosal bone is very similar to that of the oldest aeluroids, the stenoplesictines and proailurines from the Oligocene.

Plantar surfaces of hindfoot (*left*) and forefoot (*right*).

Some external characters also make *Nandinia* very different from Paradoxurinae and other subfamilies of viverrids. The area between the plantar and digital pads (digit 1 excepted) is hairy, and digital pads of the third and fourth digits are widely separated. The position of the scent gland (anterior to the penis/vulva), its flattened shape and very simple structure show no similarity at all with what is known among viverrids (Pocock 1915). In addition, other scent glands are located in the sole of the foot, chin area and also around the belly when females are lactating (Kingdon 1997).

The fossil record of *Nandinia* is limited to a single tooth (Morales *et al.* 2005), though African fossil viverrids (*sensu lato*) have been poorly studied. Some authors have suggested that this taxon belongs to a very primitive stock of aeluroids that evolved slowly in stable mesic forested biotopes of central Africa (Hunt 1974). On the other hand, the peculiar characters of the genus, together with the absence of a fossil record, could suggest that *Nandinia* is a very derived

Two-spotted Palm Civet *Nandinia binotata* skeleton.

genus within Viverridae (Pocock 1915, Gregory & Hellman 1939, Gaubert 2002b). However, the morphological phylogenetic analysis by Hunt (1987) placed *Nandinia* as a sister-taxon to the Feliformia; this clade in turn formed the sister-group to the extinct Nimravidae. Veron (1995), in a cladistic analysis, found the genus to be the most basal within Feliformia, with some affinities with the 'protoviverrid' *Paleoprionodon*. A combined molecular and morphological analysis by Flynn & Nedbal (1998) on the current families of Carnivora strongly supported *Nandinia* as being the sister-taxon of all other Feliformia. These results have been supported by subsequent molecular investigations (Gaubert & Veron 2003, Yoder *et al.* 2003, Flynn *et al.* 2005), with molecular estimates of divergence time suggesting an early Eocene split from the rest of extant feliformians (Gaubert & Cordeiro-Estrela 2006, Eizirik *et al.* 2010). Therefore, we follow the classification by Gaubert *et al.* (2005a) and Wozencraft (2005) in considering the family Nandiniidae as valid.

Philippe Gaubert

GENUS *Nandinia*

Two-spotted Palm Civet

Nandinia Gray, 1843. List Spec. Mamm. Coll. Brit. Mus. p. 54.

Nandinia is a monotypic genus, including a single species, the Two-spotted Palm Civet *Nandinia binotata*, which is found in various forest types throughout West and central Africa, and in a narrow belt of suitable forested habitats in East Africa southwards to S Mozambique. This genus is easily distinguished from other African carnivores by several external characteristics, including its short, thick legs and naked footpads, its exceptionally thick-muscled tail, and the twin yellow spots usually present on the shoulder blades. Unique cranial characters include an entirely cartilaginous posterior part of the auditory bulla, which is always lacking from prepared specimens and long, pointed, isolated paroccipital processes, more canoid than feloid in appearance (Rosevear 1974). Flower (1872) noted the absence of a caecum in *Nandinia*.

Two-spotted Palm Civet
Nandinia binotata.

Nandinia binotata TWO-SPOTTED PALM CIVET (AFRICAN PALM CIVET, TREE CIVET)

Fr. Nandinie; Ger. Pardelroller

Nandinia binotata (Gray, 1830). Spicil. Zool. 2: 9. Africa, Ashantee (Ashanti region, approximately 06° 55' N, 00° 32' E, Ghana).Two-spotted Palm Civet *Nandinia binotata*.

Taxonomy Polytypic species with four subspecies described, but little consensus on their validity (Allen 1939, Schouteden 1945, Rosevear 1974, Coetzee 1977). Synonyms: *arborea*, *binotata*, *gerrardi*, *hamiltonii*, *intensa*. Chromosome number: $2n = 38$ (Todd 1967, Wurster & Benirschke 1967).

Description Similar to dark-brown-coloured genet in general appearance but more heavily built with shorter muzzle and longer tail. Pelage short, woolly and dense with pleasant musky smell. Dorsal pelage variable shades of greyish-brown with small irregular dark brown to black spots. Spots tend to coalesce into irregular black mid-line between the ears. Whitish-yellow spot on each shoulder. Three black lines on neck. Ventral pelage grey to yellowish and without spots. Rounded broad head with moderately pointed muzzle. Ears short, round, broad at base, single brown-black spot behind ear pinnae. Iris green to orange-brown. Limbs short, thickset, similar in colour to dorsal pelage but unspotted. Strongly textured underside of forepaws naked to wrist, hindpaws naked to ankle. Five claws sharp, curved and partially retractile. Tail long (110–120% of HB), densely furred and irregularly ringed with 9–15 brown to black rings, usually less well marked on the underside. Wide range of individual variation in both colour and markings (Allen 1924, Mertens 1925, Schouteden 1945, Rosevear 1974). Males may be slightly larger than ♀♀; considerable individual differences are noticeable in both sexes

but much more pronounced in ♂♂, who compete sexually. Both sexes with glandular abdominal pouch situated anterior of the vulva or penis; this glandular zone is ca. 55 mm long, 20 mm deep, 20–30 mm wide when open, and oozes yellowish liquid with an odour that is relatively faint to the human nose. Males have a penis bone (illustrated in detail by Didier [1948]). Two pairs of nipples.

Differs from all other carnivores in the persistence throughout life of the cartilaginous condition of the posterior chamber of the auditory bulla. Consequently, the paroccipital processes have no bone to attach to, making them conspicuous and a characteristic feature of the skull. The postorbital bars are incomplete, and represented by well-developed supraorbital processes and smaller processes on the zygomatic arches; the supraoccipital crest is well developed (Rosevear 1974, Skinner & Chimimba 2005). Dental formula: $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 38$. Out of 121 specimens 91 had a normal dental formula, but ten missed both M^2 , four the right M^2 , two the left M^2 , one both M^2 , one both M^2 and right M^2 , one left P^1 , one both P^1 , three left P^1 , three right P^1 , two both P^1 , one both M^2 and both P^1 . One specimen missed the right M^2 but two had an extra P^1 .

Geographic Variation

N. b. binotata: from Gambia eastwards to Cameroon, Gabon, Congo, Central African Republic and DR Congo. See Description.

Lateral, palatal and dorsal views of skull of Two-spotted Palm Civet
Nandinia binotata.

N. b. gerrardi: S and E Tanzania, Mozambique, Malawi, NE Zambia (Nyika Plateau) and E Zimbabwe. Presumably also the form on Zanzibar. Three black stripes on neck absent; body more sparsely and finely spotted; light shoulder spots less distinct; dark rings on tail narrower, closer together and more sharply defined.

N. b. arborea: Uganda, Kenya and N Tanzania (Mts Kilimanjaro and Meru, and Eastern Arc Mts). Black stripes on neck narrower; absence of spots on the lower sides of the body; dark rings on tail narrower.

N. b. intensa: Angola, S DR Congo and NW Zambia (Mwinilunga District). Colour both dorsal and ventral much redder and brighter; spots intense black; light shoulder spots more conspicuous.

Schouteden (1945), after examining more than a hundred skins, was convinced that *intensa* and *gerrardi* had no systematic value and were synonyms of the nominate race. The boundaries between *gerrardi* and *arborea* are also poorly resolved: photos of specimens taken in the Udzungwa Mts show no white shoulder spots and also no white spots on the lower sides of the body, while others show relatively clear shoulder spots. The retention of four subspecies here is provisional.

Similar Species

Civettictis civetta. Wide distribution in sub-Saharan Africa. Substantially larger and terrestrial; black band across front of face and prominent neck stripes; tapered bushy tail half the length of head and body.

Genetta spp. Smaller, lighter and sleeker; no yellow spots on shoulders. Genet footpads fringed with hair; tail more distinctly annulated.

Distribution Endemic to Africa, ranging in the west and central African forest belt from Gambia to SW Sudan, Uganda and W Kenya south through the Congo basin to N Angola (southern limit ca. 9° S; Crawford-Cabral 1989a) and NW Zambia (Mwinilunga District; see Ansell 1978). They are more discontinuously distributed in eastern

Nandinia binotata.

and southern Africa in both montane and lowland forests of Tanzania, NE Zambia (Nyika Plateau region; see Ansell 1978), most of Malawi, E Zimbabwe and western parts of Mozambique (southern limit 20° 45' S; Smithers & Lobão Tello 1976). Occurrence on Bioko I. mentioned by several authors (Krumbiegel 1942, Basilio 1962, Eisentraut 1973). Recently observed on Zanzibar (Perkin 2004, 2005).

Habitat Deciduous forests, lowland rainforests and mountains up to 2500 m (2400 m in the Udzungwa Mts and up to 2500 m on the Mbeya range in Tanzania [D. De Luca pers. comm.]), gallery and riverine forests, savanna woodlands and logged and second-growth forests. Able to thrive in cultivation mosaic following forest clearing and known to visit cultivated fields bordering forest edge.

Abundance Widespread and locally abundant. Probably the most common African forest small carnivore, although few field censuses have been undertaken. In Gabon minimum average density estimated at ca. 5/km² with higher averages for inundated forests and river borders (8/km²) than for non-inundated primary forest (4/km²) where fruit yields were lower. Biomass estimated at close to 11 kg/km² – much higher than that of the more carnivorous sympatric carnivores, such as genets and linsangs (Charles-Dominique 1978). In Bwindi Impenetrable N. P., SW Uganda, average density was higher (3.3/km²) above 2000 m than below 1800 m (2.2/km²); higher density deeper into the park than in the periphery could mean they favour areas with minimal human presence (Andama 2000).

Adaptations Nocturnal and arboreal. Preference for heights between 5 and 35 m, possibly rarely going higher than 40 m. Usually uses larger branches and lianas (90% 1–30 cm diameter) with preference for those that are horizontal or obliquely inclined. Comes to the ground to cross deforested areas (Charles-Dominique 1978), or to forage, and is commonly captured in terrestrial traps. During the day, rests on thick horizontal branches or in dark and secluded

Two-spotted Palm Civet *Nandinia binotata*.

holes or crevices formed by vegetation 12–15 m in height. Sick or severely wounded animals sleep on the ground (Charles-Dominique 1978).

Both fore- and hindlimbs plantigrade. When walking on a branch the forefeet, when brought forward, are usually partially supinated. Adaptations to agile arboreal climbing are the large, soft and finely ridged palms on both fore- and hindfeet. The heels or tarsi of the hindfeet bear deeply carunculated, transversely ridged pads of thick skin that serve as friction pads. Able to climb a smooth post and descend head first by 'vertical looping', i.e. gripping the trunk, spread-eagled, with claws and hairless pads of forefeet, then bringing both hindfeet forward until they touch the forefeet (Taylor 1970a, 1974, 1976). Tail is used as a balancing rod when walking thin branches, and although not prehensile, can be wrapped around branches for support. Able to walk on steel wire (Van Rompaey 1997) and jump across gaps of about 1 m as well as jump as high as 1.8 m (Taylor 1970a; H. Van Rompaey pers. obs.). Thorneycroft (1958) observed an individual 'volplaning' several times from a high branch, with extended tail and legs stretched out, and making a perfect four-point landing.

Foraging and Food Predominantly frugivorous, although known to forage opportunistically for vertebrates and insects. In Gabon, 86% of 22 digestive tracts contained fruit and 32% yielded mammals, bird eggs, or insects. An average stomach contained ca. 75 g of fruit, while prey made up about 20% of fresh weight contents (Charles-Dominique 1978). In Zimbabwe, 60% of the stomachs ($n = 10$) contained vegetable matter, 30% bird remains, 10% murids and 10% Isoptera (Smithers 1983). In Central African Republic remains of eight scats contained ca. 44% fruit, 25% arthropods and 15% mammals (Ray & Sunquist 2001). In Uganda scats contained remains of bird's eggs (28.8%), wild fruits (24.3%), insects (20.3%) and rodents (20.2%) (Andama 2000). In the East Usambaras, scats had a high proportion of millipedes and fruit material of several plant species (N. Cordeiro pers. comm.).

Two-spotted Palm Civets are frequent raiders of crops and poultry (Naughton-Treves 1998, Skinner & Chimimba 2005). An individual in E Zimbabwe was killed after it had attacked and killed five full-grown turkeys; the stomach contained remains of a young turkey (J. M. Hutton pers. comm.). A captive killed a Potto *Perodicticus potto* and attacked a sleeping half-grown Mona Monkey *Cercopithecus mona* (Ewer

1973). In Cameroon a wild Potto was also attacked and eaten (Pimley 1999). Charles-Dominique (1977) observed on two occasions a fight between an adult Potto and a young Two-spotted Palm Civet; both times the carnivore gave up the struggle. Decher *et al.* (2010) observed an individual in Sierra Leone catching a small fruit bat, possibly Peter's Dwarf Epauletted Fruit Bat *Micropteropus pusillus* or Veldkamp's Bat *Nanonycteris veldkampii*. Also known to eat carrion (Bates 1905).

In attacking wild prey extensive use is made of the forefeet. Prey is usually taken with the forefeet and pressed to the substratum or held and bitten in quick succession all over the body until dead (Leyhausen 1965). Fruit is generally consumed in 5–10 min, after which the animal rests while stretched out on a branch 10–20 m away; such meals are taken about every two hours. Intestinal transit is fast and fruit is eliminated 2–3 h after it is eaten, its colour and aspect little changed (Charles-Dominique 1978). In Shimba Hills, Kenya, the Two-spotted Palm Civet probably assists the dispersal of at least 12 plant species (Engel 2000).

Captive specimens are reported to show a weakness for alcohol that may originate from consumption of fermented fallen fruit and tree exudates (Kingdon 1977). Widely reputed for drinking palm wine directly from vessels in palm trees in Sierra Leone and throughout the Niger Delta (Thompson 1858, Van Rompaey & Powell 1999).

Social and Reproductive Behaviour Predominantly solitary but young accompany the mother until approaching adult size. When in fruit, the groves of parasol trees *Musanga cecropioides* have been recorded attracting 12–15 individuals, sometimes several individuals into the same tree at the same time (Kingdon 1977). Usually they sleep alone but sometimes a ♂ and ♀ sleep in proximity to one another (Charles-Dominique 1978).

In Gabon Charles-Dominique (1978) recorded that ♂♂ have larger home-ranges than ♀♀: average 85 ha (34–153) vs. 45 ha (29–70). Male home-range size is related to number of available ♀♀ rather than nutritional needs. Although adult male home-ranges often overlap, broadly they consist of distinct sectors. Large ♂♂ will visit all sectors regularly while smaller ♂♂ tend to stay in their own sectors and away from dominant ♂♂. The home-range of a dominant ♂ can cover the home-ranges of several ♀♀. Adult ♀♀ have clearly delimited home-ranges with very narrow overlap zones along borders only a few metres wide where scent-marks are placed. Immature daughters remain with their mothers. Young ♂♂ seem to leave the maternal home-range as soon as they are weaned and inhabit a sector in the home-range of the dominant ♂. Their home-ranges being large, dominant ♂♂ seldom meet, but when they do fights can be very violent and the loser may die from his wounds. Such sexual competition appears to accentuate weight loss or gain, with dominant ♂♂ often becoming heavy while the surviving loser becomes thinner with smaller testicles and perineal glands, symptoms of social stress. Adult ♂♂ and ♀♀ and immature animals may feed at the same time at the same fruit tree, with ♀♀ having priority access to the food (Charles-Dominique 1978).

Scent-marking plays a role in communication and marking. The perineal gland is rubbed on branches while the hindlegs are flexed and the odour can persist for several months (Charles-Dominique 1978). Between the third and fourth toe of each foot there is a glandular pocket overlain with a patch of yellow fur, presumably also used to apply scent to trails and particularly to the scratch marks on bark (Vosseler 1928).

A dominant ♂ and neighbouring ♀ communicate with a loud cry, a plaintive 'hou' repeated five or six times, which can be heard over a distance of nearly 1 km. In Gabon such calls were at their maximum in Jun when one ♀ was found in oestrus (Charles-Dominique 1978). The same calls, called 'hooting' by Wemmer (1977), were made several times a night by two young captive ♂♂ up to the age of ca. one year (H. Van Rompaey pers. obs.). During courtship a captive pair produced apparently friendly close-range sounds, akin to coughing (Peters 1984).

Reproduction and Population Structure Births in Gabon occurred chiefly from Sep to Jan (long wet season and beginning of short dry season), occasionally in other months, but none was observed during Mar–Jun (Charles-Dominique 1978). In Côte d'Ivoire, a birth was noted in Oct (Bourlière *et al.* 1974). A ♀ captured in Zimbabwe in Jul had two foetuses (Smithers & Wilson 1979) while in Zambia Ansell (1960a) recorded a month-old juvenile in Oct.

Usually two young are born after a gestation of ca. 64 days; there are two litters per year (Rettig & Divers 1978). Weight ca. 56 g at birth, and young are born with eyes and ears closed. Will accompany mother to visit fruit trees as soon as able (Charles-Dominique 1978). Adult size and weight attained at 6–9 months (Happold 1987).

A captive specimen lived to 16 years and 5 months (Van Rompaey 1997) and a longevity survey listed a record of 21 years (Weigl 2005). Longevity in the wild is probably considerably less.

Predators, Parasites and Diseases Presumed to be preyed upon by larger carnivores, birds of prey and pythons. Preyed on by Leopards *Panthera pardus* in Gabon (Henschel *et al.* 2005) and Congo (Ososky 1998), and occasionally by the very arboreal African Golden Cat *Profelis aurata* in Cameroon (T. R. B. Davenport & G. Ngandjui, pers. comm.).

The following parasites have been recorded: a parasitic nematode *Kalichephalus* sp. in a captive specimen (Herman 1939); *Rictularia proni* and *R. dollfusi* in the intestines of specimens from Congo (Chabaud & Rousselot 1956, Vuylsteke 1956); *Cercopithifilaria corneti* in the subcutaneous tissues of a specimen from Central African Republic (Bain *et al.* 1987); and *Setaria* sp. in a stomach tumour (Walton 1927); nymphs of *Armillifer armillatus* in the coelomic cavity of a specimen from Cameroon (Heymons 1940); and *Trichinella britovi* from two (out of 45 examined) specimens in Guinea (Pozio *et al.* 2005). The louse *Felicola hopkinsi* (Werneck 1948) was recorded from an animal in Uganda. Ticks recorded include *Haemaphysalis (Rhipistoma) moreli* and *H. (R.) punctaleachi* in DR Congo (Camicas *et al.* 1972, 1973) and *Ixodes moreli*, *I. rarus* and *I. oldi* (Arthur 1965, Keirans *et al.* 1982).

Two-spotted Palm Civets inoculated with yellow fever virus either showed neutralizing antibodies for a while or developed a durable immunity (Dick 1952). The serum of a specimen from Kenya tested for complement-fixing antibodies reacted significantly to *Coxiella burnetii* (Heisch *et al.* 1962). Microfilariae are listed by Rewell (1948). Trypanosomes responsible for sleeping sickness, including *Trypanosoma brucei* non-gambiense group 1, *T. b. gambiense* group 1, and *T. vivax*, have been found in specimens from S Cameroon (Herder *et al.* 2002).

An old captive individual developed trophic ulcers of the tail, caudal cellulitis and died of septicaemia (Hamerton 1945); another suffered from rachitis and osteodystrophia and died of broncho-pneumonia (Hamerton 1941). Lovell (1930) described the lesions of an individual that died from tuberculosis; McKinney (1970) described lesions of hyaline arteriolosclerosis in a wild-caught specimen from East Africa.

Being arboreal the Two-spotted Palm Civet is prone to falls and fractures: a wild-caught individual had a clean break across its right femur and a fractured patella, both of which had healed (Taylor 1971b).

Conservation IUCN Category: Least Concern. CITES: Not listed. Although widely distributed, and present in many protected areas across its range, the close association of the Two-spotted Palm Civet with closed-canopy forest suggests vulnerability in the face of total deforestation, particularly in eastern and southern Africa, where the species' range is already fragmented. Two-spotted Palm Civets are commonly trapped, shot or persecuted by humans when raiding chicken coops or fields (see Campbell [2009] for results of a study of human reactions to the species in Ghana), as bushmeat, and for traditional medicine. They were the most common carnivore recorded (60% of 121 carcasses) in two markets in Rio Muni, Equatorial Guinea (Juste *et al.* 1995) as well as in Guinea (Colyn *et al.* 2004). In Kisangani region, DR Congo, they represented 10% of small carnivores trapped as bushmeat (Colyn *et al.* 1987), and in SE Cameroon 30.6% of carnivores trapped for bushmeat and 16.5% of trapped carnivore biomass (Ngandjui 1998, T. R. B. Davenport & G. Ngandjui pers. comm.). They are also hunted for meat in some parts of Uganda (Andama 2000). In Congo and Gabon, the fur is eagerly sought after to make ceremonial dresses (Malbrant & Maclatchy 1949) and in NE DR Congo to make wrist-bracelets, hats and to cover the bow (Carpaneto & Germe 1989).

Measurements
Nandinia binotata
HB (♂ ♂): 486 (398–625) mm, n = 34
HB (♀ ♀): 457 (370–610) mm, n = 38
T (♂ ♂): 538 (430–762) mm, n = 34
T (♀ ♀): 504 (340–701) mm, n = 38
HF c.u. (♂ ♂): 88 (76–100) mm, n = 29

The cat family, Felidae, is a morphologically highly uniform family of hypercarnivores, to the extent that if soft tissues are removed it is a specialist task to distinguish between such externally different species as the Lion *Panthera leo* and Tiger *P. tigris*. An important cause of this uniformity is the relatively young age of the subfamily Felinae, to which all living cats belong. This subfamily probably originated no more than about 11 mya (Johnson *et al.* 2006). As shown by the fossil record, however, felids are older and have been highly diverse: living cats are simply a restricted subset of this variation. The phylogeny and evolution of the Felidae has long been a contentious issue, especially as regards the living cats. Various ideas regarding the interrelationships of living cats were summarized in Werdelin (1996b). Johnson *et al.* (2006) carried out an extensive molecular study of cat phylogeny and have updated this issue. In their view, living cats can be subdivided into eight major clades (Panthera lineage, Bay Cat lineage, Caracal lineage, Ocelot lineage, Lynx lineage, Puma lineage, Leopard Cat lineage and domestic cat lineage). These

split off sequentially from the ancestral forms between ca. 11 and ca. 6 mya. Four of these clades have African representatives, the Panthera lineage (Lion and Leopard *P. pardus*), the Caracal lineage (Caracal *Caracal caracal*, Serval *Leptailurus serval*, African Golden Cat *Profelis aurata*), Puma lineage (Cheetah *Acinonyx jubatus*) and domestic cat lineage (Wildcat *Felis silvestris*, Sand Cat *F. margarita*, Swamp Cat *F. chaus*, Black-footed Cat *F. nigripes*). Of these, the Caracal lineage appears to be an endemic African group, with the Caracal only recently spreading to south-western Eurasia and the Indian sub-continent. This new, molecular perspective on cat phylogeny has also had an impact on taxonomy within the family, long a subject of dispute. In the primary taxonomic literature, genus-level names have proliferated (see summary in Werdelin 1996b), but it has been and still is common to see cats classified into only three genera: *Acinonyx* (the Cheetah), *Panthera* (the large 'roaring' cats) and *Felis* (all other cats). However, the study by Johnson *et al.* (2006) has shown, definitively, that this cannot be maintained. The Cheetah is related to the Puma *Puma concolor* and Jaguarundi *P. yagouaroundi* and is not distinct from other cats, and there are a number of lineages that despite the apparent morphological uniformity are as old as any lineages in other carnivore families and should therefore be accorded distinct generic names. Above the genus level, the taxonomy of cats has been equally contentious. Wozencraft (2005) has divided the family Felidae into two subfamilies, Pantherinae, including the large cats of the genera

Tentative phylogenetic tree for African Felidae; at least 6 separate ancestral immigrations shown (O) (adapted from Johnson *et al.* 2006).

Panthera, *Uncia* and *Neofelis*, and Felinae, including all other living cats. Such a subdivision is compatible with the recent phylogeny of Johnson *et al.* (2006). However, as noted, fossils show that the modern radiation of cats is a subset of the full variation within the family and the same authors have shown the radiation of modern cats to be no older than late Miocene. Division at the subfamily level is, therefore, not tenable for modern cats as it would, among other difficulties, require raising various groups of sabre-tooth cats into separate families. A subdivision compatible with the fossil record is lowering the rank of the two above-mentioned groups to the tribes Pantherini and Felini, with all living cats placed in the subfamily Felinae.

In the African fossil record representatives of the living cats are relatively rare compared with sabre-toothed cats (of the subfamily Machairodontinae). The geologically oldest cat in Africa is *Asilifelis* from the late early Miocene site of Rusinga Island, Kenya (Werdelin 2012). This taxon is of unknown relationships and origin. The continuous record of cats in Africa begins in the late Miocene (ca. 10 mya), with the appearance of sabre-tooth cats with clear antecedents in Eurasia. Fossil Felinae appear at about the same time, but remain rare in the fossil record until the Pleistocene (last 1.5 my). Sabre-tooth cats are known from a number of late Miocene sites in Africa (e.g. Werdelin 2003a). In the Pliocene, all three major lineages occur: *Homotherium*, a large genus with some cursorial adaptations, is quite ubiquitous, being found from 4 mya until about 1.5 mya. The smaller, more forest adapted, *Megantereon* occurs in only a handful of sites between 3.5 and 1.5 mya. *Dinofelis*, the commonest sabre-tooth cat in Africa, made a substantial radiation, beginning about 6 mya (Werdelin & Lewis 2001). It might have been the last sabre-tooth cat to become extinct in Africa (with a last appearance at about 1 mya). Small cats belonging to the modern Felinae make their first appearance about 4.1 mya (Werdelin 2003b). Large cats of the genus *Panthera* first appear about 3.85 mya at Laetoli in Tanzania (Werdelin & Deghhani 2011), but are subsequently very rare in the fossil record until the end of the Pliocene, ca 1.8 mya, after which they become somewhat more common, possibly as a result of the extinction of large sabre-tooth cats.

Living cats vary greatly in size, from about 2–3 kg in the Black-footed Cat, the Kodkod *Leopardus guigna* and the Rusty-spotted Cat *Prionailurus rubiginosus* to about 300 kg in a large male Tiger. Sexual

Lion *Panthera leo* myology.

Lion *Panthera leo* skeleton.

dimorphism is limited but ubiquitous, with males in most species being about 5–10% larger than ♀♀ (although difference in mass between sexes is greater, as much as 25–100%; see Sunquist & Sunquist 2002). Body shape does not vary dramatically in cats, though differences can be noticeable when comparing, for example, the Cheetah with the lynxes. In general, however, differences between living cats in this respect are slight, while the difference in body shape between living cats and sabre-tooth cats is much greater (Martin 1980, Martin *et al.* 2000).

The karyotype of all cats is $2n = 38$, except in the Ocelot lineage (though the Kodkod and Andean Mountain Cat have not yet been karyotyped), where it is $2n = 36$ as the result of a fusion of two F group chromosomes into a metacentric C3 (Collier & O'Brien 1985). Cat evolution has been marked by a number of rare insertions and deletions of genes and gene families that help systematists to characterize the various cat lineages (summarized in Johnson *et al.* 2006).

All cats, living and extinct, are hypercarnivores, and this is reflected in their shared fundamental adaptations, some of which are outlined below. The basic dental formula of the living Felidae is $I^{3/3}, C^{1/1}, P^{3/2}, M^{1/1} = 30$ (although some species, notably the genus *Lynx*, retain only two premolars in the upper jaw; Russell *et al.* 1995). Primitive fossil cats had a fuller complement of teeth, but dental reduction went further in some sabre-tooth cats, with loss of the anterior premolar in the mandible as well as in the upper jaw (Turner & Antón 1997).

The skull in small cats is rounded, while in large cats it is more elongated, with a more extended muzzle. The orbital space in the skull is large and faces more or less forwards. It is normally open to

the side, though in many cases, especially in small cats, it can be closed by cartilage. The zygomatic arches flare, leaving room for large temporal muscles, which make up the main masticatory musculature. Small cats show only limited sagittal and nuchal crests, but these are much more prominent in the larger cats. The presence of extensive crests and elongated canines in the relatively small Clouded Leopard combine with its position at the base of the molecular tree to suggest that this species evolved from larger ancestors. By contrast, less extensive crests in the larger Puma suggests that it evolved from smaller ancestors (Werdelin 1983).

All cats are digitigrade and have five toes on the forefoot and four on the hindfoot. The forelimbs of cats have dual functions; they are, of course, part of locomotion, but they also function in prey capture. These two functions are often at odds with each other, since a forelimb that has optimal running ability cannot also have optimal grasping ability. While the forelimbs of other cats are primarily adapted to grasping and prey capture, the Cheetah forelimb has evolved specializations for high-speed locomotion (Andersson 2004). All cats have protractile claws (they are retracted in the resting position)

that are protected in a fleshy sheath when retracted. The sheaths are vestigial in the Cheetah (as well as in Fishing Cat *Prionailurus viverrinus* and Flat-headed Cat *P. planiceps*) such that the claws protrude visibly.

The tail is of variable length in cats. Some cats, such as the Leopard and Cheetah, have very long tails that serve an important function in counterbalancing the weight of the body when climbing or running. Other cats, such as the lynxes and the Caracal, have short tails. The functional basis for this reduction is not fully understood. The shortening of the tail is due to a combination of a (slight) reduction in the number of vertebrae in the tail and a (considerable) decrease in the size of the individual vertebrae.

Though still important, the sense of smell is less important in cats than in other carnivores, as shown by the fact that the areas of the brain concerned with processing smell are smaller in cats than in most other carnivores (Radinsky 1975b). Further, the olfactory epithelium in cats has less surface area than in, for example, dogs. The relative reduction in the sense of smell in cats is to some degree compensated for by the whiskers or vibrissae. These are specialized sensory hairs with an important tactile function, which can be clearly seen in walking cats, which extend the whiskers on the muzzle forwards to feel the surroundings. This function is particularly important for cats that hunt at night: hence the Cheetah, which strictly hunts by day, has less developed whiskers than other cats.

Prominent features in the eyes of domestic cats are the pupils, which reduce to vertical slits in strong light. However, not all wild cats have vertical, slit-like pupils. Many species, especially among the larger cats, have round pupils. Exactly why some cats have one or the other is not well understood, but slit-like pupils possibly confer an advantage to animals that hunt in poor light, as this allows for a greater range of pupil

size, from extremely large by night to almost entirely closed in bright daylight. Preliminary study (Werdelin *et al.* 2010) shows that round pupils are never found in animals that are specialized for hunting in closed environments. The latter animals are more likely to hunt in poor light condition, lending some credence to the theory. This is only one of several adaptations in cats to activity in poor light conditions. Another is the pre-eminence of light-sensitive but colour-insensitive rods in the eye, which improves night vision but not sensitivity to colour. A third is the presence of a reflecting layer, the tapetum lucidum, in the back of the eye. Visual acuity varies in cats. Some have a relatively broad, rounded area of maximum visual acuity on the retina (the so-called visual streak). Species that hunt by sight, such as the Cheetah, often need to detect prey moving against the horizon, and their visual streak is a narrow line across the retina (Hughes 1977, 1985).

Hearing is an important sense in cats. They can hear a much wider range of sounds than humans, with the practical range being somewhere between 200 Hz and 65 kHz. The ability to hear very high frequency sounds is especially useful to small cats, as it allows them to detect the ultrasonic communication of small rodents. Since these sounds are of very low intensity, the external ear is large in some species, such as the Serval and Sand Cat. The large ear allows these cats not only to hear low-intensity ultrasounds, but also to detect the sound of small rodents running through the undergrowth. In the skull, the chamber surrounding the ear ossicles, the so-called

auditory bulla, is large in all cats. This is especially true of desert cats (and, indeed, of other desert animals). It is believed that such a large bulla enhances auditory acuity in the desert situation, where the ambient sound level is much lower than in other biotopes.

Members of the cat family are typically solitary, but they are sometimes found in pairs or larger groups, the most social species being the pride-living Lion. Communication is mainly by means of vocal, visual and chemical signals. Most species are nocturnal, but many also are active by day, and some, such as the Cheetah, do most of their hunting during the early hours of the morning and late afternoon, largely to avoid competition with other larger predators. Females are polyoestrus and although copulations are often brief, there may be repeated copulations over a short period of time (Lions, for example, have been recorded copulating 157 times over a 55-hour period; Schaller 1972). It is thought that repeated copulations may be necessary to induce ovulation, although male cats have a baculum and penile spines, suggesting a connection between sexual stimulation and ovulation (Sunquist & Sunquist 2002). Gestation length in felids varies greatly depending upon body size, with larger species having longer gestation periods, and litter-size is usually in the order of 2–3 young, although litter-sizes of as many as eight have been recorded in the Cheetah and the Sand Cat.

Lars Werdelin

Subfamily FELINAE – Cats

Felinae Fischer de Waldheim, 1817. Mém. Soc. Imp. Nat. Moscou 5: 372.

Contra the classification of Wozencraft (2005), the subfamily Felinae is here taken to include all living cats, comprising two tribes: Pantherini (for cats of the genera *Panthera* and *Neofelis*), and Felini (for the remaining members).

Tribe PANTHERINI – Roaring Cats

Pantherini Pocock, 1917. Ann. Mag. Nat. Hist., ser. 8, 20: 332.

Tribe Pantherini includes the larger-bodied cats of the genera *Panthera* and *Neofelis*. Only *Panthera* is represented in Africa (two species); *Neofelis* (clouded leopards) is Asian.

GENUS *Panthera*

Roaring Cats

Panthera Oken, 1816. Lehrb. Naturgesch. 3 (2): 1052.

The genus *Panthera*, often called the roaring cats, includes the largest members of the family. Two species, the Lion *Panthera leo* and Leopard *P. pardus*, occur in Africa; the other three species, Tiger *P. tigris*, Jaguar *P. onca* and Snow Leopard *P. uncia*, are extralimital. All species are united by the presence of an ossified hyoid bone, which gives them the ability to roar, hence the popular name (Pocock 1916d, Peters 1978, Peters & Hast 1994). The long-fanged Clouded Leopard is related to the aforementioned species, but is generally placed in a separate genus, *Neofelis*.

A recent molecular analysis by Johnson *et al.* (2006) has shown ancestral Clouded Leopards *Neofelis*, closely followed by an ancestor to the *Panthera* lineage, to be the first lineages to branch out from the main stem of emergent Felinae, some 11–10 mya. The inference that large cats emerged earlier than the smaller species has long had some support but apparently contradicts the fossil record because all known

Miocene Felinae fossils are small. However, the same study found that the radiation of modern species of *Panthera* is recent, mainly taking place in the late Pliocene, 3–2 mya. This accords well with the fossil record, as the oldest *Panthera* fossils come from Laetoli, Tanzania, with an age of 3.85–3.63 million years (Werdelin & Dehghani 2011).

The coat pattern of *Panthera* species is of spots characteristically placed into rosettes, the form and visual function of which have been analysed in some detail by Kingdon (1977), and see Volume I pp. 121–122, who suggested that this pattern type must have been developed in the common ancestral stock of Leopards, Lions and Tigers (the latter still exhibiting every graduation from lozenge-shaped rosettes to full stripes). Werdelin & Olsson (1997) have also suggested that the stripes of the Tiger may be very elongated rosettes.

Lars Werdelin

Leopard *Panthera pardus* spot patterns around eye and mouth.

Lion *Panthera leo* skinfolds between nostrils and eyes during 'snarl'.

Panthera leo LION

Fr. Lion d'Afrique; Ger. Lowe

Panthera leo (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 41. 'Africa', restricted by J. A. Allen (1924: 222) to 'the Barbary coast region of Africa, or, more explicitly, Constantine, Algeria'.

Lion *Panthera leo* male.

Taxonomy More than 20 subspecies have been described from parts of the African continent, many of which were based on specimens from zoological gardens. Since captive conditions influence skull shape (Hollister 1917), such specimens have little value for basing taxonomic descriptions. Many authorities have not recognized subspecies (Ellerman *et al.* 1953, Smithers 1975, Meester *et al.* 1986), although Hemmer (1974a) recognized seven subspecies in Africa, as did Nowell & Jackson (1996). Few quantitative data exist on the differences between the subspecies, and, in general, while isolation of Lion populations causes a loss of genetic heterozygosity in some areas (Wildt *et al.* 1987) and significant genetic differences between subspecies may exist (S. J. O'Brien pers. comm.), subspecies are morphologically indistinct. O'Brien *et al.* (1987) found that populations from the Serengeti and Kruger National Parks were so genetically similar as to warrant inclusion in a single African race, *P. leo leo*. Subsequent genetic evidence has supported distinction between an African – Asian subspecies (Dubach *et al.* 2005, Antunes *et al.* 2008). However, this seems less well supported by studies including better sampling from West and central Africa, which show a clear distinction between West and central African Lions (including India) on the one hand, and southern and East African lions on the other (Bertola *et al.* 2011). Synonyms (Africa only): *africana*, *azandica*, *barbara*, *barbarica*, *bleyenberghi*, *bleyenberghi*, *capensis*, *gambiana*, *hollisteri*, *kamptzi*, *krugeri*, *maculates*, *massaica*, *melanochaita*, *melanochaeta*, *nigra*, *nobilis*, *nubica*, *nyanzae*, *roosevelti*, *sabakiensis*, *senegalensis*, *somaliensis*, *vernayii*, *webbiensis*. Chromosome number: $2n = 38$ (Wurster & Benirschke 1968).

Description The largest of Africa's carnivores, and second largest member of the family Felidae (after the Tiger *Panthera tigris*), standing as much as 1.25 m at the shoulder. Body muscular and deep-chested;

head relatively short-muzzled and round-faced with prominent whiskers and white chin. The base of each whisker, or vibrissa, is visible as a dark spot 1–2 mm wide and the majority of vibrissae are organized into 4–5 horizontal rows on either side of the muzzle. The random spots found above the top row of whiskers act as 'fingerprints' that distinguish individuals (Pennycuik & Rudnai 1970). Ears relatively small and round, and often scarred; backs of the ears black in sharp contrast to the remainder of the body. Eyes vary from pale yellow to dark brown.

Dorsal pelage ranges from pale gold to amber, with pale or white inner limbs and ventral surface. Young animals are spotted with rosettes that fade at maturity. Some adults retain vestigial spots on abdomen and legs. Dorsal pelage short and dense. A reversal in the direction of growth of the hair on the upper parts in the lumbar region forms a short transverse crest of upstanding hair when it meets the opposite-growing hair about the mid-dorsal region. Adult ♂♂ are distinguished by a mane of longer hair covering the head, neck, chest, elbows and occasionally belly. Considerable variation occurs in the extent of mane coverage with 'maneless' prime-aged ♂♂ common in some regions. Mane colour varies from platinum to black and is often patchy with lighter hair surrounding the face. Variation in mane characteristics occurs both within and between populations. Growth of mane begins in subadult ♂♂ at approximately 6–8 months in some habitats, but appears to be delayed in warmer climates (West & Packer 2002, Gnoske *et al.* 2006).

Limbs heavy and muscular, ending in large padded feet. Front feet with five digits of which the first is set well back, not marking in the spoor; hindfeet with four digits. All digits equipped with sharp, retractable claws. Tail thick, muscular and tapered, and just over half the length of head and body. Tail tip has tuft of long, dark or black hairs concealing a horny spur present in some animals (Schaller 1972). There are anal glands present, with ducts opening either side of the anus. Sexual dimorphism pronounced in size (perhaps more so than in any other terrestrial carnivore) as well as pelage; adult ♂♂ are typically 30–50% larger than adult ♀♀. Females have two pairs of nipples, very rarely three (Ewer 1973).

In profile, the skull is comparatively flat on top compared with that of the Leopard *Panthera pardus*. The highest point of the skull lies between the postorbital process from where it slopes off gradually forwards to the nasals and rather more abruptly to the supraoccipital crest. Postorbital processes broad and incomplete. Skull high and wide relative to overall length, and braincase small relative to size of skull (and lacks the pear-shaped outward bulge seen in the Leopard). Zygomatic arches broad and robust (providing upper attachment for masseter muscles) and swing outward at the back to allow room for the massive temporalis muscles. Sagittal crest is prominent, substantially deepening the upper attachment of the temporalis muscles. Mandible massive, its processes deeply hollowed out posteriorly to accommodate lower attachments for the masseter and temporalis muscles.

The upper outer incisors are rounded, heavily built and recurved; the lower outer incisors do not reach the same size as those in the

Lateral, palatal and dorsal views of skull of Lion *Panthera leo*.

upper jaw. The upper canines are sharp, slightly flattened on their inner sides, and have a fine longitudinal groove; they are as much as 50 mm in length, only slightly longer than the lower canines. The first lower molar has a sharp edge, which, occluding on the back half of the fourth upper premolar, serves to keep the edges of these two teeth continually sharpened. The small upper first molars, set at an angle to the cheekteeth, become worn on their front edges and while they may assist in keeping food from sliding backwards during the process of slicing, have little or no grinding ability (Ewer 1973, Rosevear 1974, Skinner & Chimimba 2005).

Geographic Variation Although genetic research and much individual variation argue for African Lions being monotypic, regional differences are perceptible and have given rise to an extensive, but not always consistent, nomenclature. The following subspecific names are those listed by Hemmer (1974a) and Nowell & Jackson (1996).

- P. l. azandica* (includes *massaica* partim and *somaliensis* partim): NE DR Congo.
- P. l. bleyenberghi* (includes *bleyenberghi*) (Angolan Lion): Shaba and Kasai woodland Savanna regions of S DRC, and presumably also neighbouring parts of Zambia and Angola.
- P. l. krugeri* (includes *vernayi*) (Transvaal Lion): Kalahari region east to E South Africa.
- P. l. leo* (includes *barbarica*, *barbarus* and *nigra*) (Barbary Lion): coastal woodlands of Morocco through Tunisia. Extinct in the wild.
- P. l. melanochaita* (includes *melanochæta*) (Cape Lion): Cape region of South Africa. Extinct.

P. l. nubicus (includes *hollisteri*, *massaica* partim, *nyanzæ*, *roosevelti*, *sabakiensis*, *somaliensis* partim, and *webbiensis*) (Nubian Lion): north-east and East Africa.

P. l. senegalensis (Senegalese Lion) (includes *gambianus*, *kamptzi* and *nobilis*): West Africa, east to the Central African Republic.

The Asiatic Lion *P. l. persica* is extralimital, and now confined entirely to the Gir Forest in India. The Asian subspecies is characterized by a longitudinal fold of skin running along the belly (Pocock 1930), although this fold is also sporadically present in African populations.

Melanistic forms of the Lion are extremely rare, but very pale ones are known from some regions, such as from Kaokoland, SW Botswana and the Pangani Valley in Tanzania. The 'white Lions' from Timbavati G. R. in the Limpopo Province of South Africa and from Kruger N. P. (McBride 1977, Robinson & de Vos 1982, Smuts 1982) are not albinos; the eyes retain the normal yellow pigment as opposed to the pink-red colour observed in albinos (Cruickshank & Robinson 1997). These Lions represent one of two possible mutations known as chinchilla or acromelanic albinism. Like albinism, these mutations arise from the same gene locus in the individual's chromosomes. The white-coat phenotype likely is inherited in an autosomal recessive manner (Cruickshank & Robinson 1997).

Similar Species

Panthera pardus. Broadly sympatric. Strongly spotted and more lightly built. Possibly immature, faintly spotted Lions could be confused with Leopards.

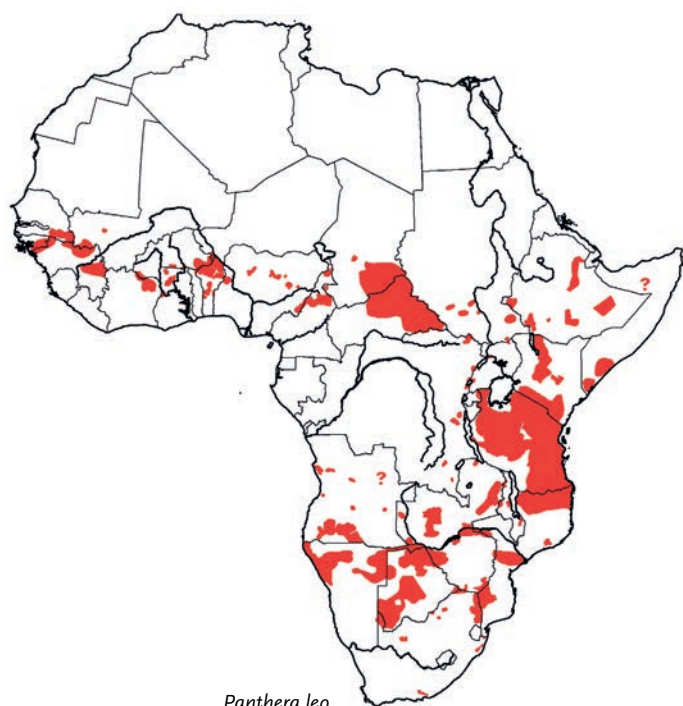

Distribution

Historical Distribution Lions formerly occurred across most of the African continent, except in equatorial forest and the inner regions of the Sahara. From North Africa, their range extended outside of the African continent, ranging through south-west Asia, west into Europe and east to India (Guggisberg 1961, Sunquist & Sunquist 2002, Schnitzler 2011). Based on fossil evidence, during the late Pleistocene, large Lion-like felids (generally considered to be *P. leo* or closely related to it) were distributed across most of Africa, Europe, Asia, North America and the northern part of South America; these Lions became extinct in the Americas and northern Eurasia ca. 10,000 years ago (Turner & Antón 1997; and see Yamaguchi *et al.* 2004a).

Lions were brought to extinction at various points in the Holocene: 3000 BC for temperate Europe; 1000 BC in the south of Greece; 12–13th century in the Near East, Arabian Peninsula, Trans-Caucasia or north of Afghanistan; and 19–20th century for North Africa and the Middle East (Schnitzler 2011).

Current Distribution Today, Lions are extinct in North Africa. They disappeared from the Moroccan coast by the mid-1800s, but may have survived in the High Atlas Mts up to the early 1940s (Cuzin 2003). The last-known Lion in Algeria was killed in 1893 near Batna, 97 km south of Constantine, while the last-known individual was killed in Tunisia in 1891 near Babouch, between Tabarka and Ain-Draham. Lions were extirpated from Tripolitania (N Libya) as early as 1700 (Guggisberg 1961, Nowell & Jackson 1996).

In general, Lions have undergone dramatic range retraction at the limits of the historical distribution: according to Ray *et al.* (2005) they have lost some 83% of their historical range in Africa. They

remain widespread in Africa from the southern Sahara to South Africa, excluding the equatorial rainforest belt, but many previously contiguous populations are now found in isolated enclaves. Populations today are largely restricted to protected areas and surrounding conservancies. There is strong evidence that no resident lion populations remain in Gabon, Congo, Côte d'Ivoire and Ghana (Henschel 2009, Henschel *et al.* 2010).

Extralimital to the African continent, Lions disappeared from Europe around AD 100 and in Palestine around the time of the Crusades (Guggisberg 1961). They remained widespread elsewhere until the mid-1800s when the advent of firearms led to the species' extinction over large areas. The last known Lion in Turkey was killed in 1870 near Birecik on the Euphrates (Üstay 1990), while the last reports from Iran and Iraq date to 1957 (see references in Schnitzler 2011) and 1918 (Hatt 1959), respectively. In India, the last report is of a sighting of a Lion in the Bolan Pass in 1935 (Guggisberg 1961). In India, Lions ranged east to the state of Bihar and Orissa, but by the turn of the century, the Asiatic Lion was confined to the Gir Forest, where it was protected by the Nawab of Junagadh in his private hunting grounds (Kinnear 1920). A detailed review of the former distribution of Lions in North Africa and extraliminally is given by Schnitzler (2011).

Habitat Lions display a wide habitat tolerance, persisting in virtually all habitats with the exception of rainforest and the interior of the Sahara Desert. They occur in semi-desert regions, as in parts of West Africa and in the Kalahari regions of South Africa and Botswana, and even formerly occurred in desert on the edge of Niger's Air Mountains (Rosevear 1974). Lions may range up to 3600 m on Mt Elgon and Mt Kenya (Young & Evans 1993), to 4200 m in the Bale Mts in Ethiopia (Yalden *et al.* 1996), and there is a record of one sighted at 4300 m on Mt Kilimanjaro (Grimshaw *et al.* 1995); formerly recorded to 3000 m in the Moroccan High Atlas (Cuzin 2003). Although they drink regularly if water is available, water is not an essential habitat requirement.

Abundance Data on the overall abundance of Lions are scarce. Two recent estimates put the total population at between 16,500 and 30,000 (Bauer & Van der Merwe 2004) and 29,000 and 47,000 (Chardonnet 2002): tallies from most of the range were 'informed guesses' or their equivalent in most cases (Bauer *et al.* 2005a, b) and should be treated cautiously. Lions are most abundant in East Africa (11,000–16,000) and southern Africa (10,000–20,000), with significantly smaller populations in central Africa (950–3000) and West Africa (850–1400) (Chardonnet 2002, Bauer & Van der Merwe 2004). According to the inventory of Bauer & Van der Merwe (2004), the largest populations in southern Africa occur in the Okavango Delta (1400), Kruger N. P. (2200), and Kafue N. P., Luangwa Valley and Lower Zambezi N. P. (1500); in East Africa, the largest populations occur in the Selous G. R. and surrounds (4500), the Serengeti ecosystem (2500; although, as of 2006, this estimate was revised to 3500, C. Packer pers. obs.) and Tsavo N. P. (675). No population in central Africa or West Africa numbers more than a few hundred individuals, the largest being that in the Benoue ecosystem (200) (Bauer & Van der Merwe 2004; but see Chardonnet 2002). The Asiatic Lion population in the Gir Forest currently stands at ~350 animals (Johnsingh *et al.* 2007).

Lion density is related to seasonal food availability with reported densities ranging from 0.17/100 km² in the Savute region of Botswana's Chobe N. P. (Viljoen 1993) to 1.5–2/100 km² (Kalahari Gemsbok N. P.: Mills *et al.* 1978; Etosha N. P.: Stander 1991), to 10/100 km² in Kruger N. P. (Smuts 1976, Funston *et al.* 2003) and the Serengeti Plains (Hanby *et al.* 1995), to as high as 40/100 km² in the Ngorongoro Crater (Hanby *et al.* 1995). Lions tend to live at densities higher than most other felids.

Adaptations As with all felids, Lions are highly specialized for a carnivorous life-style. Their tawny pelage renders them highly inconspicuous in dry grass and permits them to approach prey without being detected. Strong forearms and heavily muscled limbs enable short, powerful bursts of speed. Powerful jaws, huge canines and canine-like upper outer incisors facilitate the immobilization of prey by a strangling bite, while the remaining teeth are adapted to slicing meat. The greater size of ♂♂ assists them in capturing larger prey, as well as in monopolizing carcasses and imposing themselves upon ♀♀. As the largest of Africa's carnivores, Lions are well equipped to scavenge from other predators. Unpredictable prey availability and hunting success mean that Lions rarely capture prey every day. However, a distensible stomach enables them to gorge when meat is available and to wait several days before feeding again.

Lions prefer to drink water daily, but they can survive from the moisture obtained from fresh carcasses. Lions conserve energy and resources by spending a large proportion of each day asleep. Being sensitive to the heat of the day, they are primarily nocturnal. Panting is common only after exertion or a large meal (Schaller 1972). Other efforts to stay cool include lying on their backs and exposing their stomachs to the breeze. Tree climbing is not uncommon, especially in younger animals, and allows them to take advantage of breezes as well as to avoid flies (Fosbrooke 1963); in some situations it may also serve to keep Lions out of reach from dangerous animals (Makacha & Schaller 1969). Lions often rest on high points, including termite mounds and kopjes, and remain alert to feeding opportunities and intruding strangers.

Lions are the most social of all the felids and much of their sociality revolves around group territoriality. Both sexes are territorial,

Rooting of Lion *Panthera leo* tooththrow indicating slicing action during occlusion of upper and lower tooth rows.

marking their range with urine, roaring in chorus with pride-mates and expelling like-sexed strangers. Good territories complete with water, prey and hiding places for cubs are essential to raising offspring. Territories remain fairly constant over time with shifts in core areas coinciding with changes in water and prey availability. Males form coalitions with other ♂♂ thus increasing their ability to defeat other ♂♂ and to take over reluctant prides (Bygott *et al.* 1979). Female sociality derives from their need to exclude neighbouring ♀♀ from their territories as well as from the constant threat that incoming ♂♂ will kill their offspring. New ♂♂ accelerate the females' return to sexual receptivity by killing the cubs of the prior coalition (Bertram 1975), but groups of ♀♀ stand a chance of protecting their young from infanticidal ♂♂ whereas solo mothers are easily overpowered by the larger ♂♂ (Packer *et al.* 1990). An interesting adaptation, apparently unique among felids, is the ability of the ♀ to delay conception following the arrival of new ♂♂ to their pride. Females mate frequently with the new ♂♂, but fail to conceive over a period of approximately three months. The exact mechanism behind the delay is unclear, but it gives every appearance of allowing ♀♀ to evaluate new ♂♂ before committing to reproduction (Packer & Pusey 1983).

Physical adaptations are also related to the Lion's social system. The first Lions have been presumed to have been maneless, and maneless forms seem to have persisted in Europe, and possibly the New World, until around 10,000 years ago. It has been suggested that the maned form may have appeared between 320,000 and 190,000 years ago, and could have had a selective advantage that enabled it to expand to replace earlier maneless forms throughout Africa and western Eurasia (Yamaguchi *et al.* 2004a). The mane of the ♂ intimidates rivals and attracts ♀♀, but it also elevates surface temperatures and is associated with heat-related costs (West & Packer 2002), and manes may be reduced, or their development delayed, in hotter, moister climates (Selous 1908, West & Packer 2002, Gnoske *et al.* 2006). It has been hypothesized that the mane may also protect ♂♂ during fights with other Lions, but most attacks are directed away from the mane area and bites on the head and neck are often fatal regardless of mane characteristics (West *et al.* 2006). The possession of larger or darker manes also seems to indicate superior health and strength (West & Packer 2002). For example, in Ngorongoro Crater, a prolonged fight between a coalition of five ♂♂ and one of two ended in a draw; the smaller coalition was resident in the disputed pride and possessed much larger and darker manes. In fact, experiments using life-sized

models have revealed that both ♀♀ and ♂♂ are sensitive to variation in the characteristics of male manes; darker and longer manes seem to intimidate ♂♂ and to attract ♀♀ (West & Packer 2002). Thus, the mane appears to be a signal favoured by sexual selection occupying an important role in intra-specific communication. Spotted pelage on young animals may be the vestige of a time when Lion ancestors were restricted to forested environments, but it also renders the cubs inconspicuous while lying hidden in grassy, wooded or rocky nooks. The black ear and tail tips of adults aid in intra-specific communication, allowing Lions to follow each other through tall grass.

Roaring facilitates communication between pride members and serves as a warning to other prides (Schaller 1972, Grinnell 1994, McComb *et al.* 1994). Roaring is defined by low fundamental frequencies and lowered formant frequencies (Weissengruber *et al.* 2002) and is restricted, among the felids, to Lions, Tigers, Jaguars *Panthera onca*, Leopards and Snow Leopards *P. uncia* (sometimes called the 'roaring cats'). These species are unique among felids in having an incompletely ossified hyoid apparatus in which the epihyoideum is elastic rather than bony (Pocock 1916d, Weissengruber *et al.* 2002). This modification allows them to move the larynx from the palate and lengthen the pharyngeal passage (Hast 1989) allowing lower formant frequencies. Lower fundamental frequencies are probably produced by large, heavy vocal cords (Weissengruber *et al.* 2002). In Lions, the epihyoideum measures 150 mm when relaxed and 225 mm when stretched (Hast 1989). Although Schaller (1972) recorded several instances of purr-like vocalizations, it is generally agreed that a large pad in the vocal folds prevents Lions and the other roaring cats from true purring (Pocock 1916d, Weissengruber *et al.* 2002).

Foraging and Food Lions are generally thought of as predators of medium- and large-sized ungulates, but they are also known to eat rodents, hares, birds and reptiles (including tortoises), as well as to take down larger prey like Black Rhinoceroses *Diceros bicornis* (e.g. Brain *et al.* 1999, Matipano 2004). In a review of 32 studies from 48 different locations (all, except two, from Africa), Hayward & Kerley (2005) demonstrated a preference for prey species within a weight range of 190–550 kg irrespective of their availability, with an optimum weight of 350 kg. However, Lions often take prey substantially smaller than this range, reflecting their dietary opportunism. Species within the preferred weight range that are not significantly preferred generally have features that reduce predation either morphologically (e.g. horns of Sable Antelope *Hippotragus niger*), ecologically (e.g. Roan Antelope *H. equinus* and Sable occur at low density), or behaviourally (e.g. the large herd size and increased vigilance of Eland *Tragelaphus oryx*) (Hayward & Kerley 2005).

Most studies on foraging and feeding emanate from southern and East Africa. In Serengeti N. P., seven ungulate species account for 90% of all kills: African Buffalo *Syncerus caffer*, Common Wildebeest *Connochaetes taurinus*, Plains Zebra *Equus quagga*, Common Warthog *Phacochoerus africanus*, Thomson's Gazelle *Eudorcas thomsonii*, Hartbeest *Alcelaphus buselaphus* and Topi *Damaliscus lunatus*. During the wet season, Common Wildebeests are abundant on the plains and are then the most frequently killed prey; during the dry season, Thomson's Gazelles and Common Warthogs predominate. African Buffalo are mainstays when the migratory herds are absent (Scheel & Packer 1991). In Kafue N. P., Zambia, Giraffes *Giraffa camelopardalis*, made up 30% of kills (n = 410) followed by Impalas *Aepyceros melampus* and Common Elands

(Mitchell *et al.* 1965). In Hwange N. P., Zimbabwe, African Buffalo, Savanna Elephant *Loxodonta africana* calves, Giraffes, Common Wildebeests and Plains Zebras made up 83% of all kills (Loveridge *et al.* 2006). In Kruger N. P., Giraffes, Common Wildebeests, Plains Zebras, Impalas and African Buffalo had the highest relative frequency among prey items in stomach contents ($n = 257$) (Smuts 1979, 1982); Pienaar (1969) listed a total of 37 prey species from Kruger N. P. (and see Funston *et al.* 1998). In Lake Manyara N. P., Tanzania, African Buffalo make up more than half the diet (Prins & Iason 1989). At Phinda G. R. in KwaZulu-Natal (South Africa), Hunter (1998a) recorded Lions killing 28 different prey species, with Common Wildebeests, Common Warthogs and Nyalas *Tragelaphus angasii* the most frequent prey items accounting for 86% of estimated prey biomass (although Nyala were the most abundant prey item).

In Chobe N. P., Botswana, the majority (42%) of prey taken by Lions weighed less than 50 kg; medium-sized prey (50–300 kg) and large prey (>300 kg) constituted 30% and 29% of kills, respectively. During the wet season, Lions killed mainly medium- and large-sized prey (particularly African Buffalo and Plains Zebras), while during the dry season they killed significantly more smaller-sized prey (particularly Common Warthogs). In total, five prey species, Common Warthog (28%), African Buffalo (27%), Plains Zebra (15%), Impala (11%) and Tsesebe *Damaliscus lunatus* (9%), constituted just less than 90% of all recorded herbivores killed (Viljoen 1993). In Etosha, Lions also mainly killed prey weighing less than 50 kg (particularly Springboks *Antidorcas marsupialis*, which contributed about 73% of kills). Common Wildebeests contributed 12% of kills and 28% of edible biomass while zebras contributed 9% of kills and 24% of edible biomass (Stander 1992a). Similarly, in the Kalahari, small prey, including birds, small mammals (such as Cape Porcupines *Hystrix africaeaustralis*) and juvenile antelopes (Gemsboks *Oryx gazella* and Springboks) made up around two-thirds of the diet (Eloff 1973, 1984, 2002).

In the savannas of West Africa, scat analysis revealed that Lions in Comoé N. P. preyed predominantly upon small to medium-sized ungulates (with Buffon's Kobs *Kobus kob* and Bushbucks *Tragelaphus scriptus* the two most frequent prey species comprising a total of 44% of the biomass consumed), while large ungulates (such as Hartebeests, African Buffalo and Common Warthogs) made up only a small proportion of their diet (Bodendorfer *et al.* 2006). In a study in Faro N. P., N Cameroon, Lions preyed mainly on medium-sized antelopes, with Buffon's Kobs having the highest frequency occurrence (Breuer 2005).

Besides typical prey items, Lions have been recorded preying on other carnivores, including Spotted Hyenas *Crocuta crocuta*, Leopards, Cheetahs *Acinonyx jubatus*, Black-backed Jackals *Canis mesomelas*, Bat-eared Foxes *Otocyon megalotis*, Civets *Civettictis civetta*, Ratels *Mellivora capensis*, Caracals *Caracal caracal*, Banded Mongooses *Mungos mungo*, White-tailed Mongooses, *Ichneumia albicauda* and Zorillas *Ictonyx striatus* (Pienaar 1969, Eloff 1984, Stander 1992a, Hunter 1998a). Carnivores are typically left uneaten when killed. However, infanticidal ♂♂ and ♀♀ may eat cubs after killing them (Schaller 1972, Hunter 1998a) and Lions that find dead cubs sometimes eat them (Schaller 1972). Other recorded prey items include: Nile Crocodiles *Crocodylus niloticus*, Common Hippopotamus *Hippopotamus amphibius* and termites (Pienaar 1969), Chimpanzees *Pan troglodytes* (Tsukahara 1993) and other primates such as baboons *Papio* spp. and grivets *Chlorocebus/Cercopithecus* (e.g. Busse 1980, Bodendorfer *et al.* 2006), Cape Fur Seals *Arctocephalus pusillus* (Bridgeford 1985), pangolins (Manidae;

Lion *Panthera leo* seizing, throwing and strangling a zebra (from photographs).

e.g. Bodendorfer *et al.* 2006), Aardvark *Orycteropus afer* (Stander 1992, Bodendorfer *et al.* 2006), Ostrich *Struthio camelus* and Ostrich eggs (Schaller 1972, Stander 1992a), and even fish from shallow water. In the past, when Nile Crocodiles were widespread and common, they were a frequent prey, notably along the banks of the Rufiji R., where Common Hippopotamus were also regularly taken. Crocodiles were killed at the throat but eaten mainly around the base of the tail (Kingdon 1977). Lions have occasionally been recorded killing elephant calves (e.g. Schaller 1972, Ruggiero 1991), and they made up a considerable proportion of the diet (23% of kills) in Hwange N. P. (Loveridge *et al.* 2006); Joubert (2006) observed a total of 74 elephants killed by Lions during a four-year period with two-thirds of the kills in the age range of 4–15 years. Lions may occasionally actively feed on grass; Smuts (1979) recorded the stomach of a female containing 200 g of green grass.

Hunting is opportunistic, and occurs mostly at night (Schaller 1972, Stander 1992a, Mills & Biggs 1993) although ambushing prey at waterholes becomes more frequent during the day in dry seasons. In general, Lions hunt in areas where prey is easy to capture rather than areas where prey is more abundant (Hopcraft *et al.* 2005). Hunting typically involves a stealthy approach to within 15 m of the prey item; Lions quickly reach their top speed of 58 km/h, but as their prey is usually faster and has better stamina, most chases do not exceed 200 m. Stalking is followed by a swift charge then grabbing or slapping the quarry's flank and dragging the prey down; the prey is killed with a suffocating bite to the mouth or throat. Lions may leap on the backs of larger animals such as Gemsboks (Eloff 1973), Elands (P. M. West pers. obs.) and African Buffalo (C. Packer pers. obs.) in order to break the animal's back (Eloff 1973) or to bite the animal on the back and/or to knock it off-balance. Lions will also actively dig out prey such as Common Warthogs from shallow burrows (Guggisberg 1961, Kruuk & Turner 1967, Van Orsdol 1984).

Some evidence suggests links between pride size and foraging; for example, pride size is positively correlated with lean season prey abundance (Van Orsdol *et al.* 1985). However, while Lions enjoy the reputation of cooperative hunters, the prevalence of cooperative hunting is overestimated (Scheel & Packer 1991). Where prey is relatively easy to capture, Lions in a group often watch a companion as she begins to hunt, and only join her if and when the quarry is subdued. In mixed groups, ♀♀ older than about two years do most of the hunting (Schaller 1972, Scheel & Packer 1991); in Etosha N. P., ♂♂ only participated in 4% of hunting opportunities (Stander

1992a). Cooperative hunting is more common in harsh habitats, when the hunting success of a solitary animal is low, and when tackling large prey (Packer & Rutten 1988). In Etosha N. P., where Lions primarily prey upon Springboks, a species that is extremely difficult to catch, cooperation is not only frequent, but each Lion in a group repeatedly assumes a specific position in the hunt (Stander 1992b). Stander (1992b) classified hunting ♀♀ according to the position they assumed during the hunt, with some ♀♀ circling prey ('wings') while others ('centres') waited for prey to move towards them. The 'wings' usually initiated the attack while the 'centres' ambushed prey in flight. Hunts were most likely to succeed when ♀♀ occupied their preferred positions.

Lions throughout Africa will cooperate when hunting larger prey such as African Buffalo, first encircling the prey and then attempting to knock it down. Here the additional bulk of the ♂ is invaluable, and ♂♂ are frequent killers of African Buffalo (Funston *et al.* 1998, 2001). Females capture the majority of small- to mid-sized prey. Once the prey is subdued, ♂♂ dominate all other Lions at a kill, while ♀♀ tend to feed alongside the subadults and cubs. Feeding is a messy affair, and evidence of cooperation quickly disappears. Lions often emerge from a feeding bout bleeding at the face and ears from squabbling with companions. Prey is either consumed at the site of the kill or dragged to cover, with larger prey usually being consumed on the spot. The belly is ripped open, and the intestines, internal organs, muscle, bones and skin are consumed (Van Valkenburgh 1996).

Food consumption rates in Etosha N. P. in the dry season were around 8.7 kg/day/Lioness, while in the wet season average food intake was 14.1 kg/day/Lioness (Stander 1992a). In the Serengeti N. P., the estimated minimum daily food requirement is between 5.0 and 8.5 kg/day/Lion, with ♂♂ consuming twice as much as ♀♀ (Packer *et al.* 1990, Scheel & Packer 1991). Schaller (1972) recorded one ♂ in the Serengeti N. P. consuming 33 kg of meat in one night.

Hunting success rates vary among regions, presumably dictated by numerous ecological constraints (Sunquist & Sunquist 1989). In Etosha N. P., success rates were as low as 15% (one kill every 6.7 hunts; Stander 1992a), while in the Kalahari they were as high as 38% (Eloff 1984). In the Serengeti N. P., Schaller (1972) recorded hunting success at 23%. Van Orsdol (1984), working in Uganda, suggested that hunting behaviour varies with cover availability, prey availability and prey body size. In Etosha N. P., Stander & Albon (1993) found that hunting techniques employed by ♀♀, female group size, prey species, time of day/night, terrain, and interaction between terrain and day/night, all determined the likelihood of a hunt being successful. Hunts that involved coordinated stalking were most likely to succeed while an increase in female group size increased the success rate of hunting the five major prey species. Females also were more successful when hunting on moonless nights in undulating terrain. Stander & Albon (1993) attributed the social foraging habits of Lions in Etosha (where the solitary ♀♀ have very low hunting success, 2.5%; Stander 1992a) to their semi-arid, open habitat where there are long periods of food scarcity and where solitary hunters do not acquire the minimum food intake. In East Africa, where prey density is higher the success rates of solitary hunters is similar to groups. Funston *et al.* (2001) identified seven variables that they considered to have a significant independent influence on hunting success of male and female Lions in Kruger N. P. Those related to the Lions themselves, included the type of

hunt, wind orientation and number of adults, while those related to prey included prey species and herd size; the only two environment-related variables were moon brightness and grass height. The sex of the Lions had no effect on the overall probability of hunting success.

Lions primarily obtain their food by hunting, but scavenging can be a major source of food intake in habitats or at times when Lions can regularly find freshly dead animals. When large migratory herds are out on the treeless, open Serengeti Plains many die naturally, others are killed by Spotted Hyenas and every carcass is readily located by descending vultures or hyena calls; under these circumstances Schaller (1972) found that Lions scavenged as much as 53% of their food. In Etosha N. P. and Phinda G. R., Lions scavenged 5.5% and 8.8% of prey items, respectively (Stander 1992a, Hunter 1998a), but in the Serengeti N. P., the percentage of food scavenged was much higher (Packer *et al.* 1990). Lions scavenge opportunistically from all other predators including Spotted Hyenas, Cheetahs, Leopards and African Wild Dogs *Lycaon pictus* as well as from other Lions. Males are particularly persistent scavengers of Spotted Hyena kills. Lions locate scavenging opportunities by sight or sound (e.g. the squabbling of hyenas at a kill). Spotted Hyenas occasionally supplant Lions from their kills, particularly when they greatly outnumber Lions and when adult male Lions are absent, but typically wait until Lions abandon the carcass and then move in to consume the bones and scraps of skin that the Lions cannot eat. In Chobe N. P., hyenas located almost 80% of all kills made by Lions, usually arriving within 30 min of the kill having been made. Adult male Lions and their prides were never challenged by Spotted Hyenas, but female prides lost 20% of their food to hyenas, although hyenas had to outnumber ♀♀ by 4:1 to drive them off their kill (Cooper 1991). Cooper (1991) attributed this kleptoparasitism by Spotted Hyenas to a shortage of adult male Lions in the Savuti region (where the sex ratio was 1 ♂ to 5.7 ♀♀). In Kruger N. P., Spotted Hyenas only outnumbered ♀♀ at five out of 77 kills and never by more than 3:1 (Funston *et al.* 1998). In Etosha N. P., interactions between Lions and Spotted Hyenas are rare (Stander 1992a).

Social and Reproductive Behaviour The Lion's social organization is based on the pride, which in the Serengeti N. P. consists of 1–18 adult ♀♀, their dependent offspring and 1–9 adult ♂♂ (Packer *et al.* 1988, 2005a), although prides of 3–10 adult ♀♀ and 2–3 resident ♂♂ are more common. Prides tend to be smaller in southern Africa, particularly in arid environments where there are fewer prey species, such as Etosha N. P. (mean = 4.8 adult ♀♀; range 2–9; Stander 1991) and Kgalagadi Transfrontier Park (mean = 4.0; range 2–8; Funston 2001; and see Eloff 1998, 2002) (see also Van Orsdol *et al.* 1985).

The pride is a fission–fusion society (Schaller 1972, Packer *et al.* 1990) such that Lions spend most of their time in smaller subgroups or alone. The ♀♀ in a pride are always close genetic relatives with rare exceptions; two published cases of unrelated ♀♀ forming prides resulted from severe disturbance including prolonged drought in the Kalahari (M. Owens & D. Owens 1984) and extensive Lion culling in Kruger (Smuts 1978), and two apparently unrelated Serengeti ♀♀ formed a crèche with six cubs for at least six months although how long their association persisted is unknown (P. M. West & C. Packer pers. obs.). Resident ♂♂ are almost never related to pride ♀♀ (except in small, isolated populations) (Packer *et al.* 1991a). Females usually remain in their mothers' pride, but they will also disperse if their fathers are still resident when they reach sexual

maturity and incoming ♂♂ often evict subadult ♀♀ along with the subadult ♂♂ (Bertram 1973, Hanby & Bygott 1987, Stander 1991). In either case, dispersing ♀♀ may establish a new pride on the edge of their natal territory and neighbouring prides thus may also be closely related (Packer & Pusey 1987, Packer *et al.* 1991a, Spong *et al.* 2002). Relatedness between neighbouring prides may also result when a coalition of ♂♂ is resident with both or when young ♂♂ disperse to neighbouring prides, factors that may partially explain why the degree of relatedness does not appear to influence behaviour between neighbouring prides (Spong & Creel 2004).

In Serengeti N. P., young ♂♂ are either evicted by incoming adult ♂♂, or leave when they begin to reach maturity. While large coalitions often move directly into adjacent prides (Pusey & Packer 1987), leaving the pride can be the beginning of a long nomadic phase that can last in excess of two years. Nomadic male behaviour differs from that of residents; nomads abstain from roaring to evade detection by resident Lions (Grinnell & McComb 2001) and they rely largely on scavenging for food. Nomadic ♂♂ thus often display poor body condition, although they become more proficient at capturing large prey as they grow older and stronger. In areas dominated by migratory prey, ♂♂ may follow the migration far from their natal territory. In Kaudom G. R., nomadic ♂♂ moved over areas up to 5415 km² (Standar 1997a). Young ♂♂ from the same crèche leave the natal pride together, establishing a coalition that lasts throughout their lives; coalitions of more than three ♂♂ invariably consist of such related Lions. However, ♂♂ often end up alone either due to the lack of same-aged crèche-mates or to the death of their companions. These ♂♂ will team up with stranger Lions, and coalitions of 2–3 ♂♂ are often entirely unrelated. Such is the importance of male companionship that the behaviour of related and unrelated coalitions is virtually indistinguishable; male companions are demonstrably affectionate and highly cooperative (Grinnell *et al.* 1995).

In contrast with Lions from 'plains-like' ecosystems where small coalitions of dispersing ♂♂ usually move far away from their natal pride's range and remain nomadic for extended periods of time, subadult male Lions in Kruger N. P. had a prolonged period of association with their natal pride regardless of coalition size, either directly or in a land tenure system that has not been described previously. After leaving the pride, most (80%) of young male coalitions, rather than becoming nomadic, remained close to their natal territory, either as non-territorial subadults, adults or even as territorial adults. Of the 20% of coalitions that did not stay close to their natal range, one acquired a territory 20 km away. However, the majority of holders acquired territories closer to their natal ranges (Funston *et al.* 2003). These authors hypothesized that dense bush and access to sufficient prey resources, particularly in the form of resident African Buffalo (which comprised the majority of male Lion kills; and see Funston *et al.* 1998) might have been important factors allowing extended residence close to the natal pride's territory.

The primary benefit of sociality in both ♂♂ and ♀♀ is to reproduction. Nomadic ♂♂ appear to be constantly on the lookout for vulnerable prides where they can defeat the resident ♂♂. Larger coalitions are more successful in such competitions, and solitary ♂♂ have very little hope of gaining access to ♀♀ (Bygott *et al.* 1979). In Kruger N. P., the minimum age at which ♂♂ become territorial is five years, and the oldest territorial ♂ recorded was 11 years; thus, ♂♂ have about six years in which to acquire and maintain a

territory and sire offspring (Funston *et al.* 2003). Once established, ♂♂ dispatch the offspring of their predecessors either through infanticide or eviction (Bertram 1975, Packer & Pusey 1984, Pusey & Packer 1994). While this improves the males' reproductive success, it represents a huge loss of investment for ♀♀. By living in groups and pooling their offspring, ♀♀ improve their chances of protecting their offspring from new ♂♂ (Packer *et al.* 1990). Sociality also enables ♀♀ to protect their territories from neighbouring prides (McComb *et al.* 1994). Solitary ♀♀, while consistently better fed than their social neighbours, rarely succeed in raising offspring or maintaining a satisfactory core territory, and constant conflict with neighbouring prides and strange ♂♂ is undoubtedly the primary factor in their increased mortality (Packer *et al.* 1990).

Pride ranges in Serengeti N. P. cover an area of 20–500 km² depending on the size of the pride, availability of water and prey abundance (Schaller 1972, Bertram 1978, Van Orsdol *et al.* 1985). In harsher habitats, average pride ranges can be much higher. For example, in areas of Kgalagadi Transfrontier Park, the home-ranges of 14 prides varied between 266 and 4532 km² (mean = 1462 km²; Funston 2001). Similarly, in Etosha N. P. the ranges of seven prides and two adult ♀♀ ranged from 150 to 2075 km² (Standar 1991), while pride ranges in Kaudom G. R. were between 1055 and 1745 km² (Standar 1997a). Van Orsdol *et al.* (1985) found a strong negative correlation between home-range size and the abundance of prey during the season of least abundance. Ranges often overlap with those of neighbouring prides, although each pride maintains a central area for its exclusive use, and ♂♂ may be resident with more than one pride. Both sexes defend the territory, with ♂♂ ranging more widely, and ♀♀ defending the core area against other groups of ♀♀ (including those with whom they may share resident ♂♂). Territory boundaries are maintained by roaring, urine-marking and patrolling. Roaring also allows Lions to locate distant pride-mates. Lions do make excursions beyond their ranges, with average recorded daily walking distances of up to 40 km per day (Eloff 2002).

Intruders usually retreat at the sight or sound of residents, and actual fights are rare. The lethal teeth and claws of opponents make it likely that even a successful competitor will not emerge unscathed, and consequently Lions have evolved a number of behavioural mechanisms that enable them to avoid fights. For example, when confronted with the recorded roars of like-sexed strangers, resident ♂♂ and ♀♀ are both sensitive to the odds. Females approach only

After feeding well Lions *Panthera leo* may lie around and sleep for several days at a time.

when they outnumber their opponents, and ♂♂ temper approaches with caution when outnumbered (McComb *et al.* 1994, Grinnell *et al.* 1995, Heinsohn & Packer 1995). Lions can also distinguish between individual roars allowing ♀♀ to avoid conflicts with potentially infanticidal ♂♂ (McComb *et al.* 1993). Some evidence suggests that ♂♂ alter their roars when repelling intruders; resident male roars recorded after playbacks of unfamiliar ♂♂ within their territory were shorter and louder than controls (Grinnell 1994).

When confronted with a challenge from a larger male group, outnumbered resident ♂♂ sometimes abandon their pride rather than fight, often fleeing the territory with their successors in hot pursuit. However, coalition numbers may not be the only factor in male success. Ownership of a pride probably confers an advantage, as does the possession of larger or darker manes, as indicated earlier (under 'Adaptations'; and see West & Packer 2002).

Male tenure length in prides is highly variable but generally increases with coalition size, and the average length of time ♂♂ spend with an individual pride is two years (Bygott *et al.* 1979, Packer & Pusey 1983; and see Funston *et al.* 2003). A pride 'takeover' by new ♂♂ can be chaotic. Roaring, chasing and fighting may precede the actual event, followed by an orgy of mating. After the loss of offspring, pride ♀♀ immediately begin to demonstrate sexual behaviour, which includes walking sinuously around ♂♂ and presenting themselves with low growls (Bertram 1975). A 'consorting' ♂ closely guards each receptive ♀, and his ownership is rarely challenged. Mating often continues throughout a period of four days at the rate of approximately three times per hour (Packer & Pusey 1983); one account reports 157 copulations over a 55-hour period (Schaller 1972). During copulation, a ♂ often licks or gently bites the female's nape while she emits a low growling noise. Copulation is generally brief and often ends with a growl or yelp from the ♂ and with the ♀ turning to snarl as the ♂ dismounts. After mating, ♀♀ often roll on to their sides or backs, a behaviour that may facilitate sperm retention (Schaller 1972).

Although the resident ♂♂ father all cubs born during their tenure, many coalitions show dominance relationships, and generally only two ♂♂ in a given coalition succeed in fathering offspring (Packer *et al.* 1991a). That mating is shared at all by ♂♂ may reflect the inability of a dominant ♂ to monopolize more than one oestrous ♀ while many more may be available simultaneously. Indirectly, ♀♀ may also exercise some choice over the paternity of their offspring in spite of established male dominance hierarchies (West & Packer 2002). Regardless of its cause, this reproductive skew probably helps explain why coalitions of more than three ♂♂ are never composed of unrelated ♂♂.

In contrast to ♂♂, female Lions exhibit no signs of dominance hierarchies and their reproduction is remarkable for its even distribution (Packer *et al.* 2001). The signs of pregnancy are subtle until a few weeks before birth, at which point the udder becomes distended and ♀♀ begin ranging alone. Birth typically occurs in a confined and protected spot, and the cubs remain hidden until approximately six weeks of age. At this point they can keep up with the pride and begin to eat meat, and they are pooled with other litters to form a 'crèche'. Such crèches can consist of more than 25 cubs (though 4–10 is more typical), and the mothers of the crèche spend most of their time together, remaining somewhat separate from other pride-mates. Cooperation becomes most pronounced at such times even to the point of nursing each other's offspring. However, the nursing of non-offspring is most common among the more closely related ♀♀, and by ♀♀ with only one cub

of their own; ♀♀ with large litters primarily nurse their own young (Pusey & Packer 1994). When prey is captured at a distance, mothers often return to their offspring and lead them to the kill, calling them with soft grunts (Schaller 1972). Although ♂♂ typically displace all other Lions from a kill, the rest of the pride respect each other's 'ownership' of a feeding site, and mothers often wait until their cubs have eaten their fill before feeding themselves. Older cubs compete with younger cubs for food, and the youngest cubs in a crèche have the highest mortality. Mothers with new cubs are thus less likely to join an extremely large crèche, or one with much older cubs.

Cubs are very playful, with play behaviour mimicking skills they will need as adults. Cubs will attempt to play with any adults in the vicinity but are usually met with bared teeth or a snarl. Fathers tend to remain at a slight distance when present with mothers and cubs, and ♀♀ may threaten them if they begin to move closer. Cubs begin to show signs of independence beginning around the age of 18 months, and can survive without the protection of the pride only from about two years. As early as one month of age, cubs display a vocal repertoire similar to that of adults although in modified form; the full roar is not seen until subadulthood (Schaller 1972).

Reproduction and Population Structure In Serengeti N. P., ♀♀ typically reach sexual maturity by the age of 30–38 months (Packer *et al.* 1988, 1998). Serengeti ♂♂ are probably sexually capable at the same age as ♀♀, but they typically fail to find mating opportunities until 48–54 months at which point they are large enough to challenge rival ♂♂ (Packer *et al.* 1988). By this age, the manes of young ♂♂ have usually reached their full size, while mane colour may continue to darken until age 9–10 years. Occasionally, manes will lighten over a male's life-span, and illness or injury may drastically reduce mane size at any age (West & Packer 2002); in fact, Lions will lose their mane entirely if castrated, so manes appear to be dependent on androgens (West 2005). The ages at which Lions reach full size and sexual maturity appears to vary between habitats with Lions in harsher habitats, such as Kruger N. P., trailing those of Serengeti N. P. by as much as a year. Funston & Mills (1997) gave the mean age at first conception in Kruger N. P. at 48 months, although at least 29% ($n = 14$) gave birth at 40 months; breeding was delayed until 54–60 months in certain individuals (and see Funston *et al.* 2003). Five known-aged males of 26–28 months sired cubs at Phinda G. R. in KwaZulu–Natal, but this opportunity for mating arose only because of the lack of mature ♂♂ (Hunter 1998a).

Male scrotum and backward facing penis.

Lions are polyoestrus; the oestrous cycle lasts 16 days and oestrus 4–7 days with a two-week interval and can occur at any time of year (Packer & Pusey 1983). It is not clear whether ovulation is induced by copulation or is spontaneous. Mating may take place at any time throughout the year, although Smuts (1982) recorded a large proportion of the cubs born between Feb and Apr in Kruger N. P. (timed to the period when prey species have their young) and Packer *et al.* (1990) recorded a peak in births between Mar and Jul in the Serengeti N. P.

Gestation is 15–16 weeks (Cooper 1942). Litter sizes in the wild vary from 1–6 (Schaller 1972, Rudnai 1973, Smuts *et al.* 1978b, Packer & Pusey 1995) with an average of 2–3 (Packer & Pusey 1995) and newborn cubs weigh less than 1% of adult weight (Schaller 1972). The sex ratio at birth is generally equal with a slight increase in favour of ♂♂ directly following a takeover (Packer & Pusey 1987). This may reflect the increased probability of synchronous litters directly following a takeover, and the benefits to ♂♂ of having same-aged and like-sexed companions. Cubs are born either with eyes open, or their eyes open very shortly after birth. Milk dentition erupts around three weeks. Cubs subsist exclusively on milk, which is very high in fat (De Waal *et al.* 2004), until approximately 4–6 weeks of age, and weaning is generally complete by eight months (Schaller 1972). However, weaned cubs can continue to steal milk from the lactating mothers of younger cubs (Pusey & Packer 1994). Mean inter-birth interval in Serengeti N. P., when raised to maturity, is 20 months (range 11–25; $n = 38$) and 4–6 months if the litter is lost (Packer & Pusey 1987). In two study prides in Kruger N. P., inter-birth intervals were extended with cohorts of cubs born on average every 40 months (Funston *et al.* 2003). These researchers found that yearly variations in the population size, with cubs comprising between 7% and 34% of the population, were due to this extended inter-birth interval (Funston *et al.* 2003).

Cub mortality is generally high: in the Serengeti N. P., in particularly harsh years, as many as 80% of cubs die before their first birthday (Packer & Pusey 1995). The overall average is closer to 60% with the primary causes being infanticide (or abandonment following a takeover by new ♂♂), starvation and disease. Once cubs reach one year of age, annual mortality declines to less than 20% (Packer *et al.* 2001). In Kruger N. P., the annual survival rate of cubs up to 12 months of age was higher (84%; $n = 55$), and the role of infanticide or predation by other carnivores appeared to be small; annual survival rates of large cubs (>12 months), and subadults still associating with the pride were also high (89% and 91%) (Funston *et al.* 2003). Few ♀♀ live past the age of 18 in the wild, and most cease to reproduce after age 15 (Packer *et al.* 1998). Males rarely reach the age of 16 years (Smuts *et al.* 1978a, Whyte & Smuts 1988). In captivity, longevity is extended, but anecdotal reports suggesting that Lions can live up to 30 years are probably incorrect. The record longevity in captivity is for a wild-born ♂ that died at Cologne Zoo at about 27 years of age (Weigl 2005).

In Ngorongoro Crater, the adult sex ratio is 2.1 ♀♀ to 1 ♂, and the adult : young ratio is 30 : 37. In the Serengeti N. P., the adult sex ratio is 2.7 : 1 (C. Packer pers. obs.). Similarly, Smuts *et al.* (1978b) determined a ratio of 2.1 ♀♀ to 1 ♂ in Kruger, while Funston *et al.* (2003) recorded a sex ratio of adult territorial Lions in Kruger of 2.5 ♀♀ to 1 ♂.

Predators, Parasites and Diseases As the largest of Africa's predators, the adult Lion has no actual predators of its own although

young are still vulnerable. Leopards, Spotted Hyaenas and African Wild Dogs will kill Lion cubs when the opportunity arises, but the greatest threat comes from other Lions. Infanticide by incoming ♂♂ is ubiquitous, and ♀♀ will also kill the cubs of unfamiliar Lions. Adult Lions can be severely injured while attempting to subdue prey, especially Common Wildebeests, Plains Zebras, Gemsboks, Common Warthogs and rhinoceroses. African Buffalo are a particular danger; in Ngorongoro Crater, African Buffalo even attack and kill non-hunting Lions, and are a significant factor in adult mortality (Kissui & Packer 2004).

The most important pathogens in Lions are probably canine distemper (CDV) and bovine tuberculosis (bTB). bTB is an emerging disease threat present in Serengeti and Kruger National Parks, and Hluhluwe–iMfolozi Park in KwaZulu–Natal, and is associated with morbidity in all three (Keet *et al.* 2000, Cleaveland *et al.* 2005), though the extent of this threat appears to be minor in East Africa. Lions are probably infected when they scavenge or kill infected African Buffalo in advanced stages of bTB (Keet *et al.* 2000). CDV is known to strike East African populations irregularly, and while some outbreaks caused minimal mortality, others have killed up to 40% of the population such as the outbreak in the Serengeti–Mara in 1993–94. The reservoir for the disease in this instance was the large domestic dog population inhabiting villages adjacent to the area (Roelke-Parker *et al.* 1996, Packer *et al.* 1999). The Serengeti N. P. population rapidly recovered, reaching its original size by 1997 (Packer *et al.* 1999). In contrast, a succession of disease outbreaks (including CDV) in the Ngorongoro Crater Lions has kept this population below its carrying capacity for over ten years (Kissui & Packer 2004). Feline immunodeficiency virus (FIV) infects close to 100% of adult Lions in the Serengeti N. P., Ngorongoro Crater and Kruger N. P. but is apparently absent in Etosha N. P. and Hluhluwe–iMfolozi Park (Brown *et al.* 1993, Packer *et al.* 1999). The health effects of FIV are unclear. Some infected Lions in captivity have been suggested to show FIV-related pathology, but Lions in natural FIV+ populations generally seem as healthy as those in FIV– populations. Lions in Tanzania are also infected with coronavirus, calicivirus, parvovirus, Rift Valley fever, anthrax and influenza, but the health effect of these pathogens appears to be minimal (Packer *et al.* 1999, C. Packer pers. obs.).

Boomker *et al.* (1997) listed a total of 31 helminths that infect Lions, including 21 nematode species (including members of the genera *Ancylostoma*, *Cylicospirura*, *Diriofilaria*, *Filaria*, *Gnathostoma*, *Physaloptera*, *Toxocara* and *Trichinella*), seven cestodes (such as *Echinococcus granulosus*, which causes hydatid cysts, and *Taenia* spp.), and a trematode (*Pharyngostomum cordatum*), as well as various protozoan parasites (*Babesia* sp., *Hepatozoon* sp., *Sarcocystis* sp. and *Trypanosoma* sp.); none of these appear to inflict life-threatening illness. Bjork *et al.* (2000) documented a further 12 previously undocumented parasites, including *Aelurostrongylus*, *Capillaria*, *Denodex*, *Eimeria*, *Habronema*, several *Isoospora* species and *Trichuris* in faecal samples from N Tanzania.

A very large number of ectoparasites have been recorded from Lions. Boomker *et al.* (1997) documented 32 species of ticks (18 of them in the genus *Rhipicephalus*), several of which are implicated in the transmission of protozoal and bacterial diseases, and two species of fleas (*Ctenocephalides felis* and *Echidnophaga larina*). Lions are also harassed by stable (*Stomoxys calcitrans*) and tsetse (*Glossina morsitans*) flies and other biting insects. The Ngorongoro population crashed

in 1962 following what appeared to be an exceptional outbreak of *Stomoxys* flies, resulting in widespread mortality (numbers collapsed from nearly 100 animals to 12 over the course of one year) (Packer *et al.* 1991b). The population eventually rebounded by 1975, only to decline again after 1983 possibly due to the effects of inbreeding (see Conservation). Sarcoptic mange *Sarcoptes scabiei* has also been recorded from Lions in Kruger N. P., which may result in mortality in severe cases (Young 1975).

Conservation IUCN Category: Vulnerable A2abcd. CITES: Appendix II.

While Lions are not immediately threatened with extinction, their long-term survival is far from assured. As noted already, current estimates suggest that the Lion's range declined by 80% during the twentieth century (Ray *et al.* 2005), with fewer than 50,000 Lions remaining continent-wide. Large areas of land are necessary to support Lions and their natural prey, and the most important remaining populations are restricted to eastern and southern Africa: the Serengeti–Mara ecosystem and the Maasai Steppe (both in Tanzania and S Kenya), the Selous–Niassa ecosystem (in Tanzania and N Mozambique), the greater Ruaha–Katavi–Moyowosi–Kigosi ecosystem (in W Tanzania), the greater Kruger ecosystem (in South Africa and Mozambique) and the Okavango–Chobe–Caprivi ecosystem (in Botswana and Namibia). There may also be a large viable population in S Sudan–Central African Republic–N DR Congo.

The main conservation threats are habitat conversion, loss of prey and conflict with local people. The severe declines witnessed in Lion populations in West Africa, in particular, are attributed primarily to the spread of human settlements and agriculture into Lion habitat (Bauer & Van der Merwe 2004). Most human population growth is in rural areas with attendant pressures to convert wildlife habitat to agriculture. Economic incentives for local communities to tolerate Lions have been provided by privately owned hunting companies in Tanzania, Mozambique, Zambia and Botswana and by community programmes in Kenya and Zimbabwe. However, there is an urgent need to improve and expand these activities owing to the recent emergence among rural communities of putting out poisoned carcasses that are capable of extirpating entire prides (Frank *et al.* 2006).

It can be argued that human–Lion conflict is linked with poverty: currently the highest incidence of man-eating occurs in S Tanzania and N Mozambique, where Lions have long been a threat and people are too poor to build safe houses, and rudimentary agricultural practices require long periods preparing and harvesting crops, leaving them vulnerable to attack (Packer *et al.* 2005b). Similarly, pastoralist herders cannot afford to buy fencing, and their herds are so susceptible to disease and drought that they are increasingly intolerant of Lion depredation (Patterson *et al.* 2004, Woodroffe & Frank 2005). Annual losses of cattle to Lions in areas adjacent to Waza N. P., Cameroon, comprised only about 3.1% of all livestock losses, but were estimated to represent more than 22% of financial losses amounting to some US\$112,000 or US\$370 per owner (Bauer 2003; and see Bauer & de Iongh 2005). Likewise, in communal lands bordering Sengwa Wildlife Research Area, Zimbabwe, Lions were responsible for 34% of recorded kills, representing 58% of financial losses (Butler 2000). Studies have shown that intensive monitoring of livestock and improved husbandry practices can reduce losses to Lions (Ogada *et al.* 2003, Patterson *et al.* 2004).

Trophy hunting, which is legally permitted in 13 countries in Africa, is not a significant threat to Lion populations, provided that hunters only remove ♂♂ that are at least six years of age. Shooting too many young ♂♂ (3–4 years of age) can result in elevated rates of male takeovers and infanticide. By restricting hunting to ♂♂ of 5–6 years of age or older, younger resident ♂♂ can rear their first set of offspring, thus minimizing the impact of infanticide on the population as a whole (Whitman *et al.* 2004). International legal trade for Lion products is mostly restricted to hunting trophies and skins by hunting companies. Local markets exist for Lion claws and Lion fat as talismans and traditional medicine. In Guinea and Guinea-Bissau, Lion skins are much sought after and are openly sold in front of international hotels. Hunting for skins is considered the chief threat to the species in some West African countries (Brugière *et al.* 2005).

Inbreeding could represent a potential threat in isolated populations. The population in Hluhluwe–iMfolozi Park, for example, grew to 120 animals from only three founders, and then steadily declined due to a host of factors thought to be allied with reduced heterogeneity (Maddock *et al.* 1996). Likewise, Lions in the Ngorongoro Crater have low levels of heterozygosity and ♂♂ had high levels of abnormal sperm (Packer *et al.* 1991b); consistent declines in this population may well be due to repeated outbreaks of disease owing to this low heterogeneity (Kissui & Packer 2004). It has been calculated that in order to sustain a large outbred population of Lions, a population of at least 50 prides with no limits to male dispersal is required (Bjorklund 2003). Lions are amenable to restoration: in South Africa, Lions have been reintroduced to at least 21 sites with a combined area of over 4560 km² (Hunter *et al.* 2004). However, the majority of sites are very small, enclosed by fencing and isolated from other populations, and their long-term contribution to conserving the species remains equivocal (Hunter *et al.* 2007b).

Although Lions are present in numerous captive-breeding programmes, Barbary Lions subsist only as a captive population (numbering fewer than 90 animals) in relatively isolated zoo collections (Black *et al.* 2010), although there have probably been multiple genetic hybridization events with sub-Saharan Lions (Burger & Hemmer 2006).

Measurements

Panthera leo

HB (♀♀): 1711 (1600–1840) mm, n = 38

HB (♂♂): 1938 (1840–2080) mm, n = 12

T (♀♀): 805 (720–895) mm, n = 37

Lion *Panthera leo* female.

T (♂♂): 882 (825–935) mm, n = 10
 HF c.u. (♀♀): 689 (633–775) mm, n = 36
 HF c.u. (♂♂): 804 (762–837) mm, n = 7
 WT (♀♀): 111.0 (90.5–138.0) kg, n = 4
 WT (♂♂): 155.5, 169.0 kg, n = 2

Serengeti N. P., Tanzania (L. Herbst & C. Packer pers. obs.)

Note: In a sample of 344 individuals weighed and measured in Kruger N. P., average mass was greater than in corresponding groups further north in Africa: the mass of the largest ♂ was 225 kg, the mean being 188 kg, while the largest ♀ weighed 152 kg, the mean being about

126 kg (Smuts 1982). A male Lion shot near Mt Kenya weighed 272 kg (Nowell & Jackson 1996).

Panthera pardus LEOPARD

Fr. Panthère; Ger. Leopard

Panthera pardus (Linnaeus, 1758). Syst. Nat., 10th edn, I: 41. 'Indiis', fixed by Thomas (1911; Proc. Zool. Soc. London I: 135) as Egypt, and by Allen (1924: 249) as Algeria.

Leopard *Panthera pardus*.

Taxonomy Up to 15 African subspecies have been described (Allen 1939) based largely on pelage and cranial differences that vary widely within populations and are invalidated by recent molecular analyses. Variation in allozymes, mitochondrial DNA and feline-specific minisatellites suggests eight or nine subspecies worldwide, with all continental African Leopards classified as *P. p. pardus* (Miththapala *et al.* 1996, Uphyrkina *et al.* 2001). However, the limited sampling of African populations in both studies possibly underestimated phylogeographic population differences. The population on Zanzibar (now exterminated) is considered by some authors (e.g. Kingdon 1977) to represent a unique subspecies *P. p. adersi*.

Synonyms (Africa only): *adersi*, *adusta*, *antinorii*, *barbara*, *brockmani*, *centralis*, *chui*, *fortis*, *iturensis*, *leoparda*, *melanosticta*, *melanotica*, *minor*, *nanoparda*, *niger*, *palearia*, *panthera*, *poecilura*, *poliopardus*, *puella*, *reichenowi*, *ruwenzorii*, *shortridgei*, *suahelicus*, *varia*, *vulgaris*. Chromosome number: $2n = 36$ (Robinson 1979). In captivity, Leopards have hybridized with Lions *Panthera leo*, Tigers *P. tigris*, Jaguars *P. onca* and Pumas *P. concolor* (Gray 1972).

Description A large cat with robust, muscular forequarters, slender hindquarters, relatively short legs and a long tail around two-thirds of head and body length. Head and neck thickset, especially in ♂♂ where neck circumference may exceed head circumference by 40 mm (L.T.B. Hunter pers. obs.). Mature ♂♂ often develop a distinctive throat dewlap and, less often, an obvious belly fold. Pelage highly variable (see colour plate in Kingdon 1977: 350, and *Mammals of Africa* Volume I), ground colour ranges from pale cream, buff-grey, various shades of orange, tawny-brown or dark rufous graduating to white on belly, chest, throat, chin and underside of tail. Body is covered with rosettes, each a cluster of small, black spots surrounding a normally unspotted centre darker than the ground colour. Rosettes give way to large, solid black blotches on the distal half of limbs, belly, throat and tail. Tail tip is black with a white underside. Small, solid black spots cover the face and neck. Upper chest often has a distinctive yoke of connected or semi-connected elongated black blotches. Feet marked with small, black spots that typically thin out towards the digits but may aggregate in

Lateral view of skull of Leopard *Panthera pardus*.

dark individuals, giving a dark, almost black appearance (Henschel 2001). The pattern of rosettes and spots is unique to individuals and useful for individual identification. Guard hairs short and coarse on dorsal surfaces, shortest on head and face at 3–4 mm graduating to 15 mm on hindquarters. Ventral hair softer and longer, up to 30 mm on the belly (Skinner & Chimimba 2005). Vibrissae white. Back of the ears has prominent pale patch lighter than rest of the head, bounded by black. Cubs born with blue eyes that typically mature to yellow-green and rarely greenish-blue or rust-brown. Five digits on front feet and four on hind, all with extremely sharp, curved claws that are fully protractile. Front feet are longer and wider than hind. Forefoot's first digit rests above the ground and is not visible in the spoor, its claw, the dew claw, is the largest. Females have two pairs abdominal nipples. Sexual dimorphism is marked, with ♂ 30–100% heavier than ♀.

Skull is massively built with marked sexual dimorphism. Male skulls are larger and relatively longer with a distinct sagittal crest usually absent in ♀ (Sunquist & Sunquist 2002). In the ♂ postorbital constriction is narrower than the interorbital; the reverse applies for the ♀ (Skinner & Chimimba 2005). Dentition typically felid (though upper second premolars, absent in some smaller felids, are usually present), and is fully developed in some individuals by 12 months (L. T. B. Hunter & G. A. Balme pers. obs.), but usually at 18–24 months (Stander 1997b). Males have larger maxillary (mean = 33.2 mm) and mandibular (mean = 26.1 mm) canines than ♀ (mean = 27.2 and 22.5 mm; Stander 1997b). The canines are large, with sharp points and slightly flattened on the inner side; the cheekteeth are clearly adapted for slicing (Skinner & Chimimba 2005).

Geographic Variation Regional morphological variation is largely absent with the possible exception of Leopards from coastal mountain ranges in South Africa's Western Cape, which are apparently around half the mass of animals elsewhere in Africa (Stuart 1981). Extraliminally (e.g. Israel and Oman), individuals in some desert populations are very small but those from southern African deserts are comparable in size with Leopards from mesic areas (Bothma *et al.* 1997, Stander 1997b). Variation in pelage is extensive within populations, although Leopards inhabiting forests tend towards dark colouration while those in arid areas are pale (Pocock 1932, Kingdon 1977). Melanism is uncommon in Africa. Black individuals reputedly occur most often in humid, forested habitats and are reported from the Aberdare Mts, Mt Kenya, the Virunga Mts, Ethiopia, Zambia, Cameroon and Gabon (Turnbull-Kemp 1967, Guggisberg 1975, Kingdon 1977, Ansell 1978, Jackson 2002). D. Brugière (in litt., Jackson 2002) saw a melanistic Leopard in the Forêt des Abeilles, Gabon, but a three-year study in

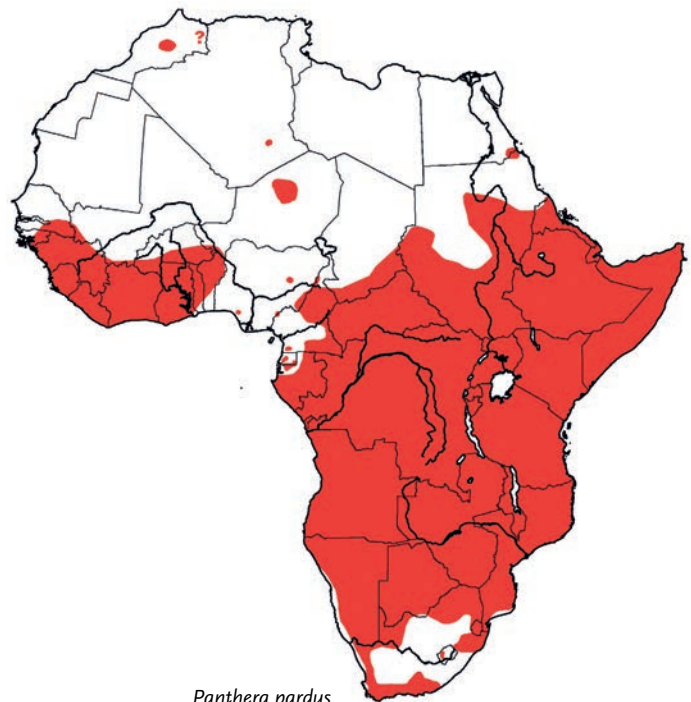

the Gabon rainforest using camera-traps recorded no melanism among at least 56 individuals (P. Henschel pers. obs.). Similarly, no melanistic individuals were found among 50 specimens collected from the Congo basin (Allen 1924). Occasional reports from savanna habitats such as near Masai Mara National Reserve (Scott & Scott 2003) and Lydenburg, South Africa (Jackson 2002) are unsubstantiated. Two aberrant individuals killed near Grahamstown, South Africa, had dark brown to black fur with lighter patches and contrasting spots on limbs and/or ventral surfaces (Günther 1885, 1886). Aberrantly marked individuals have been reported throughout the species' range (Allen 1924, Pocock 1932, Kingdon 1977).

Similar Species

Acinonyx jubatus. Sympatric. More slender, longer-legged build, uniformly marked with small, coin-shaped spots; facial tear streaks. *Profelis aurata*. Sympatric in West, Central and parts of East Africa. Smaller; ground colour dark golden to smoky-grey with variable spotting but always less distinct than Leopard; small, black-backed ears fading centrally to grey, less distinct than Leopard's unmistakable light patch; melanistic African Golden Cat might be confused for a young black Leopard.

Distribution Senegal eastwards to Sudan, Ethiopia and Somalia, south through most of Africa. Relict in North Africa. Also present in the Middle East, Turkey, throughout Central Asia into SW Russia, throughout tropical Asia into N China and Far Eastern Russia, and south to Sri Lanka, Peninsular Malaysia and Java (though naturally absent from Sumatra, Borneo and Bali) (Nowell & Jackson 1996, Sunquist & Sunquist 2002).

Historical Distribution Widespread throughout Africa in all habitats from rainforest to desert, reaching greatest densities in savanna woodlands. Naturally absent only from hyper-arid regions of the Sahara and Namib deserts.

*Panthera pardus*

Leopard *Panthera pardus* myology exposing powerful pectoral muscles.

Current Distribution Widely distributed within historical limits but with marked range retraction, especially in North Africa, West Africa, the Horn of Africa and South Africa (Nowell & Jackson 1996, Kingdon, 1997, Ray *et al.* 2005). Ray *et al.* (2005) estimated that Leopards have disappeared from at least 36.7% of their historical range in Africa. In North Africa, Leopards are relict in the Atlas Mts, Morocco; tracks of a ♀ and cubs were observed in 2002 in the eastern High Atlas (Cuzin 2003, Puroy *et al.* 2003) and there was a probable observation on the Morocco–Algerian border in Figuig in 2007 (F. Cuzin pers. comm.). Leopards have also recently been confirmed from the Ahaggar region of SE Algeria, the first record of Leopards from this region and the first direct evidence of this species in Algeria for over 50 years (Busby *et al.* 2006, 2009). Likely extinct in Egypt; five years of camera-trapping (1999–2004) failed to produce evidence of Leopards in S Sinai, where the last reliable report originates from 1963 (El-Alqamy *et al.* 2002, H. El-Alqamy pers. comm.). Leopards may be present in N Sinai and the Eastern Desert (H. El-Alqamy pers. comm.), but there are no confirmed records. Regular unconfirmed reports persist from the Gebel Elba region where a calling Leopard was heard and tracks photographed in 1994 (Hoath 2003).

In sub-Saharan Africa, they have been locally extirpated from areas densely populated with people or where habitat conversion is extreme. Leopards were extirpated from much of the West African coastal forest belt by 1945 (Bailey 2005; but see Brugière *et al.* 2005) and they have disappeared from much of the western Sahel (Anada in litt., Nowell & Jackson 1996). Leopards disappeared from Bwindi Impenetrable F. R., Uganda, in the 1960s (Andama 2000) and recent camera-trap surveys failed to find evidence of Leopards in Rwenzori Mts, Kibale N. P. and Kasyoha-Kitomi and Kalinzu Forest Reserves, Uganda (Treves *et al.* 2010). They disappeared from most forest reserves across SW Cameroon by the early 1980s (Maisels *et al.* 2001, Willcox 2002), and have been confirmed at only one site, Campo Ma'an N. P., since 2009 (Henschel 2009). In SE Nigeria, Leopard sign occurred in only two of 47 recently surveyed forest patches (Angelici *et al.* 1998). Leopards have naturally recolonized some areas in KwaZulu–Natal (South Africa), with the spread of game-farming (J. Anderson pers. comm.) and have reportedly increased in Eritrea since the cessation of human fighting in 1991 (Zinner *et al.* 2001). They are

likely extinct on Zanzibar, where there are no confirmed records since 1996 (Stuart & Stuart 1997b, Goldman & Walsh 2002).

Habitat The Leopard has a very wide habitat tolerance and is the only African felid occupying both rainforest and desert habitats. They are most successful in woodland, grassland savanna and forest but also occur widely in mountain habitats, coastal scrub, shrubland, semi-desert and desert. In central African rainforest, they inhabit all forest types including inundated forests, logged secondary forest and old-growth terra firma forest. Tracks are recorded in extensive swamp systems and Leopards are often observed crossing wide forest streams (P. Henschel & J. Ray pers. obs.). They occur in patches of mangrove and sub-humid forest in coastal West Africa (Brugière *et al.* 2005). Provided prey is available, they occur in areas where surface water is absent. They are absent from the open interiors of true desert but penetrate deeply into arid areas along water-courses and rocky massifs. Leopards rely on broken terrain and vegetation for hunting and for refuges but can occupy areas with minimal cover. They are tolerant of habitat conversion and, provided cover and prey is present, persist in reduced densities close to large human populations. A Leopard carcass was photographed on the rim of Mt Kilimanjaro's Kibo Crater at 5638 m in 1927 (Tilman 1937) and Leopards regularly traverse mountain ridges up to 4600 m on Mt Kenya (Rödel *et al.* 2004).

Abundance Continentally, Leopards are the most abundant large felid, but published total estimates are seriously flawed. Using rainfall data as a measure of productivity, Martin & de Meulenaer (1988) estimated over 700,000 Leopards in Africa though their model omitted prey availability and anthropogenic factors as explanatory variables, and is impossibly optimistic (Jackson 1989, Norton 1990, Marker & Dickman 2005a). Local Leopard densities correlate generally with prey availability (Stander *et al.* 1997a). Estimates vary from 0.5 Leopards/100 km² in Etosha N. P., Namibia (Stander *et al.* 1997a) to 30.3/100 km² for Kruger N. P., South Africa (Bailey 2005). Based on estimates from six studies, Marker & Dickman (2005a) estimated that mean density under protection (10.5 ± 4.0 Leopards/100 km²) was almost five times as high as outside protected areas (2.1 ± 1.6 Leopards/100 km²). Similarly, density estimates from camera-trap surveys in KwaZulu–Natal, South Africa, declined along a gradient associated with the level of protection. Density was 11.1 ± 1.3 Leopards/100 km² in a core protected area, 7.2 ± 1.1 Leopards/100 km² in a protected 'buffer' area suffering from strong edge effects, and 2.5 ± 0.9 Leopards/100 km² in non-protected farm land (Balme *et al.* 2010b).

Leopards reach their highest densities in protected East and southern African mesic woodland savannas. Including all individuals over one year old, Bailey (2005) estimated 30.3/100 km² for the Sabie R. area, in southern Kruger N. P., one of the most prey-rich areas of the park (Pienaar *et al.* 1966). The estimate for adults more than 3.5 years of age was 16.4/100 km². Lower densities (12 Leopards more than one year old/100 km², and 9.5 adults/100 km²) came from an adjoining area with marked seasonal absence of water. The estimate for adults across the entire park was 3.5/100 km². High estimates also come from Londolozi G. R. adjacent to western Kruger N. P. (23.8/100 km²; Le Roux & Skinner 1989) and Matopos Hills, Zimbabwe (23.6/100 km²; Smith 1977). In East African woodland savanna mosaics, estimates include 16/100 km² (Queen Elizabeth N.

Three-toned patterning on Leopards *Panthera pardus*.

Left: Two lighter toned areas balanced out by scattered clusters of small black spots. *Centre:* Rosettes consisting of black spots regularly dispersed around medium tone. *Right:* 2, 3 or 4 lesser rosettes sometimes coalesce to form larger, jaguar-like rosettes.

P., Uganda; van Ordsol 1981), 7.5/100 km² (Ngorongoro; Schaller 1972) and 5.6/100 km² (Serengeti N. P., Bertram 1982).

Few estimates exist for West and central Africa. Martin & de Meulenaer's (1988) rainfall/density regression produced inflated estimates as high as 40/100 km² but prey biomass is too low to support such numbers (Jenny 1996). In several protected Gabon rainforest sites, density estimates using mark-recapture models applied to camera-trap data varied from 4.6 to 12.1/100 km²; outside protected areas Leopards were either absent or occurred at reduced densities ranging from 0.9 to 2.7 Leopards/100 km², due chiefly to the intense demand for bushmeat (Henschel 2008, Henschel *et al.* 2011). Based on limited telemetry data from three animals, Jenny (1996) estimated densities in rainforest in Tâi N. P., Côte d'Ivoire, at 7.1–11.0/100 km² and J. Hart (in litt., Nowell & Jackson 1996) offered a preliminary estimate of 8.3–12.5/100 km² for the Ituri forest, DR Congo.

Lowest population estimates come from habitats with low prey biomass: 0.7/100 km² for Cape fynbos habitat in South Africa (Norton & Lawson 1985, Norton & Henley 1987), 1.3/100 km² for the S Kalahari, South Africa (Bothma & Le Riche 1984, Bothma *et al.* 1997), and 1.5/100 km² for NE Namibia (Stander *et al.* 1997a). Stander *et al.* (1997a) suggested 0.5/100 km² for Etosha N. P.

Adaptations The spotted pelage provides superb camouflage in a wide variety of habitats. Camouflage is important for concealment, mainly from prey but also from predators and competitors. Darker colouration in forests and paler in arid, open habitats probably enhances habitat-specific camouflage. Similarly, melanism may confer an adaptive advantage in dark, forested habitat but the rarity of specimens in Africa suggests any gain is insignificant. The bright white underside of the tail tip is held high by ♀♀ with young cubs as a signal to follow (Schaller 1972). The ears are flattened and the pale ear patch is displayed during aggressive or defensive interactions to emphasize warning.

The Leopard is a tremendous climber, with enormously powerful forequarters and an enlarged scapula with a wide, shallow attachment area for the levator scapulae and serratus magnus muscles to assist vertical lift (Hopwood 1947, Kingdon 1977, Turner & Antón 1997). Leopards retreat to a tree when threatened and haul kills to avoid kleptoparasitism. This behaviour, combined with a catholic diet and very wide habitat tolerance, enables them to successfully compete with larger carnivores (Mills & Biggs 1993). Sunquist & Sunquist (2002) suggest that the prominent sagittal crest in the skull of ♂♂ may be an adaptation for different food habits from ♀♀, but enlarged sagittal crests are common in the ♂♂ of many species, possibly as a result of sexual selection.

Free of disturbance, Leopards are often diurnal but are chiefly crepuscular or nocturnal, strictly so when hunted or harassed by humans. In Lopé N. P., Gabon, continuous camera-trapping showed that Leopard activity cycles vary with the amount of human disturbance. In sites with high hunting pressure, Leopards used trails only at night, and in an active logging concession where some hunting occurred, movements were restricted to between 18:00 and 06:00h. In an abandoned logging concession with minimal human disturbance for six years prior to the study, over 60% of activity occurred during daylight hours (Henschel & Ray 2003).

Foraging and Food Leopards have extremely catholic diets, including at least 92 species in sub-Saharan Africa ranging from arthropods to adult male Common Elands *Tragelaphus oryx* (Kingdon 1977, Bailey 2005). Reviewing datasets from 13 countries (11 in Africa), Hayward *et al.* (2006a) demonstrated a preference for prey species within a weight range of 10–40 kg, with an optimum weight of 23 kg. Within this weight range, preferred prey generally occurred in small herds, in dense habitat and incurred a low risk of injury during capture (Hayward *et al.* 2006a). In most well-studied populations, diet is dominated by one or two ungulate species weighing less than 80 kg, and typically reflecting availability. For example, Impalas *Aepyceros melampus* comprise 47.7–92.8% of kills in various southern African mesic savannas (Mills & Biggs 1993, Radloff & Du Toit 2004, Bailey 2005), Nyalas *Tragelaphus angasii* were 43% of 217 kills in KwaZulu–Natal (Balme *et al.* 2007) and Springboks *Antidorcas marsupialis* were 65% of 80 kills in the Kalahari (Mills 1984). Leopards in West African moist savannas similarly concentrate on ungulates but large rodents, specifically the Greater Cane Rat *Thryonomys swinderianus*, comprise a high percentage of kills. Estimating mass consumed from occurrence in scats, the two most important species to Leopards in Comoé N.P., Côte d'Ivoire, were Kob *Kobus kob* (24.4–31.6%, over two separate sampling periods) and Greater Cane Rat *Thryonomys swinderianus* (11.5–15.3%; Bodendorfer *et al.* 2006). In Marahoué N. P., also in Côte d'Ivoire, Greater Cane Rats (28.0%) and Hartebeests *Alcephalus buselaphus* (27%) were almost equally important. Overall, ungulates comprised 52.9% (Marahoué) to 58.9–67.6% (Comoé) of biomass consumed.

Where medium-sized ungulates are uncommon, Leopards switch to prey weighing less than 20 kg; Common Duikers *Sylvicapra grimmia* (32.8% of kills) and Steenboks *Raphicerus melanotis* (13%) in semi-arid NE Namibia (Stander *et al.* 1997a); Klipspringers *Oreotragus oreotragus*, Grey Rheboks *Pelea capreolus* and Cape Grysbocks *Raphicerus melanotis* in mountain habitat of the Western Cape (Norton *et al.* 1986, Stuart & Stuart 1993); and Rock Hyraxes *Procavia capensis* and Klipspringers in the Matopos Hills (Grobler & Wilson 1972). Rock Hyraxes comprised 65.9% by frequency and 79.8% by mass of prey items in scats of Leopards in the alpine zone of Mt Kenya, Kenya (Rödel *et al.* 2004).

Some 17–37 prey species are identified from West and central African rainforests (Hoppe-Dominik 1984, Hart *et al.* 1996, Ososky 1998, Ray & Sunquist 2001, Henschel *et al.* 2005, 2011). Duikers, Red River Hogs *Potamochoerus larvatus*, Water Chevrotains *Hyemoschus aquaticus*, African Buffalo *Syncerus caffer*, Okapis *Okapia johnstoni* and Sitatungas *Tragelaphus spekii* comprise 40–87% of prey consumed, followed by primates, rodents, pangolins and small carnivores. Mean prey weight varied from 7.3 kg (Ray & Sunquist 2001) to 31.6 kg

(Henschel *et al.* 2005, 2011). In sites with the highest recorded mean prey weight (Ituri, Lopé and Ivindo), Red River Hogs and larger duikers (Bay Duiker *Cephalophus dorsalis* and Yellow-backed Duiker *C. silvicultor*) were the most important prey species (Hart *et al.* 1996, Henschel *et al.* 2005, 2011). Blue Duikers *Philantomba monticola* were most important in all other studies, possibly because larger ungulates were uncommon and Leopards switched to smaller prey, or alternatively because of its abundance or profitability (Ray & Sunquist 2001). Blake (2004) provided evidence that Leopards may take young Forest Elephant *Loxodonta cycotis* calves.

Primates are prominent in rainforest Leopard diet. Up to 11 species occurred in 38–41% of Leopard scats in Tai N. P. (Hoppe-Dominik 1984, Zuberbühler & Jenny 2002), 34% in Ituri (Hart *et al.* 1996) and 26% in Dzanga-Sangha, Central African Republic (Ray & Sunquist 2001). Predation on Chimpanzees *Pan troglodytes* occurs (Hart *et al.* 1996, Ososky 1998, Zuberbühler & Jenny 2002, Henschel *et al.* 2005), and Leopards are believed to be the chief cause of mortality in a Chimpanzee population in Tai N. P. (Boesch 1991). Leopards occasionally attack Gorillas *Gorilla* spp. (Schaller 1963, Watson 1999), and Gorilla remains have been found in Leopard scats in Gabon (Henschel *et al.* 2005, 2011) and Central African Republic (Fay *et al.* 1995). A Leopard scat from Salonga N. P., DR Congo, contained Bonobo *Pan paniscus* remains (D'Amour *et al.* 2006). Primates are less important to savanna Leopards. East and southern African savanna Leopards regularly kill various *Papio* baboons and vervet monkeys but overall occurrence of primates in their diet rarely exceeds 5–6% (Norton *et al.* 1986, Radloff & Du Toit 2004). In West African moist savannas, where primate species diversity and biomass is higher, primates are eaten more often; six species comprised 14.2–15.3% of biomass consumed in Comoé N. P. (Bodendorfer *et al.* 2006).

Leopards readily kill other carnivores. Cheetahs *Acinonyx jubatus* and small carnivores (<14 kg) comprised 6.8% of kills consumed ($n = 9$) in semi-arid NE Namibia (Stander *et al.* 1997a) and 6.3% of kills ($n = 5$) in the Kalahari (Mills & Biggs 1993). Jackals *Canis* spp., African Civets *Civettictis civetta* and other felids were eaten in E Zambia where ungulate density was reduced due to tsetse fly control (Wilson 1976). In more productive habitats, individual preference apparently dictates how often other carnivores are consumed. A ♀ observed by Estes (1991) ate 11 jackals over a period of several weeks in Ngorongoro Crater, and a ♂ in Bailey's (2005) study ate at least two Spotted Hyaenas *Crocuta crocuta*. However, carnivores were rarely eaten in a sample of 1452 kills from Sabi Sands G. R., South Africa (Radloff & Du Toit 2004). Similarly, three adult Cheetahs killed by Leopards in Phinda G. R., KwaZulu–Natal, were left uneaten (Hunter 1998a) and no carnivores were recorded among 377 kills compiled by Walker (1999) at the same site. Leopards are occasionally cannibalistic, mostly of cubs. A ♂ ate three cubs he killed in Phinda G. R. (Balme & Hunter 2004) and ♀♀ sometimes eat their own cubs killed by other predators (Hes 1991). A fatal clash between two adults over a carcass ended in the victor partially consuming its rival (Charsley 1977) and Steyn & Funston (2006) documented a radio-collared ♀ in Botswana killed and entirely consumed by a ♂ in an apparent dispute over the female's kill. Henschel *et al.* (2005) found the remains of at least three adults in Leopard scats collected in Gabon.

Livestock losses to Leopards vary widely, depending on availability of natural prey and husbandry practices. Between 1996 and 1999, Leopards were not blamed for any of 433 livestock losses from a

690 km² ranch in S Kenya (Patterson *et al.* 2004) and were responsible for only 3% of depredations ($n = 4$) in Voi, Kenya, between 1994 and 1998 (Kerbis Peterhans & Gnoske 2002). Leopards on a 199 km² cattle ranch in N Kenya killed an average of 4.3 cattle and 10.5 sheep per annum, costing US\$0.25/ha/year and accounting for 16.4% of all depredation costs (Mizutani 1993, 1999). In arid areas, losses tend to be higher. From complaints made by pastoralists in the arid Kweneng District, Botswana, Leopards were the most injurious predator, causing 38.2% ($n = 976$) of depredations between 1999 and 2002 (M. Scheiss pers. comm.). Similarly, in NE Namibia, Leopards were the second most costly predator after Lions to rural Ju/Hoan San communities, accounting for 42% of cattle losses, all dog and 97% of chicken losses (Stander *et al.* 1997b). Leopards are rarely reported as livestock killers from rainforest, presumably because intensive pastoralism is exceptional and livestock is usually corralled in villages overnight. Three different ♂♂ that raided the same village in Ituri, DR Congo, were in poor condition, each having lost a front paw in a cable snare (A. Blom pers. comm.): two healthy ♂♂ that killed dogs and domestic fowl in Epulu, DR Congo, were young and possibly inexperienced hunters (J. Hart pers. comm.). A commercial ranch in SE Gabon lost 30 head to a healthy adult ♂ that probably turned to cattle because uncontrolled hunting had greatly reduced the availability of wild prey (Henschel 2003).

Leopards occasionally kill people as prey. Of 78 habitual man-eaters (African and Asiatic combined) listed by Turnbull-Kemp (1967), 62 (79.5%) were healthy adults in good condition. A man-eater from M'bigou, Gabon, killed about 20 people between 1947 and 1948 before it was destroyed (Malbrant & Maclatchy 1949). Thirty people were killed and 49 injured by Leopards in Tanzania between 1993 and 1999, although the proportion comprising unprovoked predation is not reported (Games & Severre 2002).

Leopards kill opportunistically around the clock but forage mainly at night, early morning and late afternoon. Continuously radio-tracked Leopards in Tai N. P. ($n = 2$) and Cederberg Mts ($n = 3$) hunted primarily during the day with crepuscular peaks, possibly reflecting the diurnal activity patterns of prey in those sites (Norton & Henley 1987, Zuberbühler & Jenny 2002). Leopards forage primarily on the ground, where they are widely supposed to prefer the densest habitats available for hunting (Hes 1991, Sunquist & Sunquist 2002, Bailey 2005, Hayward *et al.* 2006a). However, Balme *et al.* (2007) demonstrated avoidance of dense habitats in KwaZulu–Natal even though those habitats also had the highest densities of preferred prey, probably because the likelihood of detecting prey was reduced. Instead, Leopards preferred to hunt in habitats with the highest probability of making a kill, which were those with intermediate cover levels where prey densities were also intermediate. Hunting in trees is exceptional but they often climb after arboreal prey to flush it to the ground where it is killed (Kingdon 1977) or wait in ambush below trees for arboreal prey to descend (Jenny & Zuberbühler 2005). In rainforest, arboreal primates, pangolins and squirrels are killed mostly on the ground or enter the diet via scavenging (Henschel *et al.* 2005, Jenny & Zuberbühler 2005, J. Hart pers. comm.). Leopards seldom leap directly on terrestrial prey from a tree.

Leopards forage alone, including ♀♀ with large cubs that are usually left behind. Hunting strategy varies with prey species and habitat type. In open terrain in NE Namibia, 94% of hunts consisted of stalking (mean distance stalked = 29 m, $n = 94$) followed by a

short chase (mean distance = 4.4 m; Stander *et al.* 1997a). In the S Kalahari, Leopards stalked their quarry over distances of up to 3400 m (mean distance = 195.8 m, n = 117 stalks; Bothma & Le Riche 1989). Of 13 observed hunts in Kruger N. P., seven involved stalks, one was an opportunistic pursuit and five were ambushes with no stalk (Bailey 2005). G. A. Balme (pers. comm.) recorded extended pursuits of juvenile Impalas and Nyalas up to 150 m (mean = 77.4 m, n = 6). In dense habitats with limited visibility, long stalks and chases are rare and Leopards appear to wait where encounters with potential prey are likely. Hart *et al.* (1996) observed Leopards in Ituri rainforest waiting at fruiting trees that attract duikers and Red River Hogs. Based on signs at freshly killed carcasses, Leopards ambushed their prey from a few metres away. Gabonese Leopards were observed ambushing prey along well-used game trails (P. Henschel pers. obs.), and in N Congo, a Leopard took a Red River Hog from a herd moving along a game trail (D. Morgan pers. comm.). Zuberbühler & Jenny (2002) observed a female Leopard hide in dense vegetation near monkey groups (n = 91), presumably waiting for them to move close, which they did on 61.8% of occasions; one successful attack on a Sooty Mangabey *Cercocebus atys* was observed (Jenny & Zuberbühler 2005).

Most prey species, especially larger ungulates, are killed by asphyxiation with a bite to the throat. For oversized prey, a muzzle hold is sometimes used; a 14-month-old female Leopard weighing 20 kg suffocated a mature male Impala approximately three times her weight by this method, taking 14 minutes (G. A. Balme pers. comm.). Smaller prey is typically killed by biting the back of the skull or neck. Prey is often plucked of fur or feathers before eating, which usually begins at the rump or groin. Large carcasses are consumed over a number of days and often cached in trees, less so in kopjes, Aardvark *Orycteropus afer* burrows and caves (De Ruiter & Berger 2001). Stevenson-Hamilton (1947) estimated a young Giraffe *Giraffa camelopardalis* cached in a tree at no less than 91 kg and a Kenyan ♂ hauled a month-old Black Rhino *Diceros bicornis* calf it had killed (Scott & Scott 2003). In Matopos Hills, where competitors are largely absent, only one of 38 kills was found in a tree (Smith 1977) and kills are rarely hauled in rainforest where the Leopard is the only large predator (P. Henschel pers. obs.). Most kills made by NE Namibian Leopards are dragged for long distances (mean = 140 m, range 0–762 m) and hidden on the ground in dense vegetation even though Lions, Spotted Hyaenas and other competitors are present (Stander *et al.* 1997a). Similarly, at Phinda G. R. where there are Lions and Spotted Hyaenas, Leopards stored 91% (n = 198) of their kills in dense vegetation on the ground; the rest were cached in trees (Balme *et al.* 2007). Leopards cache multiple kills up to 2 km apart and generally utilize all over a number of days (Hes 1991).

Scavenging occurs; ♂♂ sometimes usurp kills from ♀♀ (G. A. Balme pers. obs.) and Leopards appropriate kills from competitively inferior carnivores such as Cheetahs, lone Spotted Hyaenas and jackals (Hunter 1998a, L. T. B. Hunter pers. obs.). Forest Leopards scavenge the remains of Crowned Hawk-eagle *Stephanoaetus coronatus* and Chimpanzee kills, and apparently appropriate carcasses from eagles feeding on the forest floor (J. Hart pers. comm.).

Hunting success in Leopards has been most accurately established by spoor tracking in semi-arid habitat or by continuous following in southern Africa. In KwaZulu–Natal savanna woodlands, 20.2% of observed hunts ($n = 129$) during continuous follows resulted in a

Leopard *Panthera pardus*.

kill (Balme *et al.* 2007). Based on spoor-tracking, Leopards in NE Namibia killed on average every 2.7 hunts, a success rate of 38.1% (Stander *et al.* 1997a). In the S Kalahari, mothers with cubs had the highest success rate (27.9%) compared with ♀♀ without cubs (14.5%) and ♂♂ (13.6%; Bothma & Coertze 2004). Kalahari mothers killed smaller prey than lone ♀♀ or ♂♂ but travelled less for each kill and killed more often. In contrast, Namibian mothers killed only slightly more frequently than lone ♀♀ but they killed larger prey resulting in higher per capita food acquired. Annually, Kalahari Leopards average 111 (♂♂) to 243 (♀♀) kills, the higher figure for ♀♀ reflecting smaller kills (Bothma & Le Riche 1986). Kruger N. P. Leopards make fewer but larger kills, estimated at one adult Impala per week (Bailey 2005). Namibian Leopards average 1.6 kg (♀♀) to 3.1 kg (♂♂) of meat per day while Kruger N. P. ♀♀ averaged 2.9 kg/day and two ♂♂ ate 4.4–4.7 kg/day (Bailey 2005).

Social and Reproductive Behaviour Leopards are solitary and territorial. Adults socialize mainly when mating but familiar non-mating pairs regularly meet and associate briefly (<24 hours) without aggression. Males are tolerant of cubs belonging to ♀♀ they have mated and interact with mothers and cubs more often than widely reported but never as long-term associations (L. T. B. Hunter pers. obs.).

Both sexes maintain enduring home-ranges in which ranges of ♂♂ are large and typically overlap one or more smaller ranges of ♀♀ (but see Marker & Dickman 2005a). Range size is broadly correlated with prey availability; where prey availability and hence Leopard density is high, ranges are small though high levels of human persecution possibly elevate range size above that predicted by prey availability alone (Marker & Dickman 2005a). Range size of adults estimated from radio-tracking varies from 5.6 to 2750.1 km². In Kenya, ranges were 14.4 km² for a ♀ and averaged 52.0 km² (17.9–63.9 km², *n* = 3) for ♂♂ in Tsavo N. P. (Hamilton 1981), and 16.9 km² (*n* = 2) for ♀♀ and 37.1 km² (*n* = 2) for ♂♂ on ranchlands (Mizutani & Jewell 1998). In a W Tanzanian hunting concession ranges for ♀♀

averaged 25.1 km² (17.7–36.6 km², *n* = 4) and 136.4 km² for ♂♂ (87.0–164.7 km², *n* = 3; Caso 2002). Southern Kruger N. P. ♀♀ had ranges averaging 16.4 km² (5.6–29.9 km², *n* = 5) while ♂♂ averaged 52.0 km² (16.4–96.1 km², *n* = 5; Bailey 2005). Range size for three ♂♂ in Cederberg Wilderness, South Africa, averaged 51.0 km² (40–69 km², Norton & Henley 1987). In rainforest, Jenny (1996) estimated range sizes of 22 km² and 29 km² for two ♀♀, and 86 km² for a ♂. Ranges are much larger in less productive habitats. NE Namibian ranges averaged 188.4 km² (182.9–194.4 km², *n* = 3) for ♀♀ and 451.2 km² (210–1163.5 km², *n* = 6) for ♂♂ (Stander *et al.* 1997a). This is comparable with range size on commercial Namibian farmlands (♀♀, 179.0 ± 148.2 km², *n* = 4; ♂♂ 229.0 ± 95.1 km², *n* = 3), though prey biomass was significantly higher and anthropogenic factors may have elevated range size (Marker & Dickman 2005a). In the Cape Fold Mts, South Africa, a female's range was 487 km² and a male's was 388 km² (Norton & Lawson 1985). In the S Kalahari, mean range size for ♀♀ was 488.7 km² (94.0–693.0 km², *n* = 5) and two males' ranges were 1893.0 and 2750.1 km² (Bothma *et al.* 1997). Marker & Dickman (2005a) found no difference between wet and dry season range size in NC Namibian leopards.

Although territorial adults curtail intrusion by same-sex conspecifics, overlap of home-ranges within sexes is often considerable. Leopards avoid conflict by temporally separating activity in overlapping areas (Stander *et al.* 1997a). Mean intra-sexual range overlap for two separate tenure periods in NE Namibian Leopards was 35.3–42.7% in ♀♀ and 29.3–46.0% in ♂♂ (Stander *et al.* 1997a). In NC Namibian farmlands, female Leopards overlapped by 22 ± 13% while ♂♂ overlapped by 24 ± 13% (Marker & Dickman 2005a). In Tai N. P. rainforest, a male's range encompassed the entire range of one ♀ and 73% of the second female's range while range overlap between both ♀♀ was about one-sixth of their respective ranges (Jenny 1996). Mizutani & Jewell (1998) observed no overlap between four Kenyan ♂♂ and little or no overlap between five ♀♀ except for an adult and subadult, probably mother and daughter. Average territorial tenure for male Leopards in Phinda was 2.4 years (*n* = 7, range 0.5–7.3 years), though four animals were replaced due to human-mediated mortality (Balme *et al.* 2010b).

Both sexes scent-mark by cheek-rubbing and spraying vegetation, and by depositing scats and scraping the ground with hindfeet. Scent marks are deposited along frequently used routes including roads, trails and game paths, and along range boundaries. Following a territorial male Leopard for 65 min, when he was never out of sight, G. A. Balme (pers. comm.) observed 17 sprays, six scrapes and five territorial calls. Both sexes in Tai N. P. carried out regular marking 'tours' along trails 1–3 times a week, placing scrapes at more or less regular distances averaging 3.6 scrapes per km (S.D. = 0.4, *n* = 471); defecation occurred on average every 2.1 km (Jenny 1996). In Gabon, camera traps placed along trails where Leopard scats and scrapes were abundant showed that male Leopards revisited sites every ten days on average (S.D. = 5.3, *n* = 25). The abundance of fresh Leopard sign suggested that renewing the markings was one of the chief purposes of these regular movements (P. Henschel pers. obs.).

Leopards have a limited vocal repertoire. The most distinctive call, sawing (also called coughing or rasping) carries up to 3 km and probably serves a dual function in advertising territorial occupancy and reproductive availability. Sawing is most frequent during peak activity periods at dawn and dusk. Bailey (2005) identified known

individuals by this call so Leopards probably make a similar distinction. Leopards also make a puffing sound through the nose and lips called chuffing, used as a close-range call during friendly encounters, appeasement or courtship. Leopards growl, snarl, spit and hiss during aggressive encounters and mothers call cubs with a soft grunt.

Scent-marking and vocalizations ensure Leopards usually avoid territorial confrontations. When they occur, encounters are largely demonstrative with typically ritualized feline aggression; lateral presentation, arched back, stiff-legged walk, bared teeth and flattened ears displaying the white patches. On rare occasions when encounters escalate, fights are sometimes fatal. A ♂ and a ♀ killed in separate same-sex territorial fights both died from a single nape bite in which one or both maxillary canines punctured the spinal column and/or a mandibular canine pierced the external jugular vein (Balme & Hunter 2004).

Oestrous ♀♀ show increased rates of vocalization and scent-marking (G. A. Balme pers. comm.), the latter likely associated with elevated sex hormones. Females sometimes wander far outside their territory during oestrous periods, presumably to locate ♂♂; G. A. Balme (pers. comm.) recorded such excursions measuring up to 4.7 km. Mating is typically feline. G. A. Balme (pers. comm.) recorded 215 copulations over a 48-hour period while continuously monitoring a mating pair. In 13 copulations observed by Laman & Knott (1997), all were initiated by the ♀ walking from side to side in front of the ♂, brushing against him and waving her tail in his face. Males usually bite the ♀ on the nape during mating and both sexes growl continually during copulation. Copulation averages 3.0 sec (range 2.0–4.0 sec, *n* = 7) and the average interval between 11 observed copulations was 6.5 min (2–17 min, Laman & Knott 1997). Mating reaches a peak around dawn and dusk when the interval between 452 recorded copulations was 5.4 min (G. A. Balme & L. T. B. Hunter pers. obs.); the interval was 14.7 min (52 copulations) at midnight, and 21.2 min (37 copulations) at midday. Mating associations are brief, averaging 2.8 days at Phinda (range 1–5 days; G. A. Balme pers. comm.), two days in Kruger N. P. (range 1–4; Bailey 2005) and no more than a day in Kalahari observations (Bothma & Le Riche 1984). Contrary to Laman & Knott's (1997) suggestion that one ♂ has exclusive mating access to one or more ♀♀, high overlap between female and male ranges as well as between male ranges facilitates oestrous ♀♀ meeting numerous ♂♂ (Stander *et al.* 1997a). A radio-collared ♀ in Phinda G. R. mated with at least three ♂♂ in three days (L. T. B. Hunter pers. obs.). As well as increasing chances of conception and male competition for mates, female promiscuity probably reduces the risk of infanticide by confusing paternity. Infanticide by non-sire ♂♂ occurs (Scott & Scott 2003, Balme & Hunter 2004).

Reproduction and Population Structure Leopards give birth year round. Bailey (2005) suggested a weak peak among six litters associated with the birth flush of Impalas in Kruger N. P. though 16 litters recorded in the neighbouring Londolozi G. R. showed no peak (Hes 1991). In captivity, oestrus lasts 7–14 days and the oestrous cycle averages 45 days (range 20–50 days; Sadlier 1966). Gestation lasts 90–106 days. Litters normally comprise 1–3 cubs, though up to six have been recorded in captivity. Mean litter-size at emergence was 1.7 at Phinda (range 1–3, *n* = 15; Balme *et al.* 2009), 1.8 at Londolozi G. R. (range 1–3, *n* = 13; Hes 1991) and 2.3 in Masai Mara National Reserve (range 1–3, *n* = 14; Scott & Scott 2003). Newborn cubs

weigh 430–1000 g (captivity) and open their eyes on Day 6–10 (Skinner & Chimimba 2005). Cubs are denned in thick vegetation, among rocks, tree roots, in caves or Aardvark burrows. The ♀ observed by Le Roux & Skinner (1989) moved her young cubs to new dens every 2–3 days. She first presented them with meat at day 65 and suckling ceased after 101 days. Cubs are led to kills from weaning.

Mean interval between successfully raised litters was 16.2 months at Phinda ($n = 6$, range 11–20 months; Balme *et al.* 2009), 16.6 months at Londolozi G. R. ($n = 11$; Hes 1991), 25 months for a Serengeti female's consecutive two litters (Schaller 1972), and ranged from 24 to 36 months for five Kruger N. P. ♀♀ (Bailey 2005). Females resume oestrus rapidly after losing a litter, giving birth again within 5–7 months (mean = 5.7, $n = 3$; Seymour 2004). Two ♀♀, in Kenya and South Africa, each had nine litters between 1979 and 1989; the South African ♀ raised at least one cub to independence in eight of her litters (Hes 1991, Scott & Scott 2003). Cub mortality in the first year varies from 50% (Kruger N. P.; Bailey 2005) to 90% (S Kalahari; Bothma & Walker 1999). The average proportion of ♀♀ producing cubs in Kruger N. P. was 27.7% (Bailey 2005). Stander *et al.* (1997a) calculated that NE Namibian ♀♀ spend about half of their adult lives with dependent cubs, though a South African ♀ intensively monitored between 1979 and 1991 (139 months) had dependent cubs for 108 months (78%; Hes 1991). Adoption of related cubs has been documented; for example, a 15-year-old ♀ adopted the 7-month-old male cub of her 9-year-old daughter and successfully raised him to independence (Balme *et al.* 2012).

Cubs reach independence at 7–18 months; mean at Phinda was 12.3 months ($n = 8$, range 7–15 months; Balme *et al.* 2009) and at Londolozi G. R. was 12.8 months (range 10–14 months, $n = 8$; Hes 1991). Dispersal of subadults is poorly known but ♀♀ sometimes inherit part of their mother's range while ♂♂ tend to disperse more widely (Le Roux & Skinner 1989, Hes 1991). Two subadult ♂♂ in Namibia stayed in their mother's range for 6–8 months before dispersing 25 km and 162 km, respectively (Stander *et al.* 1997a). One died in his new range six months later while the other (the further disperser) returned to his mother's range, which he occupied for five months before being killed for livestock raiding. A Kalahari subadult ♂ settled in a new range 112.6 km from its natal range (Bothma *et al.* 1997). Estimated annual mortality of subadults is 32% (Kruger N. P.) to 52.6% (Phinda G. R.) compared with adult mortality of 18.5% (Kruger N. P.; Bailey 2005) to 38.9% (Phinda G. R.; Balme & Hunter 2004). Stander *et al.* (1997a) suggest that mortality among subadults is high when the population is at ecological carrying capacity, supporting the notion that population regulation is density-dependent.

Leopards of both sexes are sexually mature at 24–28 months though wild ♀♀ rarely have their first litter before 33–36 months (Hes 1991, G. Balme & L. Hunter pers. obs.). Mean age at parturition for four known-age ♀♀ at Phinda was 43.3 months (range 36–48 months; Balme *et al.* 2009). Males are unlikely to win territory and access to ♀♀ until age 3.5 at earliest; a four-year-old immigrant ♂ in Phinda G. R. killed a resident ♂ about twice his age and mated numerous ♀♀ in the months immediately following (L. T. B. Hunter pers. obs.). Longevity in wild Leopards is poorly known; a Namibian ♀ of 15.4 years is recorded (Stander & Hanssen 2001) and a known-age female at Londolozi G. R. died aged 16.7 years (L. Hes pers. comm.). Adults can probably reproduce until death; the same Londolozi ♀ gave birth when she was 16.3 years old (Seymour 2004,

L. Hes pers. comm.) and captive animals of both sexes reproduce up until 19 years (Shoemaker in litt., Nowell & Jackson 1996). Sex ratio of adults in a protected population is 1 ♂ to 1.8 ♀♀ (Bailey 2005).

Predators, Parasites and Diseases The Lion is the only African carnivore in which a single aggressor is easily capable of killing a healthy adult Leopard. Lions exert considerable effort in pursuing Leopards even though they probably represent little competition; two Lionesses treed an adult male Leopard for over 30 hours before it slipped away while the Lions were sleeping (L. T. B. Hunter pers. obs.). Other large, group-living carnivores working in concert occasionally kill Leopards. Several Spotted Hyaenas can kill a Leopard, and a pack of 10 African Wild Dogs *Lycaon pictus* killed a young adult Leopard caught on open ground in N Botswana (K. Leo-Smith pers. comm.). Pairs or groups of adult male baboons have killed Leopards, usually in defence (Marais 1939, Cowlshaw 1994). At least one adult ♂ during Bailey's (2005) study was killed by a Nile Crocodile *Crocodylus niloticus* and Turnbull-Kemp (1967) reported an adult Leopard disgorged by an African Rock Python *Python sebae*.

Young animals are especially vulnerable to predation from Lions and, less so, Spotted Hyaenas, which account for most first-year mortality in protected populations. Unattended cubs could be killed by Brown Hyaenas *Hyaena brunnea*, Striped Hyaenas *H. hyaena*, Cheetahs, Caracals *Caracal caracal* and jackals though there are no reports and predation by these species is probably rare. An adult male Chimpanzee in Mahale N. P., Tanzania, snatched a very young cub from a cave with the mother Leopard present, eventually killing it but not eating it (Byrne & Byrne 1988). A 15-month-old independent ♂ weighing approximately 36 kg died of wounds inflicted by a single Spotted Hyaena (Balme & Hunter 2004). Intra-specific clashes account for significant mortality in some populations. Of 35 radio-collared Leopards monitored for 69 months in Phinda G. R., four adults and three cubs were killed by conspecifics (Balme *et al.* 2009). Seymour (2004) suggests infanticide is the chief cause of mortality in Londolozi cubs, but cause of death was inferred rather than observed.

Leopards test positive for numerous infectious diseases but known mortalities are restricted to individuals, and epidemics are unknown

Leopard *Panthera pardus*; black and white markings around mouth emphasize expression.

(Spong *et al.* 2000b). Four Leopards died of anthrax in northern Kruger N. P. after scavenging from infected carcasses (Pienaar 1969) but carnivores, including Leopards, are resistant and deaths are uncommon (Meltzer 1997). Rabies in Leopards has been confirmed from Botswana, Namibia and Zimbabwe at low incidences (van Vuuren *et al.* 1997). Canine distemper occurs widely in Leopard populations and bovine tuberculosis infection in African Buffalo has spilled over into Kruger N. P. Leopards but few deaths are known from either (Keet *et al.* 1996). Leopards have tested positive for feline immunodeficiency virus, feline calicivirus, feline panleukopenia, parvovirus and herpes virus, apparently without clinical signs or mortality though some of these diseases are occasionally fatal in captives. Southern African Leopards tested negative for feline leukaemia virus (van Vuuren *et al.* 1997).

Boomker *et al.* (1997) provide a comprehensive list of parasites, most with little zoonotic or disease significance. Leopards carry at least 32 species of ticks but grooming usually ensures infestations are moderate. The most common ticks on Kruger N. P. Leopards were *Rhipicephalus* spp. (Bailey 2005; and see Horak *et al.* 2000). The feline ear mite *Notoedres cati*, which gives rise to mange, affected 53% ($n = 16$) of Leopards in Bailey's study population in the Kruger N. P. Mange was worse in Leopards already in poor condition and probably contributed to mortality by secondary infections. There is no evidence that *Sarcoptes* mites, common in Lions, affect Leopards (Boomker *et al.* 1997). Walsh *et al.* (2004) provide anecdotal evidence from Lopé, Gabon, that stings of introduced Little Red Fire Ants *Wasmannia auropunctata* causes blindness in Leopards, but no data are available on survival or other impacts. At least two-dozen helminth parasites have been isolated from Leopards, the most important being *Trichinella*, various hookworms and ascarids (Boomker *et al.* 1997). Protozoan parasites include *Trypanosoma brucei rhodesiense* for which Leopards are a potential reservoir and were implicated in an outbreak of human sleeping sickness in Uganda (Kangwagye 1977). Leopards carry *Babesia* protozoans that are transmitted by the bites of ticks and give rise to potentially lethal babesiosis (Boomker *et al.* 1997, Bailey 2005).

Conservation IUCN Category: Near Threatened. CITES: Appendix I.

Although Leopards occur in numerous protected areas across their range, the majority of the population occurs outside of protected areas. Leopards are at risk mainly from habitat conversion and intense persecution, especially in retribution for real and perceived livestock loss (Ray *et al.* 2005). Estimates of removals by pastoralists are poorly reported; between 2001 and 2005, at least 41 Leopards were removed from 14 commercial Namibian farms with a combined size of 1484 km² (Stein 2005). Leopards are surprisingly resilient and persist where other large cats cannot, albeit at severely reduced densities estimated at 0.1–0.01 of normal (Martin & de Meulenaer 1988, Marker & Dickman 2005a, Henschel 2008). Outside protected areas, tourism can offset livestock losses to Leopards and foster their conservation; in a trial programme among a Ju/Hoan San community in Namibia, revenue generated by Leopard-viewing tourism exceeded losses to Leopards by 12-fold and all livestock losses by 2.6-fold (Stander *et al.* 1997a). In intact African rainforest, the chief threat to Leopards is probably competition with human hunters for prey (Henschel *et al.* 2011); the tremendous volume of

wild meat harvests denudes forests of prey and may drive localized extinctions (Wilkie *et al.* 2000, Ray 2001, Henschel 2009).

Legal international traffic is limited largely to exports of skins and hunting trophies by 13 countries (2011 CITES quota is 2648). The impact of trophy hunting on populations is unclear but it may constitute additive rather than compensatory mortality, especially when ♀♀ are shot (Spong *et al.* 2000a, Balme *et al.* 2010a). In Tanzania, which allows only ♂♂ to be hunted, ♀♀ comprised 28.6% of 77 trophies shot between 1995 and 1998 (Spong *et al.* 2000a). Overhunting (legal and illegal combined) of ♂♂ may diminish female reproductive output; preliminary evidence from 29 months of intensive monitoring at Phinda G. R. suggested that elevated turnover of ♂♂ due to human hunting gave rise to increased rates of infanticide and reduced rates of conception (Balme & Hunter 2004). Illegal killing of Leopards is poorly quantified, but occurs widely. Eight of 17 human-mediated deaths adjacent to Phinda were illegal (the rest were legal removals or accidents). Leopards were illegally shot on community land ($n = 1$), farmland ($n = 2$) and commercial game ranches ($n = 3$), and two adult ♂♂ were killed in poachers' snares. In the same population, one juvenile was hit by a vehicle on a public road, and two additional Leopards were hit by vehicles just prior to and immediately after the study (Balme *et al.* 2010b). Annual mortality rates in the same population dropped from 45% to 11% and population growth improved from 0.972 to 1.217 after the introduction of mitigation measures designed to improve the sustainability of legal anthropogenic mortality and reduce illegal persecution (Balme *et al.* 2009, 2010a).

Skins and teeth (canines) are still widely traded domestically in some central and West African countries where parts are used in traditional rituals and sold openly in villages and cities (Henschel & Ray 2003). In Guinea and Guinea-Bissau, Leopard skins are valued for traditional ceremonies, and as trophies by a wealthy urban middle class and tourists; skins are openly sold in front of international hotels in Conakry, Guinea, and hunting for skins is considered the chief threat to the species in the two countries (Brugière *et al.* 2005). In N Congo, 15 Leopard skins were seized from local hunters over a two-week period in 2000 (Ray & Quigley 2001) and skins are common in the large markets of Côte d'Ivoire where they fetch up to US\$250 (Gross 1998). In Ghana, Leopard parts have been recorded only six times since 1999 in urban bushmeat markets but hunter interviews suggest that most (perhaps 60–95%) of large carnivore parts are traded outside formal markets (J. Brashares pers. comm.). Djibouti is an important conduit for Leopard skins from East Africa, which are bought mainly by French military personnel and carried illegally to Europe. Künzel *et al.* (2000) counted 44 Leopard skins in tourist shops on one day in 1999. Leopard skins reportedly from Niger and Chad are freely available in markets in Morocco. Shipp (2002) counted 17 skins in a two-hour period in one Marrakech market and was offered a further 20, including courier delivery to the UK. Illegal traffic of skins was previously considered less common in southern Africa, but there is increasing evidence for organized trade; skins of at least 150 individuals were seized between 2004 and 2008 from a single supplier in KwaZulu-Natal where the demand is for Nazareth Baptist ('Shembe') Church religious attire. At least 1000 *amambatha* (shoulder capes) representing a minimum of 500 leopards were counted at one Shembe gathering in 2011 (T. Dickerson pers. comm.). With the rapid growth of the Shembe church in southern Africa, the demand for skins is expected to grow (Papini 2004, Tishken 2006).

Felini Fischer de Waldheim, 1817. Mém. Soc. Imp. Nat. Moscow 5: 372

In Africa, tribe Felini is represented by five genera: *Felis*, comprising four species, and *Profelis*, *Caracal*, *Leptailurus* and *Acinonyx*, each includinga single species. Felini mostly radiated outside Africa; however, *Profelis*, *Caracal* and *Leptailurus* likely represent a single intra-African radiation.**GENUS *Profelis*****African Golden Cat***Profelis* Severtzov, 1858. Revue Mag. Zool. Paris (2), 10: 386.*Profelis* is a monotypic genus endemic to Africa. Although some authors have included its single representative, the African Golden Cat, in the genus *Felis* (e.g. Král & Zima 1980, McKenna & Bell 1997), many authors have followed Pocock (1917) in placing the species in the genus *Profelis* (e.g. Van Mensch & Van Bree 1969, Groves 1982, Wozencraft 1993, 2005). Despite studies that show affinity with *Catopuma* (which includes the Asian Golden Cat *C. temminckii*) (e.g.Weigel 1961, Bininda-Emonds *et al.* 1999), more recent molecular data unequivocally reveal that the Caracal *Caracal caracal* and the Serval *Leptailurus serval* are closely allied with the African Golden Cat, having diverged 8.5 mya (Janczewski *et al.* 1995, Johnson & O'Brien 1997, Mattern & McLennan 2000, Johnson *et al.* 2006).**Justina C. Ray & Thomas M. Butynski*****Profelis aurata* AFRICAN GOLDEN CAT**

Fr. Chat Doré Africain; Ger. Afrikanische Goldkatze

Profelis aurata (Temminck, 1827). Monogr. Mamm. 1: 120. 'Nous ne savons pas au juste dans quelle partie du globe a été trouvé'; fixed by Van Mensch & Van Bree (1969) to 'probably the coastal region of Lower Guinea (Between Cross River and River Congo ...)'.

Taxonomy Marked variability across the range in pelage colour and pattern is responsible for a number of independent descriptions. Colour phases have been described as several species, but Pocock (1907), Van Mensch & Van Bree (1969) and others found pattern ofpelage more important for taxonomy than colour. Two subspecies are usually recognized (Smithers 1975). Synonyms: *celidogaster*, *chalybeata*, *chrysothrix*, *cottoni*, *maka*, *neglecta*, *rutila*. Chromosome number: 2n = 38 (Malouf & Schneier 1965).

Dorsal views of skulls of left to right,

Golden Cat *Profelis aurata* (spotted morphs
more common in West Africa, unspotted
morphs more common in East Africa)

African Golden Cat *Profelis aurata*.

Description Medium-sized, solidly built cat with short face, heavy muzzle, small head, rather small black-backed ears and medium-length tail. Head round and small with distinctive light patches around eyes and above mouth. Chin, cheeks, throat, chest and belly off-white to pure white. Eyes green to golden-brown. Ears short, rounded, untufted and shiny black on the back. Hair on back of neck reverses direction, orienting forwards in one or two whorls and a low ridge. Pelage colour highly variable, ranging through pale sandy, reddish-brown, chestnut-red, chocolate-brown, greyish-brown, silver-grey, bluish-grey, to jet-black (melanistic) (see Geographic Variation). Pelage texture varies from short and rough to long and soft. Hairs on mid-dorsal line dark, tipped black or brown; may have distinct or obscure banding. Underhairs always grey; dark grey to dark brown spots nearly always visible on belly and inside limbs; spotting elsewhere ranging from absent to densely covering entire body. Spots vary from large and distinct circles or rosettes, to small and obscure freckles. Limbs short, stout and strong. Claws fully retractile, soles densely haired between pads. Tail 35–45% length of head and body. Sexes alike in colour, but ♂♂ have body measurements ca. 10% longer than ♀♀, and weigh about one-third more.

Skull relatively elongated; muzzle heavy and slightly enlarged. Sagittal crest well developed, and zygomatic arches more or less straight. Foramen large, narrow and elliptical. The auditory bullae are well developed. The carnassial teeth are relatively large, and the first premolar is reduced to a peg; third premolar with anterior cusp very small or absent.

Geographic Variation

P. a. celidogaster: west of Cross R. Usually with spotting all over body, with dark mid-line along back and tail banded, either distinctly or indistinctly.

P. a. aurata: east of Congo R. to Kenya. No spotting except on flanks and belly; dark mid-dorsal line absent; tail not banded or indistinctly banded.

East of the Cross R. and west of the Congo R. there is a large intermediate or clinal zone (Van Mensch & Van Bree 1969).

Pelage colour, and dorsal pelage spotting and texture are variable throughout the range (described and illustrated in detail by Van Mensch & Van Bree [1969] and Kingdon [1977]; and see Boy [2003]). Colour phases do not represent geographic races, as individuals of

*Profelis aurata*

different colours are present in the same areas (Van Mensch & Van Bree 1969, Rosevear 1974, T. Butynski pers. obs., T. Davenport, J. Hart, & P. Henschel pers. comm.). Captive individuals have reportedly changed colour from rufous to grey or vice-versa in a period of months (Pocock 1907, Brooks 1962, Boy 2003). In a study of incidence of colour phase among 186 skins, Van Mensch & Van Bree (1969) found no correlation between pelage colour and season, age, size, sex, locality, or climate. Of these 186 skins, 50% were russet/brownish, 46% grey/greyish and 4% black (melanistic); roughly the same percentages held when data from 68 additional individuals were combined (T. M. Butynski & J. C. Ray pers. obs.).

Similar Species

Leptailurus serval. In forest edge, savanna and woodland from S Senegal eastwards to Ethiopia and S Somalia south to South Africa and SW Angola. Build sligher; ears larger with white patch on backside; muzzle smaller; fur on neck does not change direction; limbs longer and thinner; parastyle of upper third premolar present. Van Mensch & Van Bree (1969) detail distinguishing characteristics between the skull of the African Golden Cat and Serval.

Caracal caracal. Largely allopatric, being absent from the forest zone of Equatorial Africa. Ears longer and triangular with long tufts; muzzle smaller and shorter; fur on neck does not change direction; hindquarters higher.

Panthera pardus. Broadly sympatric. Larger build, with distinct spotting including on face and neck; back of ears with prominent pale patch.

Distribution Endemic to the forest zone of Equatorial Africa, from S Senegal eastwards through Guinea, Sierra Leone, Côte d'Ivoire and Ghana, and again from E Nigeria and Cameroon through Gabon, Equatorial Guinea, Congo, SW Central African Republic, DR Congo, S Sudan to Uganda; the southern limit ranges from N Angola through DR Congo to Rwanda and Burundi (Rosevear 1974,

Lateral view of skull of African Golden Cat *Profelis aurata*.

Monfort 1992, Nowell & Jackson 1996). Also, in Omo N. P., Ethiopia (Schloeder & Jacobs 1996), and Mau Forest, Kenya (Toschi 1946). No other specimens known for Kenya, but reliable sightings reported for Mt Kenya (T. Archer pers. comm.; although not reported by Young & Evans [1993]), Aberdares Range (Hardy 1979, Watson 1980, Seth-Smith 1995), Ol Keju R. and Natron Swamp (Boy 2003) and Arabuko-Sokoke Forest (Virani 1993). Although suitable habitat exists in parts of Tanzania, there is no evidence for their presence to the east of L. Tanganyika.

Since most museum specimens of African Golden Cat were purchased by collectors from hunters or markets, the precise origin of many is in doubt (Rosevear 1974). A record from Chad (mapped in Boy 2003) was a captive zoo specimen (Van Mensch & Van Bree 1969). A record from Gambia (Van Mensch & Van Bree 1969) was rejected by Grubb *et al.* (1998); there also are no confirmed records from Guinea-Bissau, Togo and Benin (Van Mensch & Van Bree 1969, Sayer & Green 1984). Hapold (1987) noted there was no evidence that the species occurs in Nigeria as suggested by earlier authors, but the species definitely does occur at least in the Gashaka-Gumti N. P. on the Cameroon border (Nicholas 2004). A record from Mali (with locality given as Nioro; Bigourdan & Prunier 1937) is likely to be in error (Van Mensch & Van Bree 1969).

Habitat Africa's only forest-dependent felid, occurring in lowland and montane rainforest, swamp forest, bamboo forest, as well as alpine moorland (Rahm & Christiaensen 1963, Nowell & Jackson 1996, Andama 2000, Boy 2003). Penetrates drier regions by using gallery forest along major rivers (Van Mensch & Van Bree 1969, Kingdon 1977), wooded savannas (Brugière 2001), and savanna/forest mosaics (C. Tutin pers. comm.). Recorded from near sea level up to 3600 m in Uganda (Guggisberg 1975). Adapts well to selectively logged areas, presumably in response to increased prey abundance in dense secondary growth; also seen on roads, in banana plantations and near small villages (Kingdon 1977, Watson 1980, Virani 1993, Davenport 1996, C. Chapman, A. Gautier-Hion & J. Hart pers. comm.).

Abundance Thought to be very rare, based on the fact that African Golden Cats are so rarely observed in the field, even by field biologists who have spent many years within the species' range. However, the relatively high frequency at which skins are found among hunters, in bushmeat markets and in museums, may be an indication that they are more abundant than suggested by the low incidence of observations in the wild (Malbrant & Maclatchy 1949, Rosevear 1974, T. Davenport pers. comm.). In most localities, African Golden Cats seem to be more abundant in undisturbed and little-disturbed forest than in savanna woodland, highly disturbed, or fragmented forests (Nowell & Jackson 1996, Andama 2000, T. Davenport pers. comm.). By contrast, in Ituri Forest, NE DR Congo, African Golden Cat sign is more frequent in

Frontal, profile and dorsal views of African Golden Cat *Profelis aurata* head.

secondary areas and toward the savanna-forest ecotone (J. Hart pers. comm.).

Adaptations Generally considered to be crepuscular and nocturnal (Rosevear 1974, Guggisberg 1975, Andama 2000), but may also be active during the day (Kingdon 1977, Davenport 1996); in Lopé N. P., Gabon, 21 of 37 camera-trap captures were during daylight hours (Bahaa-el-Din *et al.* 2011). Almost all sightings are of animals on the ground, although occasional sightings are above ground (A. Gautier-Hion & J. Hart pers. comm.). Hart *et al.* (1996) found a nursing mother and one kitten in a den in a fallen hollow log in the Ituri Forest.

Foraging and Food Carnivorous. Principal prey are birds and small- and medium-sized mammals, especially rodents and duikers (Basilio 1962, Rahm & Christiaensen 1963). In the Ituri Forest, 60 scats (identified on the basis of diameter and bone fragment size) contained muroid rodents and squirrels (70%), Blue Duikers *Philantomba monticola* (25%), birds (18%), Giant Sengis *Rhynchocyon cirnei* (12%), Bates' Pygmy Antelopes *Neotragus batesi* (7%) and monkeys *Cercopithecus* spp. (5%). Modal prey weight was <1.5 kg, with only 1% of prey with adult weights greater than 5 kg (Hart *et al.* 1996). In Dzanga-Sangha, SW Central African Republic, 17 scats (identified by thin-layer chromatography) contained shrews, squirrels and other rodents (62% of 21 prey items), small- and medium-sized duikers (33%) and primates (5%). Mean adult weight of prey was 3.6 kg, and 17% of prey had adult weights greater than 5 kg (Ray & Sunquist 2001). Stomach

African Golden Cat *Profelis aurata*.

contents of one specimen from S Senegal contained bird remains, while a second held a frog cf. *Amnirana galamensis* (Gaillard 1969). Behavioural observations centred on primates indicate that African Golden Cats may be important predators of arboreal monkeys (Struhsaker 1981, A. Gautier-Hion pers. comm.). Seth-Smith (1996) observed a female with two kittens in S Sudan hunting bats as they swooped for insects feeding on fallen mangoes.

African Golden Cats probably catch most prey while on the ground, presumably by stalking and rushing, and by ambushing prey from low tree branches (Basilio 1962, Davenport 1996). Boy (2003) provides an eye-witness account of an African Golden Cat killing a Sykes's Monkey *Cercopithecus mitis* on the ground in riverine forest, south-east of Aberdare N. P., and Sheil (2011) observed an animal in Bwindi Impenetrable N. P. feeding on a long-tailed mouse on the ground while holding it between its front paws. Captive animals hook into prey with their claws and deliver a rapid bite to the back of the neck (Kingdon 1977). Hart *et al.* (1996) suggested that they scavenge the remains of eagle kills on the forest floor.

Several authors have reported African Golden Cats raiding poultry coops, and killing domestic goats and sheep (Van Mensch & Van Bree 1969, Kingdon 1977, Davenport 1996); however, many of these reports probably are due to misidentification with Servals *Leptailurus serval*.

Social and Reproductive Behaviour Solitary; almost all sightings are of single individuals. Tenure system probably like other felids, with core areas of home-range defended from same-sex adults

and overlap at edges. Exposed faeces on trails suggestive of marking behaviour (Kingdon 1977, J. C. Ray pers. obs.).

Vocal repertoire of captives described by Tonkin & Kohler (1978) as 'extensive'. Principal vocalization is a strong, abrupt and husky 'meow'. A female with kittens emits shrill meows accompanied by sequences of abundant trembling notes. Kittens often chirp (Jackson & Farrell Jackson 1996). During instances of friendly close contact (e.g. mother with young, courtship, mating), the most common vocalization is a 'gurgling' – a low-volume, short (0.5 s) rhythmical sound sequence (Peters 1984). Captives also give other common cat-like sounds: 'hisses', 'snarls' and 'growls' (Kingdon 1977).

Reproduction and Population Structure There is limited information on when young are born. A mother with one nursing kitten in Ituri Forest was found in Jun (Hart *et al.* 1996), and a ♀ in the final trimester of pregnancy was trapped in SW Uganda in early Sep (Kingdon 1977). Gestation period of a single animal in captivity was 75 days. Three captive litters each had two kittens (Tonkin & Kohler 1978). Birth-weights 180–235 g (n = 3). Two captive kittens had eyes completely open by Day 6, were walking by Day 13, taking meat by Day 40 and had permanent dentition erupting by 14 weeks (Tonkin & Kohler 1978). Compared with other small felids, there is more rapid development of physical agility. Weights of 2.5 kg (♀ ♀) and 2.9 kg (♂ ♂) are attained by 12 weeks. A captive ♀ reached sexual maturity at 11 months, and a captive ♂ at 18 months (Tonkin & Kohler 1978). A wild-caught animal could have been around 21 years old when it died in captivity (Weigl 2005).

Among those African Golden Cat specimens for which data on sex are available, 25 (74%) were male and nine (26%) female (T. M. Butynski & J. C. Ray pers. obs.). Of 13 animals found during a bushmeat survey in Lobeké Forest, SE Cameroon, 12 (92%) were male and 11 were adult (T. Davenport pers. comm.). The reason for the strong bias towards ♂♂ in these samples is unknown.

Predators, Parasites and Diseases African Golden Cat remains were recovered in five of 197 Leopard *Panthera pardus* scats from Lopé N. P. (Henschel 2001); a single carcass killed by a Leopard was found in Ituri Forest (Hart *et al.* 1996). Three individuals were found dead in an emaciated state from unknown causes in Lopé Reserve over 15 years (C. Tutin, pers. comm.). Three species of ectoparasites were collected by Gaillard (1969) from an adult ♂ in Senegal: *Dirofilaria granulosa*, *Taenia taeniformis* and a *Ligula* sp.

Conservation IUCN Category: Near Threatened. CITES: Appendix II.

The primary threats to African Golden Cats are habitat loss and hunting. Skins appear regularly in markets within the range of the species (Kingdon 1997), and in Yaoundé and Kampala these often are sold alongside medicinal herbs and fetishes (T. Davenport pers. comm.). Skins may be used during circumcision rites or to wrap valuable objects (Van Mensch & Van Bree 1969), or as good luck charms for hunting success (Guggisberg 1975). In a sample of 254 animals taken by hunters in NE Gabon, two (0.8%) were African Golden Cats (S. Lahm pers. comm.), while among 921 carnivore carcasses found in markets in E DR Congo, four (0.4%) were African Golden Cats (Colyn *et al.* 1987). Over the course of a three-month period at four sites in Lobeké Forest, 13 African Golden Cats were recorded killed by

wire snares (Davenport, in Ray *et al.* 2005). Bushmeat hunting heavily impacts many prey species, thereby posing a threat to the prey-base of African Golden Cats. Two of the four principal game species for hunters in Dzanga-Sangha, SW Central Africa Republic, are among the main prey of African Golden Cats (Ray 2001). About 47% of mammals in the bushmeat off-take in Lobeké Forest were prey species of African Golden Cats (T. Davenport pers. comm.). Hunting is prohibited or regulated in about half the range countries (Nowell & Jackson 1996), but there is little or no enforcement of laws.

Dependence on forest cover means that habitat loss is a threat particularly in West and East Africa. None the less, within their range, African Golden Cats occur in a number of key protected areas, including: Gola F. R. (Sierra Leone), Mount Nimba Strict N. R. (Liberia, Côte d'Ivoire, Guinea), National Park of Upper Niger (Guinea), Sapo N. P. (Liberia), Taï and Comoé National Parks (Côte d'Ivoire), Gashaka Gumti N. P. (Nigeria), Korup N. P. and Dja Faunal Reserve (Cameroon), Lopé and Ivindo National Parks (Gabon), Odzala and Nouabalé-Ndoki National Parks (Congo) and Dzanga-Ndoki National Parks (Central African Republic), Virunga N. P. (DR Congo), Queen Elizabeth and Bwindi Impenetrable National Parks (Uganda) and Aberdares N. P. (Kenya).

Measurements

Profelis aurata

HB (♂ ♂): 766 (616–935) mm, n = 18

HB (♀ ♀): 699 (630–750) mm, n = 8

T (♂ ♂): 319 (254–370) mm, n = 18

T (♀ ♀): 293 (280–300) mm, n = 7

HF c.u. (♂ ♂): 171 (155–193) mm, n = 9

HF c.u. (♀ ♀): 162 (140–170) mm, n = 6

E (♂ ♂): 56 (51–60) mm, n = 10

E (♀ ♀): 51 (44–55) mm, n = 4

WT (♂ ♂): 11.0 (8.0–14.0) kg, n = 6

WT (♀ ♀): 6.2, 8.2 kg, n = 2

Throughout range: museum data (AMNH, CMNH, FMNH, MCZ, NMNH), literature (especially Van Mensch & Van Bree 1969) and unpublished data (D. Brugière, T. Butynski, J. Kerbis, S. Lahm & E. Sarmiento pers. obs.)

GENUS *Caracal*

Caracal

Caracal Gray, 1843. List. Spec. Mamm. Coll. Brit. Mus. p. 46.

Once traditionally included in the genus *Felis* (e.g. Roberts 1951, Smithers 1975, Groves 1982, Meester *et al.* 1986), the Caracal *Caracal caracal* at one stage even saw its generic designation changed to *Lynx* (Roberts 1926) based primarily on superficial resemblances, although Werdelin (1981) could find no phylogenetic evidence to support such a relationship. Wozencraft (1993, 2005) placed the species in the monotypic *Caracal*, following others (Weigel 1961, Hemmer 1978, Werdelin 1981), a treatment that has since been widely accepted. Molecular data reveal that the Caracal is closely allied with the African Golden Cat *Profelis aurata* and Serval *Leptailurus serval*, having diverged around 8.5 mya (Janczewski *et al.* 1995, Johnson & O'Brien 1997, Johnson *et al.* 2006).

Lars Werdelin

Caracal *Caracal caracal* facial expressions.

Caracal caracal CARACAL

Fr. Caracal; Ger. Karakal (Wüstenluchs)

Caracal caracal (Schreber, 1776). Die Säugethiere 3 (16): pl. 110 [1776]; text 3 (24): 413, 587 [1777].
 'Vorgebirge der guten Hofnung', restricted by J. A. Allen (1924: 281) to 'Table Mountain, near Cape Town, South Africa'.

Caracal *Caracal caracal*.

Taxonomy Seven subspecies have been recognized (Smithers 1975), but their validity seems questionable and they are perhaps best considered as geographical variants. Synonyms: *aharonii*, *algira*, *bengalensis*, *berberorum*, *coloniae*, *corylinus*, *damarensis*, *limpopoensis*, *lucani*, *medjerdae*, *melanotis*, *melanotix*, *michaelis*, *nubica*, *poecilotis*, *roothi*, *schmitzi*, *spatzi*. Chromosome number: $2n = 38$ (Hsu & Arrighi 1966).

Description Medium-sized, robustly built, uniformly coloured cat with dark-backed ears with distinct terminal tufts averaging 45 mm in length. Head typically cat-like with short face prominently marked with black and white patches, notably around eyes and mouth. Chin and throat are white, with variable extent of white on cheeks. The large ears pointed with a tuft of longish black hair at the tip. Back surfaces of the ears predominantly black but liberally sprinkled with white hairs; inner surfaces white. Hindquarters slightly higher than shoulders due to powerfully muscled and elongated hindlegs. Pelage thick but short and soft, the colour varying from pale reddish-fawn with a greyish infusion, to rich brick-red. Underparts, including inner leg surfaces, paler than rest of pelage and faint spotting or blotching may or may not be present. Extent of white on chest and belly very variable. Tail is similar in colour to the dorsal aspect and approximately one-third of head-body length. In temperate regions, guard hairs of the winter coat up to 30 mm long but usually less than 20 mm in the summer coat. Colour of guard hairs variable but pale at the base, with either broad annulations in off-white, dark brown or black. In temperate regions underfur in winter is thick but in summer greatly diminished. Paws proportionally large, with five digits on the forefeet and four on the hindfeet. The first digit on the forefoot is higher than the other four and does not make contact with the ground but is equipped with a substantial claw (dew claw). Claws of the forefeet are sharp, retractable and curved (about 25 mm along the upper curve). The claws on the hindfeet are less curved but larger (exceeding 30 mm). Males are consistently larger than ♀♀ in all respects (Stuart & Stuart 1992).

Skull high and rounded in profile, with particularly short, blunt rostrum. Supraoccipital crest well developed and in older animals

Caracal *Caracal caracal*.

joined at right-angles by sagittal crest. Ear bullae large and well developed. An overall heavily built skull, with stout mandible and tall, narrow coronoid process (Skinner & Chimimba 2005). Dentition is typically felid; the second upper premolar is usually absent (present in only eight of 100 skulls examined by Stuart & Stuart [1985]), unlike the Serval *Leptailurus serval* in which they are usually present.

Geographic Variation Separating the seven described subspecies occurring in Africa is based in most cases on small samples and minor differences in pelage colouration (Smithers 1975). Animals from arid low rainfall areas tend to be paler than those from higher rainfall regions. Within the southern African populations, from where the largest samples are available, there is considerable variation in overall pelage colour. Melanic individuals have been recorded from Kenya and Uganda (Rosevear 1974).

Similar Species

Leptailurus serval. Sympatric in most parts of the range, except, most notably, in the drier western and south-western parts of southern

Lateral view of skull of Caracal *Caracal caracal*.

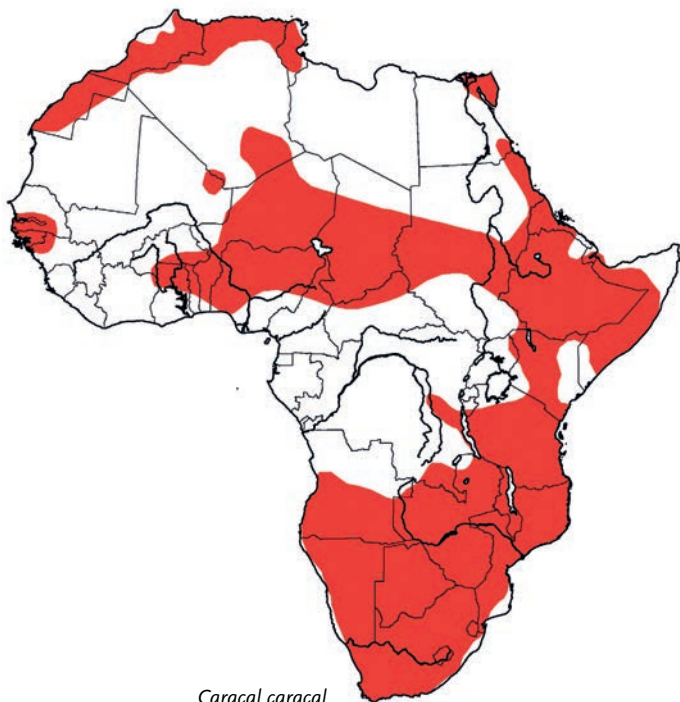

Africa. Distinctive spotting and barring, a ringed tail and a large white spot at back of each ear, with terminal tuft absent.

Profelis aurata. Largely allopatric, occurring in the forest zone of equatorial Africa. Dark-backed ears that lack a terminal hair tuft, have variably dark spotted upper- and underparts, the latter pelage being white to off-white.

Distribution The Caracal is widely distributed on the African continent, being absent only from the equatorial forest belt and from much of the central Sahara, but they are present in the montane massifs of that desert and its fringes, including the Adrar des Iforas in NE Mali (Sidiyène & Tranier 1990), Hoggar and Tassili mountains of SE Algeria and the Saharan Atlas (De Smet 1988, Kowalski & Rzebik-Kowalska 1991), the Aïr of Niger (Dragesco Joffé 1993), and edges of the great sand areas of the Eastern Great Erg.

The presence of Caracal in the savanna regions of the Congo basin, north of the Congo R., is equivocal. The form *lucani* is described from Landana, which is in Cabinda, Angola. Coetzee (1977) gave the range of this subspecies as N Angola, Gabon, and south-western DR Congo (it is also mentioned by Malbrant & Maclatchy 1949); however, the species is not mentioned in N Angola by Crawford-Cabral (1989a) or Hill & Carter (1941).

Extralimital to the African continent, the Caracal has a very wide distribution, occurring in suitable habitats to the Arabian Peninsula,

Caracal caracal

the Middle East and Turkey, and then eastwards to C India and northwards to Kazakhstan and Turkmenistan (Stuart 1984, Nowell & Jackson 1996, Sunquist & Sunquist 2002).

Habitat The Caracal occupies a wide variety of habitats from semi-desert to relatively open savanna and scrubland to moist woodland and thicket or evergreen/montane forest (as in the Western Cape of South Africa), but favours drier woodland and savanna regions with lower rainfall and some cover (Stuart & Wilson 1988). They range from sea level in many parts of their range, to 2,260 m in the Moroccan Atlas Mts (Cuzin 2003) and 3300 m in the Ethiopian Highlands (Yalden *et al.* 1996). In KwaZulu-Natal (South Africa), recorded in commercial forests (*Eucalyptus* spp. and *Pinus* spp.) (Rowe-Rowe 1992a), and in areas of intensive wheat cultivation in the Western Cape they hide up during the day in adjacent scrubland, moving at night on open fields. Particularly common in the Cape fynbos, an area of low and often dense scrub (Stuart 1981). On the Pro-Namib plains of Namibia Caracal are closely associated with lightly wooded dry river courses and rocky inselbergs, and on South Africa's central Karoo plains they are strongly associated with rugged mountain and hill ranges.

Abundance The Caracal is common in parts of its range, especially in South Africa and S Namibia where it is expanding into new, and recolonizing vacant, areas (Stuart 1984, Stuart & Wilson 1988). Found in all major national parks and many other conservation areas within their range (Stuart 1984, C. Stuart & T. Stuart pers. obs.). In central and West Africa, where they are largely absent, densities are apparently lower, possibly due to finer partitioning of resources in a more diverse carnivore community (Kingdon 1977, Stuart 1984, Nowell & Jackson 1996), while north of Sahara densities are very low, and Caracal could be on the verge of extinction at least in Morocco (F. Cuzin pers. comm.). In South Africa, Grobler (1981) estimated the population density of Caracal in Mountain Zebra N. P. in the Eastern Cape as 1/2.6 km², while Avenant & Nel (1998) recorded a density of 0.23–0.47/km² in West Coast N. P. in the Western Cape.

Adaptations Large pinnae and well-developed ear bullae reflect the important role played by hearing in hunting, but colouring and tufted tips appear to be elaborated to serve communication by means of frequent ritualized ear movements (Kingdon 1977). Skull and dentition (in particular the sharp canine teeth) are stoutly structured, an adaptation to taking relatively large prey in proportion to its size. The masseter and temporalis muscles are well developed to deliver the killing bite. As in other felids, the teeth of the carnassial shear are adapted to cutting, although the teeth in the lower jaw show no adaptation to crushing. Paws notably large and the well-developed claws also indicate an ability to take larger prey. Normally terrestrial, they are adept tree climbers, using their powerful dew claws in this pursuit.

Caracals are principally nocturnal, although in protected areas they may occasionally hunt during the day, especially in the early morning and late afternoon, and particularly on cooler days or if overcast.

Foraging and Food Caracal prey mainly on small- to medium-sized mammals, from small murids to antelope up to the size of around 50 kg, but they will also take birds, reptiles, invertebrates, fish and some plant matter. The most detailed studies of diet have

Caracal Caracal caracal.

been undertaken in South Africa (Grobler 1981, Moolman 1984, Palmer & Fairall 1988, Stuart & Hickman 1991, Avenant & Nel 1997, Melville *et al.* 2004); in these studies, the mammal component of the diet ranged from 86% to 100%. Small mammals in the form of rodents and springhares *Pedetes* spp. make up the bulk of the mammal component; the largest wild prey species recorded include Bushbuck *Tragelaphus scriptus* ewes, Mountain Reedbucks *Redunca fulvorufula*, Grey Rheboks *Pelea capreolus*, Springboks *Antidorcas marsupialis* and young Greater Kudus *Tragelaphus strepsiceros*. In the area to the north of L. Chad the local name for Caracal means 'gazelle cat' (Dragesco-Joffé 1993), where they are said to hunt Dorcas Gazelles *Gazella dorcas*. The same author records Barbary Sheep *Ammotragus lervia* ewes and lambs, Rock Hyraxes *Procavia capensis*, hares and birds (pigeons and doves, bustards) (Dragesco-Joffé 1993). The remains of small carnivores have been found in most studies, and have been noted as a prominent feature of the diet in Caracals in the Kalahari (Melville *et al.* 2004).

In most areas where Caracal diet has been studied, birds (ranging in size from Ostrich *Struthio camelus* to Cape Sparrows *Passer diffusus*) make up only a minor percentage of their prey. However, on South Africa's west coast, Avenant & Nel (2002) recorded average 23.3% bird occurrence, reaching more than 50% in some months. In the Kalahari, birds were an abundant prey resource, especially the larger ground-roosting species such as korhaans (Melville *et al.* 2004). Birds may be taken at night when roosting, ground birds such as francolin after stalking, or at waterholes (C. Stuart & T. Stuart pers. obs.). Avenant & Nel (2002) recorded 12.4% reptile occurrence in diet in West Coast N. P. and 17.4% on surrounding farms, but in other areas reptiles make up an insignificant contribution.

There appear to be regional and seasonal variations in diet but only limited information is available. Rodent remains were found to occur in 89% of the samples collected in West Coast N. P. (Avenant 1993), 39% in Karoo N. P. (Palmer & Fairall 1988), as low as 5.3% in Mountain Zebra N. P. (Grobler 1981, Moolman 1984), and over more extensive areas of South Africa 29% (Stuart & Hickman 1991).

In areas of sheep and goat farming Caracal are significant predators of these domestic animals. Percentage occurrence of domestic stock remains, as evidenced from scats and kills, ranged from a low of 3.6% (Avenant & Nel 2002) to a high of 55% (Pringle & Pringle 1979). Brand (1989) found that Caracals were responsible for the loss of up to 5.3 domestic stock per 100 km² per annum in the former Cape Province. Severity of depredation appears to be dependent on the availability of wild prey and husbandry techniques. Avenant & Nel (2002) demonstrated that predation on small stock and introduced Springboks was seasonal when alternative prey was scarce. Similarly, no remains of domestic livestock were found in 200 Caracal scats collected in Mountain Zebra N. P. (including boundary areas with farms) where wild prey was abundant (Grobler 1981). Comparative figures are not available from other regions of Africa. Surplus killing of domestic stock has been recorded in parts of South Africa (Skinner 1979, Stuart 1986) and on several occasions in Algeria (De Smet 1988). Although uncommon, eating of carrion has been recorded (Skinner 1979, Stuart 1982, Van Heezik & Seddon 1998, Avenant & Nel 2002); in coastal areas, scavenging of marine carrion (e.g. Cape Fur Seal *Arctocephalus pusillus*) is not uncommon (Stuart & Hickman 1991, N. Avenant pers. comm.).

Caracal are solitary hunters, except when a ♀ is accompanied by cubs (Stuart 1982). Prey is located mainly by hearing and sight.

Caracals are principally stalk and pounce, or stalk and short sprint hunters, and are considered to be amongst the fastest of most cats in short sprint situations. Use is effectively made of even minimal cover to allow close approach to intended prey. Avenant & Nel (2002) posited that Caracals are familiar with the areas of high prey availability within their home-ranges and that they select paths that maximize their encounter rates with prey. Melville & Bothma (2006) studied the foraging behaviour of Caracal relative to the dispersion of Brants' Whistling Rats *Parotomys brantsii* in the southern Kalahari, and found that foraging paths used by Caracal in the hot season did increase the likelihood of encountering colonies, but that in the cold season foraging appeared to be random.

Larger prey may be killed by a bite to the throat, to the nape, or initially to the nape and then switching to the throat (Grobler 1981, Stuart 1982, Moolman 1986). Medium-sized prey such as hyraxes and hares taken by captives were usually held by the throat, with the Caracal falling on its side and vigorously raking the belly and chest of the prey with the claws of the hind paws (Stuart 1982). Birds are taken from the ground or at roosts, but a number of authors have commented on their adeptness at hooking flying birds out of the air (Kingdon 1977, Stuart 1982, Skinner & Chimimba 2005). A hand-raised ♂ was observed hooking several bird species from the air at different times, including Cape Weavers *Ploceus capensis*, Cape Sparrows and on one occasion a Great Spotted Cuckoo *Clamator glandarius*. The same individual was seen on several occasions stalking feeding Laughing Doves *Streptopelia senegalensis* and Ring-necked Doves *S. capicola* and catching them on the ground, either swiping at them with a sideways action or occasionally with both front paws together (C. Stuart & T. Stuart pers. obs.).

Small prey is usually eaten at the site of capture but larger prey items may be dragged, or carried, to cover; in 27 of 28 kills recorded by Stuart & Hickman (1991) prey was eaten where it was killed and in only two cases was the prey dragged away to cover. Mills *et al.* (1984) report a Caracal caching the remains of a kill in a tree (and see Stuart & Hickman 1991). In the case of larger prey animals, such as antelope, the principal mode of eating is to open the skin in the buttock and inner thigh region and feed on muscle tissue. Grobler (1981) estimated the meat consumption of a free-ranging hand-raised Caracal to be 796 g per 24-hour period, whereas Stuart (1982) found consumption to average 536 g in ten captive Caracal held in large enclosures. In protected areas Caracals will frequently return to feed at larger kills (Grobler 1981, Avenant 1993) but this is rare on farmland where they are persecuted (Pringle & Pringle 1979, Stuart & Hickman 1991).

Social and Reproductive Behaviour Caracal are normally solitary, except when a pair briefly consort during the oestrous period, or when a ♀ is accompanied by cubs (Stuart 1981, Avenant & Nel 1998). Of 40 sightings in the wild, all were of solitary animals (Smithers 1983), and in a further 27 sightings on South Africa's central plain, 25 were lone individuals and the remainder ♀♀ accompanied by two and three cubs, respectively (C. T. Stuart pers. obs.).

On the African continent the only home-range studies have been undertaken in South Africa and Namibia. In the eastern Karoo three ♀♀ had slightly overlapping home-ranges from 11.8 to 26.7 km², with a ♀ on the coast occupying 11.9 km²; a ♂ in the Karoo had a home-range of 48 km² (Stuart 1982). In Mountain Zebra N. P., Moolman (1986) also found that female home-ranges, from 3.9 km² to

6.5 km² in extent (mean = 5.5 km²), overlapped each other slightly. In the same study it was found that male home-ranges showed considerable overlap, including over those of ♀♀, and varied from 5.1 km² to 30.6 km² (mean = 15.2 km²). In West Coast N.P., male home-ranges (26.9 ± 0.75 km²; $n = 2$) were much larger than those of ♀♀ (7.39 ± 1.68 km²; $n = 3$) and overlapped completely with them; those of ♀♀ overlapped as much as 19% (Avenant & Nel 1998). In Kgalagadi Transfrontier Park, Northern Cape, Bothma & Le Riche (1994) found the home-range of a single adult male to be 308.4 km², with a core area of 93.2 km², while in NC Namibian farmlands, mean home-range size for three ♂♂ was 312.6 km², with a mean range overlap of only 19.4%, which is considerably less than that noted in West Coast N. P. (Marker & Dickman 2005b). Considering the latter figure, and studies conducted in Arabia, home-range sizes in Sahara are probably much larger. In Saudi Arabia, a radio-tracked ♂ ranged over 270 km² to 1116 km² in different seasons (Van Heezik & Seddon 1998), while in an Israeli study, home-ranges of ♂♂ averaged 220.6 km² and 57.3 km² for ♀♀ (Weisbein & Mendelssohn 1990).

Males and females scent-mark by spraying urine on rocks, bushes and tree trunks (De La Fuente 1970, Stuart 1982). In captivity individuals sometimes follow urine spraying with vigorous claw scratching on logs (C. Stuart & T. Stuart pers. obs.). Scats appear to be dropped at random along pathways, with no indication of midden development.

Observations of sexual behaviour in the wild are unrecorded. A total of 12 copulations were observed in captive Caracal, ranging from 90 sec to 8 min (mean = 3.8 min) in duration (Bernard & Stuart 1987). The prelude to coitus followed a set pattern. When a ♂ was first introduced to an enclosure holding a receptive ♀ the first action was to smell at one or more of the female urine spray sites before approaching her (Bernard & Stuart 1987). Females made no attempt to approach ♂♂. Actual mating and copulation are very similar to that of the domestic cat. After copulation the ♂ rapidly disengages and moves away from the ♀. On two occasions the ♀ turned aggressively on the ♂ but without making contact. No calls were noted during copulations but snorting, growling and spitting were recorded before and after coitus. In most cases the ♂ proceeded to lick his genital area after copulation, but ♀♀ lay on their side or rolled in the sand (Stuart 1982). Cubs are born in abandoned Aardvark *Orycteropus afer* and porcupine burrows, in rock crevices and amongst dense vegetation tangles (Stuart 1982, Skinner & Chimimba 2005).

Vocalizations recorded in captive animals include miaowing, gurgling, growling, purring, spitting hisses, a 'wah-wah' call and loud coughing barks by both ♂ and ♀ before and after mating (Peters 1983, C. Stuart & T. Stuart pers. obs.).

Reproduction and Population Structure In the south of their range litters have been recorded in all months of the year but with a peak between Oct and Feb (Bernard & Stuart 1987, Stuart & Wilson 1988). Cade (1968), on the basis of captive and wild records, stated that the breeding season in Kenya was from Nov to May. Reproduction in Israel is apparently non-seasonal (Weisbein & Mendelssohn 1990). In captivity, the oestrous cycle has been recorded as 14 days ($n = 15$) and oestrus 1–3 days ($n = 7$) (Bernard & Stuart 1987). Bernard & Stuart (1987) give the gestation period

Caracal *Caracal caracal* yawning.

as 78–81 days, although shorter gestations are reported; litter-size averages 2.2 (range 1–4; $n = 37$) (Bernard & Stuart 1987), which is similar to the mean of 2.2 recorded by Avenant (1993).

In kittens the eyes open within ten days of birth but clear vision is only achieved several days after opening. At birth the ears are flattened against the head and only stand erect between the second and fourth week, but in most cases ($n = 12$) they are fully erect by the third week. The claws are non-retractable until the third week, but fully retractable by the fourth week. Full deciduous dentition is apparent at 50 days after birth, with permanent canines emerging at 4–5 months, displacing the deciduous canines at 5–6 months. Permanent dentition is complete at 10 months. The first recorded call is a bird-like chirrup emitted shortly after birth. This call was the only vocalization noted up to the age of 2.5 weeks, and persisted in a tame, house-trained Caracal to the age of one year. At 3.5–4 weeks the kittens start to wander around the den entrance. At 5–6 weeks curiosity and playfulness are well developed. Captive kittens were weaned between 15 and 24 weeks, with first solid food being taken at 3.5–8 weeks (Stuart & Stuart 1985).

Age at first reproduction in ♂♂ is 12.5–15 months and 14–16 months in ♀♀, but gametogenesis can occur earlier (Bernard & Stuart 1987). Females probably produce only one litter per year (Bernard & Stuart 1987). One ♀ is recorded as giving birth at 18 years, and longevity is up to 20 years in captivity (Nowell & Jackson 1996, Weigl 2005).

Predators, Parasites and Diseases Predation on Caracal by a number of carnivores has been recorded, including Lions *Panthera leo* (Pienaar 1969), Leopards *P. pardus* (Wilson 1976), Cheetahs *Acinonyx jubatus* (Frame 1986) and Black-backed Jackals *Canis mesomelas* (C.T. Stuart pers. obs.). In the latter case, remains of cubs were found in two stomachs. Several instances of cannibalism have been recorded, probably attributable to infanticide, with cub remains found in the stomach contents of adult ♂♂ (Stuart & Hickman 1991).

Various ecto- and endoparasites have been recorded from South Africa, including fleas (*Ctenocephalides felis*, *Echidnophaga gallinacea*, *Procatiopsylla divergens*), ticks (*Amblyomma marmoreum*, *Boophilus decoloratus*, *Haemaphysalis colesbergensis*, *H. elliptica*, *H. muhsamae*, *H. spinulosa*, *H. zumpti*, *Hyalomma marginatum*, *Ixodes pilosus*, *I. rubicundus*, *Margaropus winthemi*, *Rhipicentor bicornis*, *R. nuttalli*, *Rhipicephalus arnoldi*, *R. distinctus*, *R. evertsi*, *R. gertrudae*, *R. glabroscutatum*, *R. lounsburyi*) and cestodes (*Taenia hydatigena*, *Joyeuxiella* sp., *Mesocestoides* sp.) (Stuart 1981, Horak *et al.* 1987, 1991, 2004, 2010).

Conservation IUCN Category: Least Concern. CITES: Appendix II (the Asian population is listed on Appendix I).

Caracal are heavily persecuted in a number of countries throughout their range, including South Africa, Namibia, Niger and Morocco, during carnivore control activities (Stuart 1981, 1982, Avenant 1993, Dragesco-Joffé 1993, F. Cuzin pers. comm.). Stuart (1982) recorded that over the years 1931–52 an average of 2219 Caracals per year were killed in control operations in the Karoo, South Africa; Brand (1989) recorded 0.02–1.6 Caracals killed or captured per 10 km² a year in the former Cape Province. The Caracal has legal status as a ‘problem animal’ in South Africa and Namibia, and despite such heavy hunting pressure in these countries, it not only seems to be holding its own but in some areas is actually expanding its range and increasing in numbers. Elsewhere in its African range it is generally considered to be uncommon to rare and even threatened

over much of North Africa. In West Africa Caracals are increasingly seen in bushmeat markets, which could pose a serious long-term threat to its survival in that region.

Measurements

Caracal caracal

HB (♂ ♂): 868 (750–1080) mm, n = 97

HB (♀ ♀): 819 (710–1029) mm, n = 94

T (♂ ♂): 264 (210–340) mm, n = 99

T (♀ ♀): 252 (180–315) mm, n = 101

HF c.u. (♂ ♂): 193 (170–215) mm, n = 101

HF c.u. (♀ ♀): 180 (160–208) mm, n = 101

E (♂ ♂): 80 (65–92) mm, n = 98

E (♀ ♀): 76 (60–94) mm, n = 100

WT (♂ ♂): 12.9 (7.2–19.0) kg, n = 77

WT (♀ ♀): 10 (7.0–15.9) kg, n = 63

Northern Cape, Western Cape and Eastern Cape, South Africa (Stuart & Stuart 1992)

Chris Stuart & Tilde Stuart

GENUS *Leptailurus*

Serval

Leptailurus Severtzov, 1858. Rev. Mag. Zool. Paris (2), 10: 389.

A monotypic genus represented only by the Serval *Leptailurus serval*. Severtzov originally included it as a subgenus of *Felis*, but it was later elevated to generic rank (Roberts 1926: 248) based on gross morphological differences from other *Felis* species. Some authors subsequently reverted back to including it as a subgenus of *Felis* (e.g. Ellerman *et al.* 1953, Groves 1982, Meester *et al.* 1986, McKenna & Bell 1997). However, Wozenkraft (1993; and see 2005) reinstated *Leptailurus* as a monotypic genus following others (Weigel 1961, Hemmer 1978, Kratochvíl 1982) and this has since been widely accepted.

The relationship of the Serval to other felids has also been the matter of some debate, with the species variously allied with, for example, *Felis*, *Lynx* and *Caracal* (Weigel 1961, Bininda-Emonds *et al.* 1999) and with *Caracal* and *Profelis* (Johnson & O’Brien 1997, Mattern & McLennan 2000). A highly resolved molecular phylogeny has corroborated the later grouping (Johnson *et al.* 2006) as a lineage that diverged some 8.5 mya.

Luke Hunter

Serval *Leptailurus serval* male in mild threat posture.

Leptailurus serval SERVALFr. Chat-tigre (*Lynx tachete*); Ger. Serval*Leptailurus serval* (Schreber, 1776). Die Säugethiere 3 (16): pl. 108 [1776]; text 3 (23): 407 [1777].‘Ostindien und Tibet in gebirgigen Gegenden, vielleicht auch am Vorgebirge der guten Hoffnung und dem heissen Afrika’;
restricted by Allen (1924) to the ‘Cape region of South Africa’.Serval *Leptailurus serval*.

The name Serval is taken from the Portuguese name for the Iberian lynx *Lynx pardinus*, ‘lobo-cerval’. Forster, 1781 described the species as *Felis capensis*, using the colloquial name of ‘Tyger bosch katten’.

Taxonomy A speckled form, known as the servaline cat, was described as a separate species, *Felis servalina* Ogilby, 1839 or *Felis brachyura* Wagner, 1841. Pocock (1907) accepted that the two forms represent distinct species, but later (1917) considered them conspecific. Subsequent reports (e.g. Hollister 1918, Allen 1924, Pitman 1934) have illustrated the wide variability of maculation within populations and both forms have been recorded from the same litter (Kingdon 1977). Seventeen subspecies were listed by Allen (1939);

Smithers (1978) recognized six subspecies, while seven are listed by Nowell & Jackson (1996). The validity of subspecies has been brought into question by numerous authors because descriptions have been based on ground colour and size of spots, which, as noted above, are considerably variable. Synonyms: *algericus*, *beirae*, *brachyura*, *capensis*, *constantina*, *faradjus*, *ferrarii*, *galeopardus*, *hamiltoni*, *hindei*, *ingridi*, *kempi*, *kivuensis*, *larseni*, *limpopoensis*, *liposticta*, *lonnbergi*, *mababiensis*, *niger*, *ogilbyi*, *pantasticta*, *phillipsi*, *pococki*, *poliotricha*, *senegalensis*, *servalina*, *tanae*, *togoensis*. Chromosome number: $2n = 36$ (Wurster & Benirschke 1968). In captivity, Serval have hybridized with Caracal *Caracal caracal*, African and European Wildcats *Felis silvestris* and domestic cats.

Description A medium-sized cat with slender build, notably long legs, short tail and large ears. Overall ground colour varies from buffy to golden-yellow with black spots and stripes. Muzzle and chin whitish, blending into golden-yellow face, with small black spots on cheeks and above eyes, nose black occasionally with a pink mark or completely pink. Copper-brown or greenish eyes, rimmed with black. White vibrissae on muzzle and temples. Pinnae shaped like a domestic cat's ears though much larger relative to head size; very mobile, almost meeting at centre of crown when animal is focusing attention forwards. Long white hairs inside the ears, backs black with broad white band horizontally across middle. Three or four black stripes extend from back of head, along nape onto shoulders. Stripes break up into elongated spots along the back with smaller spots in rows on the shoulders, flanks and outer thighs. Throat whitish and chest buffy with small black spots in a full or broken 'necklace'. Outer limbs golden with horizontal black stripes or spots getting smaller distally. Inner legs whitish with greyish markings. Pelage on ventral surface soft and fluffy, white or buffy, with long guard hairs (5–10 cm), and dense wavy underfur. Neck, back and flank guard hair about 3 cm in length and facial hair about 1 cm long. Tail shortish, reaching about half-way to the ground when the animal is standing, golden-yellow with five or six black bands. Tail tip black. Feet, pads black, pelage on upper surface short, buffy. Five digits on forefoot and four on hindfoot. There are two pairs abdominal and one pair inguinal nipples. Males are more heavily built than females.

Skull is domed, rounded in profile, lightly built, and narrow compared with the similarly sized Caracal, with a more elongated rostrum and lacking well-developed sagittal and supraoccipital crests. The top of the skull is smooth and lacks well-defined muscle attachments. The coronoid process of the mandible is less developed than in the Caracal and lacks the central ridges seen in that species. Dentition is typically felid, and in contrast to most Caracal specimens, P^2 is always present (Skinner & Chimimba 2005).

Geographic Variation Wide variation occurs in the colouration of the pelage, ranging from differing numbers of stripes and rows of spots to the small spotted or servaline morph, which has a freckled appearance. The latter occurs more frequently in West Africa, and in the humid savanna at the ecotone of the equatorial rainforest belt; for example, 62% of skins from E DR Congo (Rahm & Christiaensen 1966). Melanistic forms occur, mainly in East Africa in the Aberdares, Kilimanjaro, Mt Kenya, Mkomazi, Tsavo and the Ethiopian Highlands (York 1973, Kingdon 1977, Grimshaw *et al.* 1995), although there are recent photographic records from the Bateke Plateau, SE Gabon (N. Bout, pers. comm.).

Similar Species

Caracal caracal. Sympatric across much of the range, except the western and south-western parts of southern Africa. Powerfully built, hindlimbs longer than forelimbs; largely unmarked red to fawn colour, with faint spots on underparts; black-backed ears with long terminal tuft.

Profelis aurata. Forest-dependent species, from Senegal through the Congo basin to Uganda, with isolated records from Kenya. Powerfully built, with limbs robust; small, black-backed ears lacking distinct white patch; ground colour dark golden to smoky-grey with variable spotting. Van Mensch & Van Bree (1969) detail

Serval *Leptailurus serval* myology.

Serval *Leptailurus serval*. Myology of ears.

distinguishing characteristics between the skull of the African Golden Cat and Serval.

Acinonyx jubatus. Sympatric across parts of Sub-Saharan range, with wide, but patchy, distribution from Senegal to Somalia and south to South Africa. Adult much larger, and with smaller ear pinnae; cubs uniformly marked with coin-shaped spots, facial tear streaks and have a silvery-grey mantle.

Distribution Endemic to Africa. Senegal eastwards in a narrow band of savanna-dominated habitat to S Sudan, Ethiopia and S Somalia, expanding into the mesic regions of East and southern Africa south to South Africa and SW Angola. Relict in North Africa.

Historical Distribution Widespread throughout Africa in two populations separated by the Sahara. Naturally absent from the Sahara, Congo basin, West African coastal rainforest, Horn of Africa and south-west Africa.

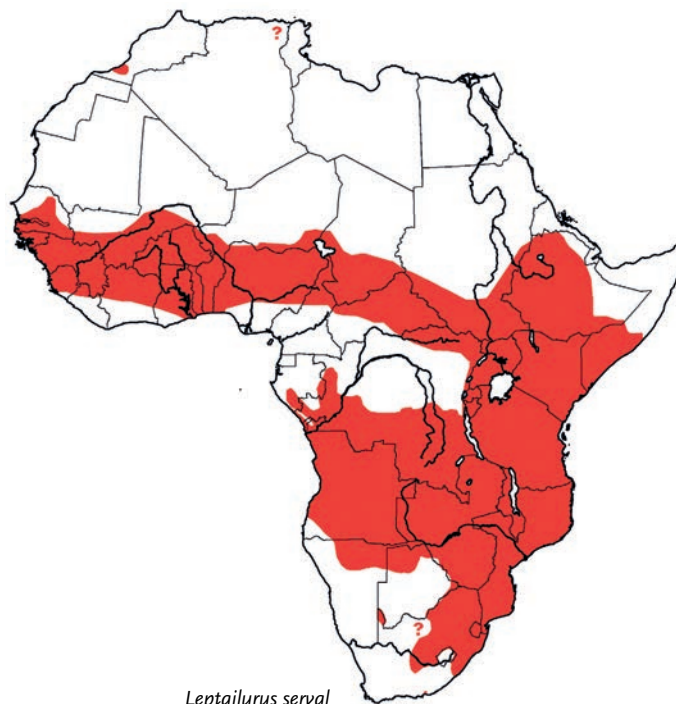

Current Distribution Widely distributed within historical limits, but localized in areas densely populated with people; they have suffered marked range loss, particularly at the north and extreme south of their range (Smithers 1978, Nowell & Jackson 1996).

In North Africa, an animal killed on the north-west coast of Algeria, east of Oran, in 1936 was said to be the last confirmed record from this country (Nowell & Jackson 1996), but they were recorded in El Kala N.P. in NE Algeria around 1992/93 (K. de Smet pers. comm.). Servals are also relict in SW Morocco in an arid littoral area (Cuzin 2003), and were reported from the Ifrane N. P. in the north in 2005 (F. Cuzin pers. comm.). In West Africa, in S Senegal's Casamance Province, they have increased in numbers due to the prolonged civil war and resulting human depopulation (O. Burnham pers. comm.); they still persist in N Senegal, as evidenced by a recent record from Ferlo North (Clément *et al.* 2007).

In South Africa, Serval probably occurred along the entire coastal belt and in water-courses from the Cape Peninsula to the former Transkei (Skead 1980, Stuart 1981, 1985). However, by the time of Stuart's survey, the species was on the verge of extinction in the then Cape Province, with only a single proven record of a specimen collected near Groenriver in Namaqualand in 1975 (Stuart 1981) as well as several unsubstantiated records. Lynch (1989) provided a few additional historical records from the Eastern Cape, while Lynch (1983) recorded the species from only three localities in the north-eastern Free State. Since these studies, there is evidence that, in a few regions, Serval have expanded their range; for example, they are known to be re-colonizing parts of the Free State (Herrmann *et al.* 2008, C. Stuart pers. comm.). There is also an interesting record of a Serval sighted in the dry river bed of the Nossob R. in Kgalagadi Transfrontier Park between South Africa and Botswana in 1990 (T. P. Jackson, in Skinner & Chimimba 2005, G. Mills pers. comm.), though this is well outside of historical range and ad hoc releases by private landowners cannot be ruled out. At least at the time of Stuart's survey Serval supposedly still occurred in what is today the western North West Province (P. Visser, in Stuart 1981). Serval are also possibly benefiting from forest clearance and resulting encroachment of savanna habitats around the fringes of the equatorial forest belt in central Africa (Ray 2001).

Captive-raised Servals of East Africa stock have been released in Feidja N. P. in Tunisia (K. De Smet & F. Cuzin pers. comm.), and 17 Servals of southern African origin have been reintroduced into Shamwari G. R. in the Eastern Cape, South Africa (L. T. B. Hunter pers. obs.).

Habitat The Serval is strongly associated with permanent water sources and it requires cover such as tall grass, reed-beds and underbrush for refuges and for rodent prey. Most common in savanna, grasslands and dry forest where it is typically associated with wetlands, rivers and flood-plains. Also favours alpine grasslands (to altitudes of

Leptailurus serval

3800 m in Kenya), moorland (to at least 3850 m near Mt Kilimanjaro; Grimshaw *et al.* 1995) and high-altitude bamboo forests (Andama 2000). In Somalia, Funaioli & Simonetta (1966) noted their occurrence along the rivers in the south of the country. Recorded from rainforest and coastal scrub in Sierra Leone (Grubb *et al.* 1998), in rainforest-savannah mosaic in SE Gabon (Bout 2011), in coastal and mountain fynbos (heath) in South Africa (Stuart 1981) and in riparian habitat in the Haremma Forest, Ethiopia (Yalden *et al.* 1996). Servals are able to tolerate agricultural areas provided cover is available. Rahm & Christiaensen (1966) recorded them from banana and coffee plantations in DR Congo, and Scaramella *et al.* (1974) stated that they are often killed around human habitations in Somalia. Short grassland or shrubland with few or no trees is considered marginal habitat (Nowell & Jackson 1996). The relict population in Morocco lives in arid dense shrubland, and wetlands (F. Cuzin pers. comm.), and elsewhere in North Africa, it inhabited scrubland and forest in more humid areas (Kowalski & Rzebik-Kowalska 1991). Absent from the Congo basin rainforest, semi-desert and desert.

Abundance Found in most major national parks and reserves within their range (Nowell & Jackson 1996), reaching their greatest abundance in protected areas in East and southern Africa. Considered fairly numerous in reserves throughout West Africa (I. Di Silvestre pers. comm., H. Bauer pers. comm.) though illegal hunting in Niokolo Koba N. P., Senegal and Badiar N. P., Guinea, has significantly reduced their numbers in the past ten years (O. Burnham pers. comm.). Status outside reserves uncertain, but they are inconspicuous and may be common in suitable habitat as they are tolerant of farming practices provided there is cover and food available. Minimum density of Servals in optimal habitat in Ngorongoro Crater during a good rainfall period was recorded as 0.42 animals/km² (Geertsema 1985). Andama (2000) calculated a density of 0.09 ± 0.08 animals per km² for Bwindi Impenetrable N. P., Uganda, where the extinction of the Leopard *Panthera pardus* may have resulted in predator release. Much

Lateral view of skull of Serval *Leptailurus serval*.

of Bwindi is rainforest where Serval density is very low and densities in more open habitat along the periphery of the park are comparable with the Ngorongoro figures (E. Andama pers. comm.). In Niokolo-Koba N. P., Servals were observed at a frequency of 0.6 individuals/100 km along road transects driven by vehicle (Sillero-Zubiri *et al.* 1997). No estimates exist for the Servals occupying arid shrublands in Morocco but densities there are probably very low.

Adaptations Well-developed ear bullae and large pinnae reflect this species' reliance on hearing for prey detection. The skull is lightly built, especially in comparison with the similarly sized Caracal, as it is adapted to small rodent and avian prey. Their long legs and slender build enable stealthy movement through long grass and allow high jumping to pounce upon its prey. The slender forelegs combined with long, loosely knit metatarsals and strongly curved claws are well suited to pinning rodents in long grass and also allow them to efficiently angle for prey in tree hollows and burrows, and hook fish from water (Kingdon 1977, Geertsema 1985). Although an efficient climber up to heights of at least 9 m (Smithers & Wilson 1979), they are predominantly terrestrial. Pelage colouration is probably more important for reducing visibility to predators than for concealment from prey. Darker toned Servals (melanistic and 'servaline') are associated with moister, equatorial regions; the selective advantages conferred are unclear though it may afford better camouflage in poorly lit habitats. Servals appear tolerant of low temperatures, possibly an adaptation for living at altitudes where they are often exposed to snow. They minimize heat loss at low temperatures by piloerection, curling up and remaining inactive, and can tolerate reductions in body temperature (e.g. to 35.2°C at ambient temperature of 15°C) before needing to increase oxygen consumption (Downs *et al.* 1991).

Servals are primarily crepuscular or nocturnal but often become diurnal in protected areas; for example, Servals in Serengeti N. P. were often diurnal (Geertsema 1976), Servals in Ngorongoro and Niokolo-Koba N. P. were largely crepuscular (Geertsema 1985, Di Silvestre & Novelli 1998), while Servals on farmland in Zimbabwe and South Africa were primarily active at night (Smithers 1978, Bowland 1990). Verheyen (1951) and Rowe-Rowe (1978a) recorded both nocturnal and diurnal activity in protected areas in DR Congo and KwaZulu-Natal (South Africa), respectively. Overcast conditions promote diurnal activity, and ♀♀ with litters devote proportionally more time to diurnal hunting than when they are without kittens. Servals rest in woody patches, ravines or clumps of long grass and seldom frequent the same resting site, probably to avoid attracting predators. When threatened, they crouch low in long grass remaining extremely well hidden until flushed when they flee using a 'zig-zag bouncing' gait that may confuse the pursuer (Geertsema 1985).

Foraging and Food Carnivorous. Servals prey mainly on small mammals, with murids particularly important. In Zimbabwe, analysis of 65 stomachs revealed that murids were present in 97% of stomachs (Smithers 1978), while scat analyses indicated that rodents and shrews accounted for over 80% of Serval diet in Uganda's Bwindi Impenetrable N. P. (Andama 2000) and 93.5% on farmland in the Drakensberg Mts of South Africa (Bowland & Perrin 1993). Small mammals accounted for 89% of direct observations of Serval feeding in the Ngorongoro Crater, Tanzania (Geertsema 1985). *Otomys* spp. (especially Angoni Vlei Rat *O. angoniensis* and Southern African Vlei Rat *O. irroratus*) are particularly common in the diet of Servals, reflecting both local abundance and their common association with rank grassland and wetlands. Other favoured rodent prey include multimammate mice *Mastomys* spp., Tiny Pygmy Mouse *Mus minutoides* and Nile Rat *Arvicanthis niloticus*. Shrews have been recorded from the diet of Servals in some parts of southern Africa (Smithers & Wilson 1979, Bowland & Perrin 1993); the latter are nocturnal and therefore likely prey where Servals are more active at night. Mole-rats *Tachyoryctes* spp. and *Cryptomys* spp., ground squirrels *Xerus* spp. and cane rats *Thryonomys* spp. have also been recorded (Verheyen 1951, Verschuren 1958, Rahm & Christiaensen 1963, York 1973, Kingdon 1977).

Birds are the second most common prey in the diet, mostly smaller birds such as weavers *Ploceus* spp., bishop and widow birds *Euplectes* spp. and flufftails *Sarothrura* spp., but significantly larger species including flamingos, herons and storks, are taken. Frogs comprise a significant proportion of the diet in Ngorongoro (77% occurrence), where Serval frequently hunt in shallow water (Geertsema 1985). Other prey includes reptiles, insects (notably termites and grasshoppers), crabs, eggs and fish. There are a few references to Servals taking larger prey such as the young of small antelope (Verheyen 1951, Pienaar 1969, York 1973), hares *Lepus* spp. (York 1973, Smithers & Wilson 1979) and Southern African Springhare *Pedetes capensis* (P. Viljoen pers. comm.). Small carnivores are occasionally killed: T. Dickerson (pers. comm.) saw a Serval consume an adult genet *Genetta* sp. in KwaZulu-Natal, and an adult Serval in Lower Zambezi N. P., Zambia, killed two Banded Mongooses *Mungos mungo* in quick succession and ate both (G. Cumming pers. comm.). Small quantities of grass are frequently eaten, possibly aiding digestion, and other vegetable matter such as bananas and avocados has been recorded (Rahm & Christiaensen 1966).

Servals locate prey in long grass by roaming around with frequent pauses to listen for potential targets. They often use established paths or roads to hunt or to commute to favoured hunting areas. Once prey is located they position themselves with a slow stalk, followed by a high pounce with forelegs tucked into the chest, descending on to the target with both forelegs extended. This technique possibly stuns the prey with a swift blow from one or both forefeet though vegetation usually impedes direct observation; it may be that the action simply secures the prey. Servals also flush prey using a series of high bounds on stiff legs with back straight and tail erect, a practice often employed for small birds and insects. They are exceptionally agile; a pounce may measure up to 3.6 m long and over 2 m high and they are able to change direction in mid-air when chasing prey (Smithers 1978, Estes 1991). They will leap high to grab fleeing birds and insects from the air. Large birds such as storks and herons are often stalked for some distance and captured after a sprinting charge and high leap as the quarry takes flight (Newman 1998). Servals sometimes excavate fossorial rodents from their burrows and Verheyen (1951) reported

individuals scratching at the plugged entrances of mole-rat burrows to draw them to the surface. Rarely, Servals hunt in trees, usually in pursuit of a fleeing terrestrial target such as rodents or lizards and seldom beyond 2 m high. Most prey is killed by an accurate bite to the head or neck; two Banded Mongooses were killed by a neck bite followed by violent shaking (G. Cumming pers. comm.). Snakes and lizards are often killed by repeated forceful slaps by one of the front paws (Geertsema 1976, 1985). Servals eat rodents head first, gulping them down with little chewing, often discarding the viscera (Geertsema 1976, J. Bowland pers. obs.). Feathers are plucked from larger birds prior to consumption and Kingdon (1977) recorded fur plucking from hares by captive Servals.

In Ngorongoro hunting success was about 50%, although it increased to 62% in an adult ♀ with kittens. Success did not differ between day and night hunts. They killed 15–16 times per 24-hour period, making 0.8 kills per hour during the day and 0.5 kills per hour at night. In terms of distance, this equates to 2.5 kills per km and 1.9 kills per km, respectively. Juveniles kill more frequently (4.2 kills/km) but hunt smaller prey with lower energy yields. Each Serval in Serengeti N. P. eats about 4000 rodents, 260 snakes and 130 birds per year (Geertsema 1985, Kitchener 1991). Maximum passage rate time is seven days for hair and the same prey item may appear in up to seven successive scats (Bowland & Bowland 1991). Caching by raking leaf litter and dead grass over large food items has been recorded in captivity (Kingdon 1977).

Scavenging appears to be very rare. Newman (1998) filmed a female Serval usurp a Black-backed Jackal *Canis mesomelas* from a juvenile Common Wildebeest *Connochaetes taurinus* carcass, and Geertsema (1985) observed two incidents of scavenging in more than 1300 hours of observation in Serengeti N. P.; in one of these cases, a young adult male Serval confronted an adult Spotted Hyaena *Crocuta crocuta* over a juvenile Common Hippopotamus *Hippopotamus amphibius* carcass. Conversely, York (1973) studied Servals in the Aberdares by drawing them to fresh carcasses laid along roads. Livestock predation is considered rare (Lawson 1987, Bowland 1990), though local people blamed Servals for 60 kills of sheep and goats between November 2001 and October 2002 in the Web Valley of Bale Mountains N. P., Ethiopia (Atickem 2003). Goats were most vulnerable, apparently because they foraged in mountainous areas away from villages where Servals were common (A. Atickem pers. comm.). All kills were juveniles except for one female goat.

Serval *Leptailurus serval* hunting mice.

Social and Reproductive Behaviour Servals are normally solitary, although during oestrus a ♂ and ♀ may hunt and rest together for several days (Geertsema 1976, 1985), and juveniles stay with their mothers for up to a year (Skinner & Chimimba 2005).

Home-range size varies considerably but female ranges are typically smaller than those of ♂♂. The home-ranges of two ♀♀ and one ♂ on farmland and an adjacent nature reserve in the KwaZulu–Natal Drakensberg were 19.8 km², 15.8 km² and 31.5 km², respectively (Bowland 1990). In Ngorongoro Crater, Tanzania, the home-range of an adult ♀ and adult ♂ was 9.5 km² and 11.5 km², respectively (Geertsema 1985). The home-ranges of two reintroduced, captive-bred adult ♂♂ observed by Van Aarde & Skinner (1986) were somewhat smaller at 2.0 and 2.7 km² and a reintroduced hand-reared ♀ had a home-range of 6.2 km² (Perrin 2002). The factors affecting home-range size have not been clearly delineated though the availability of prey and cover are certain to exert a strong effect. Geertsema (1985) suggests that disturbance such as fires, and human and livestock movements increase home-range sizes.

Home-ranges of Servals, especially ♀♀, overlap spatially but individuals normally avoid each other. In the KwaZulu–Natal Drakensberg, a mature ♂, a subadult ♂ and four ♀♀ were captured and radio-tracked for varying amounts of time within a period of seven months in a study area of about 30 km². However, only two of these, the mature ♂ and a ♀, were actually recorded within the study area at the same time. The subadult ♂ moved out of the study area within eight weeks of capture (Bowland 1990). In Ngorongoro, 17 different Servals were seen in an area of 30 km² over 2½ years. Some of the adult ♀♀ were probably related as female offspring are tolerated more than ♂♂, the latter being driven away by the mother and resident ♂ when almost fully grown at approximately one year old. Juveniles utilize their mothers' home-ranges intensively, gradually moving further afield as they mature. Young adults often wander quite widely, utilizing small areas for a few months before moving on and eventually settling in a permanent home-range. Local prey abundance such as rodent or insect irruptions may attract a few individuals to the same site.

Male and female Servals scent-mark along the paths they use by spraying (♂♂) or squirting (♂♂ and ♀♀) urine on grass clumps and bushes. Both sexes also rub their faces on the ground and grass stalks while salivating freely. Scats are dropped along pathways (Smithers 1978, Bowland 1990), in grass and occasionally on top of hyaena faeces (Geertsema 1985). Captive animals show a sexual difference in scat deposition, ♀♀ using the same site while ♂♂ scatter their faeces more randomly (Kingdon 1977). Latrines have not been observed in the wild. Resident adult ♂♂ spend more time than ♀♀ patrolling and marking their range (41 times per hour for ♂♂ cf. 20 times per hour for ♀♀), but do not regularly re-use the same marking site. Few direct aggressive or territorial confrontations have been observed as Servals seem to use a system of mutual avoidance rather than territorial defence (Geertsema 1985). Agonistic behaviour is largely demonstrative, with highly arched back, raised tail and hair, and lateral presentation. Heads are thrown up and down with bared teeth and flattened ears, which very effectively 'flags' the white patches on the ears (A. Geertsema pers. comm.). The action is usually accompanied by yowling while forefeet are raised and lowered (York 1973, Geertsema 1976, Leyhausen 1979).

Rosevear (1974) notes that Serval utter several different sounds, including a purr not unlike a domestic cat, only louder; a high-pitched,

Serval *Leptailurus serval* facial expressions.

slightly raucous miaow, expressed as a nasal 'mwa-mwa' slowly repeated six or eight times; and a complaining moan ending with a low purring growl, which becomes like a loud hiss. A swallowed mew signifies friendly recognition, often followed by an abrupt about-turn and distinctive shiver-display of the tail (Kingdon 1977).

Sexual behaviour is poorly known from the wild. A single mating filmed in Ngorongoro Conservation Area was preceded by numerous 'false alarms' in which the ♀ lay down and was circled repeatedly by the ♂ without mounting taking place (O. Newman & A. Barrett pers. comm.). After approximately an hour of this, the ♀ raised her rump and the ♂ immediately mounted and achieved intromission. In captivity, oestrous ♀ give repeated short, sharp miaows or bouts of yowling with constant pacing and frequent urine squirting. Occasionally, claws are raked down tree trunks. When approached by a ♂, she purrs and rubs the sides of her mouth and cheeks against him, salivating copiously and then walks along his length, leaning heavily against him. When the rump is reached, she turns sharply to repeat the action or presents for mating (Kingdon 1977). Copulation appears to be prolonged for felids; an observed copulation between wild Servals lasted for 30 sec (O. Newman & A. Barrett pers. comm.) and the copulation period may last for up to 10 days (Wackernagel 1968). The ♀ is often highly vocal during copulation, emitting screams and growls audible up to 200 m away (Stuart & Wilson 1988). The end of each copulation is typically feline; the ♂ leaps away from the ♀ who turns on him with momentary aggression, followed by her rolling from side to side. Kittens are well hidden in dense vegetation, disused Aardvark *Orycteropus afer* or porcupine holes, tree hollows or rocky outcrops, and they are moved frequently. Females' home-ranges and activity patterns alter radically when young are born. Far more time is spent hunting in the core area of the home-range and food is carried back to the kittens' hiding place (Geertsema 1985).

Reproduction and Population Structure In captivity oestrus lasts up to four days ($n = 4$), and the female may come into oestrus several times during the course of the month (Wackernagel 1968). Gestation lasts about 65–75 days (Geertsema 1976, Stuart & Wilson

1988) and litter-size ranges from 1–5, usually 2–3 (Smithers 1978, Stuart & Wilson 1988) and exceptionally 6 (Poonacha 1997). Sex ratio at birth in Johannesburg and Pretoria Zoological Gardens was recorded at 1 : 1 (Skinner & Chimimba 2005), not dissimilar from that recorded by Wackernagel (1968). Newborns weigh about 250 g and have a soft woolly grey coat, with indistinct markings. Eyes open between Day 7 and Day 10 (Stuart & Wilson 1988), and permanent dentition is fully erupted after six months; however, they take solid food as early as 2–3 weeks.

In the wild, birth peaks seem to be correlated with highest rodent densities, which are in turn correlated with rainfall and vegetation growth. In southern Africa, pregnant ♀♀ have been taken from Nov to Mar, with one record for Jul, indicating that the young are usually born during the middle or latter part of the warm, wet season (Smithers 1978, Skinner & Chimimba 2005). Geertsema (1985) suggests most births in the Ngorongoro Crater occur between late Aug and Nov, the mid- to late dry season. In Uganda and E DR Congo, births ($n = 8$) were clustered around the beginning and end of the wet season (Kingdon 1977). The ♀ brings prey to kittens in the den when they are about one month old and they accompany her when foraging from around three months of age (Geertsema 1985). Kittens are independent at 6–8 months, but juveniles may remain in their mother's range for over a year (Geertsema 1985). Individuals reach sexual maturity at 17–26 months (Farmer 1971, Bloxam 1973).

The shortest inter-litter interval with normal lactation recorded from captivity was 184 days (Wackernagel 1968) but wild litters are more widely spaced; a wild ♀ in Ngorongoro had two litters in 2½ years (Geertsema 1985). Longevity is around 22 years in captivity (Weigl 2005), and ♀♀ can breed until 14 years; a wild breeding female of 11 years is recorded (A. Geertsema pers. comm.).

Predators, Parasites and Diseases Servals are apparently very wary of Spotted Hyaenas (Estes 1991) though adult Servals sometimes do confront them (Geertsema 1985). Lions *Panthera leo* also will kill Servals (Lewis 1986, L. T. B. Hunter pers. obs.) and Leopards have been observed with cached Serval carcasses (L. T. B. Hunter pers. obs.). Turnbull-Kemp (1967) witnessed 'wild pigs' (presumably Bush Pig *Potamochoerus larvatus*) killing Servals. A Martial Eagle *Polemaetus bellicosus* in the Masai-Mara was observed taking a kitten despite its mother attempting to intervene (Butchart 2000). Black-backed Jackals (on kittens), Nile Crocodiles *Crocodylus niloticus* and African Rock Pythons *Python sebae* are probably occasional predators.

Cat fleas *Ctenophalides felis damarensis* and hard ticks *Haemaphysalis spinulosa* have been recorded from a South African ♂ (Hoffman 1987) and a single, unsexed, adult animal taken from Kruger N. P. was host to ixodid ticks *Amblyomma hebraeum*, *Rhipicephalus appendiculatus* and *R. simus* (Horak *et al.* 1987). Hookworms *Ancylostoma paradoudenale* were found in Servals from Somalia (Macchioni 1995). Two Servals (from a sample of eight) collected in S Sudan tested positive for leptospirosis (Sebek *et al.* 1989), while babesiosis was confirmed from a Serval in Lydenburg, South Africa, although the *Babesia* species involved was not established (B. Penzhorn pers. comm.).

Conservation IUCN Category: Least Concern. CITES: Appendix II.

Threatened mainly by wetland habitat loss and degradation. Degradation of grasslands through annual burning followed by over-

grazing by domestic livestock, thereby leading to reduced abundance of small mammals, is also a threat (Rowe-Rowe 1992a). Servals are also used in the local skin trade in West Africa (C. Stuart pers. comm.), East Africa and Sudan (Kingdon 1977), Somalia (Funaioli & Simonetta 1966), Uganda (Andama 2000), E DR Congo (J. Hart pers. comm.), South Africa (A. E. Bowland pers. obs.) and Morocco (F. Cuzin pers. comm.). Commercial trade is generally declining (Nowell & Jackson 1996), though skins are still traded in large quantities in some countries, such as Senegal, Gambia and Benin (O. Burnham & I. Di Silvestre pers. comm.). They are highly valued for traditional medicine in Nigeria: among markets surveyed in five SW Nigerian towns in 1994, they were the second most commonly offered mammalian species (Sodeinde & Soewu 1999). In rural areas throughout Africa, they are persecuted for taking poultry (Andama 2000) and indiscriminate predator control methods practised by pastoralists frequently kill them (L. T. B. Hunter pers. obs.).

Servals occur in a number of protected areas across their range, including: Ifrane N. P. (Morocco), possibly El Kala N. P. (Algeria), Feidja N. P. (Tunisia), Comoé N. P. (Côte d'Ivoire), 'W' N. P. (Burkina Faso, Benin, Niger), Zakouma N. P. (Chad), Simien and Bale Mountains National Parks (Ethiopia), Virunga N. P. (DR Congo), Queen Elizabeth N. P. (Uganda), Aberdare Mountains N. P. (Kenya), Serengeti and Selous National Parks (Tanzania), Moremi G. R. and Chobe N. P. (Botswana), and Kruger N. P. and Ukhahlamba-Drakensberg Park (South Africa).

Measurements

Leptailurus serval

TL (♂ ♂): 1111 (960–1205) mm, n = 23

TL (♀ ♀): 1097 (970–1230) mm, n = 23
 T (♂ ♂): 314 (280–380) mm, n = 23
 T (♀ ♀): 290 (254–330) mm, n = 23
 HF c.u. (♂ ♂): 193 (180–205) mm, n = 23
 HF c.u. (♀ ♀): 182 (165–194) mm, n = 23
 E (♂ ♂): 91 (83–97) mm, n = 23
 E (♀ ♀): 86 (80–97) mm, n = 23
 WT (♂ ♂): 11.1 (8.6–13.5) kg, n = 20
 WT (♀ ♀): 9.7 (8.6–11.8) kg, n = 23
 Zimbabwe (Smithers 1978)

TL (♂ ♂): 1122 (1010–1250) mm, n = 6
 TL (♀ ♀): 1026 (930–1090) mm, n = 8
 T (♂ ♂): 282 (250–330) mm, n = 6
 T (♀ ♀): 262 (230–290) mm, n = 9
 HF c.u. (♂ ♂): 186 (180–195) mm, n = 6
 HF c.u. (♀ ♀): 174 (160–190) mm, n = 9
 E (♂ ♂): 86 (82–90) mm, n = 6
 E (♀ ♀): 85 (79–90) mm, n = 9
 WT (♂ ♂): 10.7 (7.9–12.4) kg, n = 7
 WT (♀ ♀): 8.1 (6.0–9.8) kg, n = 9
 KwaZulu–Natal, South Africa (Bowland 1990)

Luke Hunter & Jane Bowland

GENUS *Acinonyx*

Cheetah

Acinonyx Brookes, 1828. Cat. Anat. Zool. Mus. Joshua Brookes, London p. 16, 33.

Formerly included in a monophyletic group, the subfamily Acinonychinae (e.g. Wozencraft 1993), recent molecular evidence now clusters the Cheetah *Acinonyx jubatus* with the Puma *Puma concolor* and Jaguarundi *P. yagouaroundi*, which diverged some 6.7 mya (Johnson *et al.* 2006), in agreement with earlier studies (Johnson & O'Brien 1997, Bininda-Emonds *et al.* 1999, Mattern & McLennan 2000).

Cheetah-like felids once ranged across Asia, Africa and North America 10,000 years ago (Kurtén 1968). Two extinct species, the giant cheetah *A. pardinensis* and the smaller *A. intermedius*, have been found in the Pleistocene of Eurasia, as well as fragmentary remains of unknown species in Africa. In North America, two Cheetah-like species, *Miracinonyx studei* and *M. trumani*, have been described from the late Pleistocene. For many years it was uncertain whether similarities between *Acinonyx* and *Miracinonyx* were due to convergent evolution or common descent (if the latter, it would place the origin of *Acinonyx* in the New World, Adams 1979). Recent work involving ancient DNA indicates that *Puma* and *Miracinonyx* are more closely related than either is to *Acinonyx* (Barnett *et al.* 2005).

Tim Caro

Cheetah *Acinonyx jubatus*, alert and resting.

Acinonyx jubatus CHEETAH

Fr. Guepard; Ger. Gepard

Acinonyx jubatus (Schreber, 1775). Die Säugethiere 2 (15): pl. 105 [1775]; text 3 (22): 392 [1777]. 'südliche Afrika; man bekommt die Felle vom Vorgebirge der guten Hoffnung' [South Africa, Western Cape Province, Cape of Good Hope].

English name derived from the Hindi *chita*, meaning spotted one.

Taxonomy Previous generic names include *Cynilurus*, *Guepardus* and *Cynofelis*; *Acinonyx* derived from the Greek *akaina* (a thorn) and *onyx* (a claw), referring to the non-retractable claws. The species name, *jubatus* (Latin), refers to crest or mane seen in young and certain adults. Allen (1939) listed eight subspecies from Africa, while Smithers (1975) reduced the number to five (accepted by Krausman & Morales 2005). The subspecies *A. j. venaticus*, which formerly occurred in India, and throughout the Asiatic part of the range, but survives only in Iran, has generally been considered to be the subspecies occurring in North Africa (see Ellerman & Morrison-Scott 1951, Smithers 1975, Krausman & Morales 2005). However, Charruau *et al.* (2011) demonstrated the extant Iranian cheetahs are an autochthonous monophyletic population and the last representatives of the Asiatic subspecies *A. j. venaticus*. Consequently, North African cheetah may deserve independent subspecies status, although the population also may be genetically contiguous with those from West Africa, historically classified as *A. j. hecki*. Charruau *et al.* (2011) also confirmed the distinctiveness of *A. j. soemmerringi*. On the other hand, there was little genetic variation between two sub-Saharan subspecies, *A. j. jubatus* and *A. j. raineyi* (although minisatellite variation supports their separation; Menotti-Raymond & O'Brien 1993).

The so-called 'king cheetah', the form described as a new species of Cheetah, *Acinonyx rex*, from southern Africa (Pocock 1927, Hills & Smithers 1980) is synonymous with *A. j. jubatus* with a homozygous recessive gene for blotched coat pattern (Van Aarde & Van Dyk 1986); it is very rare in the wild.

Synonyms: *fearonii*, *fearonis*, *guttata*, *hecki*, *iubata*, *lanea*, *megabala*, *megabalica*, *ngorongorensis*, *obergi*, *raddei*, *raineyi*, *rex*, *senegalensis*, *soemmerringi*, *velox*, *venaticus*, *venator*, *wagneri*. Chromosome number: $2n = 38$; the X chromosome is a small metacentric, and the Y is acrocentric (Pathak & Wurster-Hill 1977).

Description Medium-sized, spotted felid, with a tall, slender build, long, thin legs, a deep, narrow chest, and a long tail measuring about half the head and body length. Head rounded, muzzle short, with small, rounded ears, set far apart and black when viewed from behind. A characteristic lachrymal or 'tear streak' extends from medial corner of eye to upper lip just behind canines. In profile, the back is slightly concave. Light brown or tan pelage covered with solid round or slightly oval black spots, the smaller of which are interspersed with larger ones. Chin, throat and upper lip white, as are the posterior parts of the belly, but the chest and anterior part of the belly is spotted. The tail is also spotted, the spots on the distal third coalescing into black rings; the tip of the tail is white. The spot patterning on the face and chest differs among individuals and is a useful feature for field identification; variations in coat patterns have been used to reveal

Cheetah *Acinonyx jubatus*.

family resemblances (Caro & Durant 1991). The fur is short and coarse, except for an erectile crest of greyish hair up to 80 mm long on the nape and shoulders, and which sometimes continues down the back, and that accentuates the height. Front feet with five digits, hindfeet with four. The first digit on the forefoot (the dew-claw) sits high and does not mark in the spoor. Claws are blunt and slightly curved, and slightly retractile; they are visible in the spoor due to the lack of claw-sheaths. Males heavier than ♀♀ and have larger chest girths. Females usually have six pairs of nipples, in contrast to the three or four pairs in other large cats.

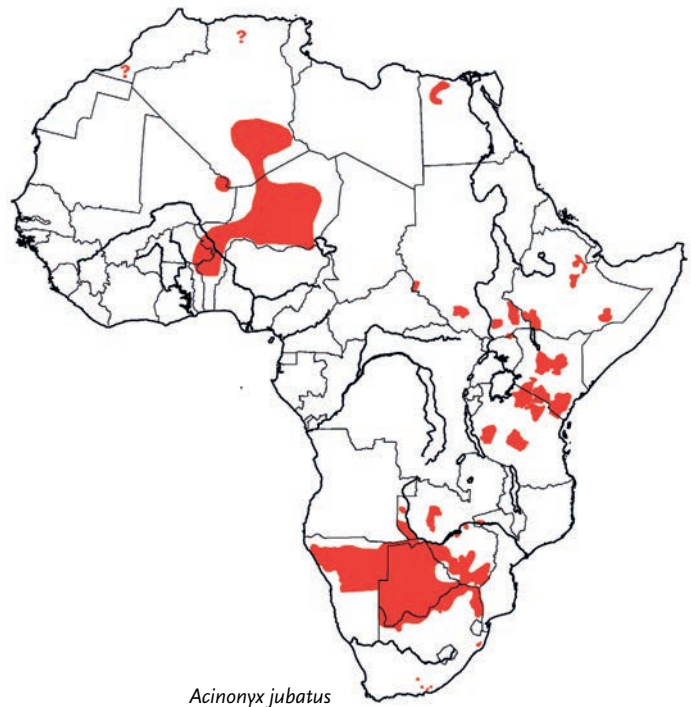

The skull is high domed, highest at the level of the middle of the orbits, then slopes abruptly forward to the nasals and back to the well-developed supra-occipital crest. The braincase is rounded, the poorly developed sagittal crest dividing into two low ridges to end on the postorbital processes (which are incomplete). The rostrum is short and wide, and the nasal openings are enlarged. The zygomatic arches are broad in the front, narrower behind and widen out posteriorly. Unlike other felids, they are distinctly upcurved when viewed from the side (Skinner & Chimimba 2005). The dental formula is typically felid, although P^2 is sometimes absent (and see Marker & Dickman 2004). The canines are short, sharp and rounded, not as long as in other felids where they are used for severing the spinal cord. The antero-internal cusp, which is well developed in other felids, is barely in evidence, represented by a small knob that occludes between the P^4 and M_1 . Its reduction allows the jaws to close tightly (Pocock 1916e, Ewer 1973, Skinner & Chimimba 2005).

Geographic Variation

A. j. hecki (includes *senegalensis*): West African Cheetah. Senegal, S Mauritania, Mali, Burkina Faso, Benin and Niger. Cheetahs from

Cheetah *Acinonyx jubatus*: (above) regular, even spotting; (below) typical 'King Cheetah' marbling.

Acinonyx jubatus

North Africa are provisionally included here pending further sampling to determine the phylogenetic position of this population.

- A. j. jubatus* (includes *rex*, *fearonii*, *guttata*, *lanea*, *obergi*): Southern African Cheetah. Angola, Zambia, S DR Congo, STanzania, Malawi, Mozambique and southwards.
- A. j. raineyi* (includes *velox* and *ngorongorensis*): East African Cheetah. Kenya, Uganda, N and C Tanzania and S Somalia. Genetic data indicate that there is very low genetic variation between this and the nominate subspecies.
- A. j. soemmeringi* (includes *megabalica* and *wagneri*): Central African Cheetah. N Somalia, Ethiopia, Sudan, N Central African Republic, N Cameroon, N Nigeria and S Niger. Intergradation with *hecki* not clear.
- A. j. venaticus* (includes *raddei* and *venator*): Asiatic Cheetah. Extralimittally in Iran. Formerly more widespread throughout the Arabian Peninsula, the Caspian to India.

A variant known as the 'king cheetah', characterized by a unique pattern of striped markings and slightly longer and distinctly silkier hair, was first described as a new species of Cheetah from skins (Pocock 1927), and first observed in the wild in 1928. Apart from one king skin recovered from Singou Faunal Reserve in Burkina Faso in 1992 (Frame 1992), all the skins and subsequent sightings come from a restricted area in E and SE Zimbabwe, E Botswana and South Africa's Limpopo Province and Mpumalanga (Hills & Smithers 1980, Skinner & Chimimba 2005). Research has confirmed that the king cheetah merely represents a colour variant and that the 'king' trait is inherited as an autosomal recessive allele, which probably arose as a mutation at the 'tabby' locus (Van Aarde & Van Dyk 1986). Melanistic and white Cheetahs are also known (Wrogemann 1975, Sunquist & Sunquist 2002). Cheetahs from the Sahara are considerably lighter in colour than those in sub-Saharan Africa (Dragesco-Joffé 1993), and Saleh *et al.* (2001) remark that skulls examined from Egypt and Libya are smaller than those from elsewhere.

Similar Species

Panthera pardus. Shorter legged and marked with rosettes, not single spaced spots. Lacks distinctive 'tear-streak'.

Leptailurus serval. Savanna habitats from Senegal to Ethiopia and S Somalia and southwards to South Africa and SW Angola. Adults smaller in size; ear pinnae larger; lacks facial tear streaks; cubs lack bluish-grey mantle of dorsal fur.

Distribution Widely, but sparsely, distributed from Senegal to Somalia (both countries where their status is unclear) and south to South Africa, with small, isolated populations existing in Morocco, Algeria and Egypt (Myers 1975, Nowell & Jackson 1996, Sunquist & Sunquist 2002). Outside of the African continent, individuals survive only in extremely small fragmented populations in Iran and possibly Pakistan.

Historical Distribution At least until the nineteenth century Cheetahs had a wide range across much of Africa and south-west Asia. Their range extended through much of North Africa and the Saharan regions, through Arabia and the Middle East to the Caucasus and eastwards through Central Asia to about Kazakhstan and eastwards through Pakistan to India. In North Africa, the last record for the Cheetah in Western Sahara dates to 1976, when an animal was given to the Algiers Zoo, while the last known Cheetah in Tunisia was killed in 1960 near Bordj Bowrgiba in the extreme south. The last observation of a Cheetah in Libya was in 1980 in the south-western part of the country bordering Algeria (Nowell & Jackson 1996). In Saudi Arabia, the last record dates to 1973 (Nader 1989), in Yemen to 1963 (Harrison & Bates 1991), in Israel to 1959 (Ilani 1979, Shalmon 2004) and in India to 1947 (Nowell & Jackson 1996). In sub-Saharan Africa, they were widely distributed from Senegal to the Horn of Africa and then southwards at least as far south as about Beaufort West in the Western Cape and just north of Grahamstown in the Eastern Cape of South Africa (Skead 1980, 1987).

Serial silhouettes of running Cheetah
Acinonyx jubatus.

Current Distribution The current distribution of the Cheetah is much changed from its historical range; Ray *et al.* (2005) estimated that the Cheetah has disappeared from at least 76% of its historical range in Africa. In their once expansive range stretching from North Africa to India, populations remain only in a few isolated regions. In Egypt, the entire population has been reduced to a few nomadic individuals surviving in a highly inaccessible area in the northern and western parts of the Qattara Depression, in the northern section of the Western Egyptian Desert (Saleh *et al.* 2001). In Morocco, observations in the last 20 years come only from the contiguous areas of the Western Draa Mts, Bas Draa-Noun and the Aydar-Ouarkiz (Cuzin 1996, 2003) and the species may now be extinct (F. Cuzin pers. comm.). There is evidence for the persistence of the species in the Algerian high plateaux (Fellous 2007). In the southern Sahara, Cheetahs still persist in mountain ranges in SE Algeria, Mali and Niger, although they can range far out onto sandy plains where there is sufficient prey (Kowalski & Rzebik-Kowalska 1991, Dragesco-Joffé 1993, Nowell & Jackson 1996, Hamdine *et al.* 2003, Wachter *et al.* 2005, Busby *et al.* 2006, 2009).

In sub-Saharan Africa, they are now rare across most of their range in West Africa, and are considered regionally extinct in Nigeria and Cameroon (De Iongh *et al.* 2011). Likewise, they are now thinly distributed across the remaining parts of their range, and no longer occur in Djibouti, Eritrea, Rwanda or Burundi; a small resident population persists in NE Uganda. The indigenous population in Swaziland was also extirpated, but they have been reintroduced (Monadjem 1998), and widely so elsewhere, such as in South Africa's KwaZulu-Natal (Hluhluwe-iMfolozi Park, Mkhuze G. R., Ndumo G. R. and Phinda G. R.) (Rowe-Rowe 1992a). Their current status in eastern and southern Africa has been recently reviewed (IUCN SSC 2008, 2009), but their status in several countries, particularly Somalia and Angola, remains poorly known.

Extralimital to the continent, populations of Asiatic Cheetahs survive only in central Iran (Farhadinia 2004). The animals occur in the foothills and dry water-courses of desert massifs, where prey is more common than on the flats (Farhadinia & Hemami 2010).

Habitat Generally depicted as a species frequenting open plains, particularly the open grasslands of East Africa, but in much of their range also found in savanna woodlands, including the miombo and *Acacia* woodlands of southern and central Africa (Mills *et al.* 2004). They also are associated with the lowveld (and formerly highveld) of southern Africa, sparsely vegetated areas of the Sahel, and even semi-desert, as in the pro-Namib of Namibia. Some still survive in parts of the Sahara, where they lie up during the day in cover (Dragesco-Joffé 1993); the surviving population in Egypt inhabits uninhabited oasis depressions within the Qattara Depression, where large groves of

Acacia raddiana west and south-west of these habitats appear to be regularly visited by Cheetahs (Saleh *et al.* 2001). They are absent from rainforest and closed woodland. There are reports of Cheetah at altitudes of 4000 m on Mt Kenya (Young & Evans 1993), and in the central Sahara Cheetahs also occur in high mountainous habitat (K. De Smet pers. comm.).

Abundance Surveys in the 1970s indicated that the total population of Cheetahs stood at between 7000 and 25,000 in 25 African countries (Myers 1975). Numbers certainly are considerably lower today, but reliable data estimates exist for only a few countries. National interview surveys conducted in the mid-1990s suggested that Tanzania contained 569–1007 individuals (Gros 2000, 2002), 40–295 in the Karamoja Region of Uganda (Gros & Rejmanek 1999), 793 in protected areas in Kenya (Gros 1998) and 15–30 in Malawi (Gros 1996). More recent figures put the total population of resident Cheetahs in eastern Africa at ~2570 adults in 15 populations, the largest of which is in the Serengeti/Mara/Tsavo (710) (IUCN SSC 2008).

In southern Africa, previous estimates have put the population at between 2000 and 3000 in Namibia, 1000 and 1500 in Botswana, less than 1000 in Zimbabwe and 500 in South Africa (with the largest population in Kruger N. P.) (Nowell & Jackson 1996, Marker 1998, 2003). Recent estimates cautiously put numbers in southern Africa at ~6260 adults in unfenced areas, although the overwhelming majority occurs in the transboundary population traversing Botswana, Namibia, South Africa, Zambia and Zimbabwe; in addition, around 200 adults occur in more than 20 fenced reserves (IUCN SSC 2009).

Reliable data regarding population status of the Cheetah in the Sahara are lacking, and summarized by Belbachir (2007). Dragesco-Joffé (1993) proposed approximately 300–500 individuals, while in Algeria, De Smet (1989) estimated 'several dozens' in the central Saharan massifs. Hamdine *et al.* (2003) suggested the population in the Ahaggar massif could be 30–40 individuals. Estimated at 200 animals in the 1970s, the last Asiatic Cheetahs are now thought to number around 60–100 animals (Hunter *et al.* 2007a).

Densities of Cheetah in protected areas are generally low (0.25–5.0/100 km²) but seasonally can reach 40/100 km² (Caro 1994). Sparse food supply outside protected areas in some parts of the range (though not, for example, outside protected areas in Namibia, where minimum density was 2.5 Cheetah/1000 km²; Marker 2003), human persecution, and high cub mortality from predation within protected areas, keep population densities relatively low (compared with Lions, for example).

Adaptations Cheetahs are designed for short, explosive sprints and are famed as the fastest animals on earth over short distances, able to

Lateral, palatal and dorsal views of skull of Cheetah *Acinonyx jubatus*.

attain a speed of at least 105 km/h when fully extended (Sharp 1997, and see Hildebrand 1959), although speeds of 85 km/h probably are more the norm (Frame & Frame 1980). To attain such speeds, Cheetahs have a number of important adaptations. The radius, ulna, tibia, fibula, metacarpals and metatarsals of the lower leg are elongated for increased stride length (Kitchener 1991). The tibia and fibula are firmly bound together with fibrous tissue that allows very little rotation about the lower leg, thereby providing much needed stability at top speeds, though at the same time hampering climbing ability (Ewer 1973). The spine is long and flexible, and flexing and straightening of the vertebral column while running increases stride length (Hildebrand 1961). At top speed, stride length approaches 7 m, and with three-and-a-half strides per second, the Cheetah can cover as much as 25 m per second (Hildebrand 1959, Ewer 1973, Taylor 1989b). The long, muscular tail functions as a counterbalance when turning or changing direction at high speeds (Kitchener 1991). Cheetahs also have a preponderance of fast-twitch fibres in their locomotor muscles (83% of the vastus lateralis and ca. 61% of the gastrocnemius), and the locomotor muscles are capable of anaerobically based exercise (Williams *et al.* 1997). Contrary to widely held belief, the Cheetah's claws are partially retractile, the modifications in the Cheetah's lower limbs resulting in somewhat diminished retractile function. The paws are small and compact, and reduced webbing between digits means the toes can be splayed more

widely. Furthermore, the absence of a protective sheath into which the claws can retract means that the claws protrude even when retracted, serving a function similar to running spikes to increase grip while pursuing prey (Kitchener 1991). Londei (2000) has remarked that the dew-claw in the Cheetah seems to have taken on the predatory function of the entire forepaw, as the other claws lost this function because of locomotory adaptation. Cheetahs also have very firm foot pads, with longitudinal ridges that act like the tread on car tyres running along the foot pads (Ewer 1973).

To facilitate rapid intake of air, the nasal passages are short and enlarged; reduction in the size of the teeth, particularly the canines, and root canals permits the enlarged nasal openings. The wide and large nasal passages help increase the concentration of oxygen in the blood during the sprint and during prey suffocation, allowing the Cheetah to regain its breath after capture. Furthermore, the respiratory tract has a wide cross-section, further facilitating rapid movement of air during breathing. During sprints, their respiratory rate climbs from 60 to 150 breaths per minute. In experimental trials, Cheetah refused to run when their core body temperature reached 40.5°C (Taylor & Rowntree 1973). As Cheetah store about 90% of the heat they produce while sprinting, their endurance is limited by the amount of heat they can store before body temperature reaches such a level.

An unusual, but important, dietary adaptation is the absence of a post-canine gap, present in other felids that kill with a neck bite where the canines need to gain maximum penetration in order to sever the spinal cord. In the Cheetah, the narrow upper and lower cheekteeth overlap such that there is no gap behind the canines; however, this arrangement does mean that the teeth are particularly well adapted to slicing and shearing (Ewer 1973).

The pelage of the Cheetah helps insulate the body from temperature changes, and the coat colour and spot patterning probably serve as camouflage. Young are born with a long mantle of dorsal fur, bluish-grey in colour, and forming a sharp boundary to dark fur below. The mantle gradually recedes as the cubs get older, until, at about four months of age, it is little more than a ruff of hair (and which is retained as the erectile crest or mane on the nape and shoulders). The adaptive significance of this mantle in young Cheetahs is still unknown. One suggestion is that the cubs' coat pattern mimics the colouring of the Ratel *Mellivora capensis* and therefore might deter predators (see Estes 1991), but the resemblance is poor. The very pale fluffy dorsal fur could also be seen as resembling dry grass, thereby assisting crypsis.

Foraging and Food Prey consists principally of small- to mid-sized ungulates, usually weighing less than 40 kg; however, body weights of prey have a large range, from the calves of African Buffalo *Syncerus caffer* and Giraffes *Giraffa camelopardalis* to ground-living birds and small mammals, including hares, porcupines, rats and guinea fowl (Pienaar 1969). Hayward *et al.* (2006b) used data from 21 published and two unpublished studies from six countries throughout the African distribution of the Cheetah to determine which prey species were preferred and which were avoided. Their results show that Cheetahs prefer to kill and actually kill the most available prey present at a site within a body mass range of 23–56 kg with a peak (mode) at 36 kg. Blesboks *Damaliscus pygargus*, Impalas *Aepyceros melampus*, Thomson's Gazelles *Eudorcas thomsonii* and Grant's Gazelles *Nanger granti*, and Springboks *Antidorcas marsupialis* are

significantly preferred, whereas prey outside this range are generally avoided. The preferred prey species offer minimal injury risk and their small size means Cheetahs can bolt down their meat before kleptoparasites arrive (as reflected by the speed with which they eat; see later), without risking losing too much food.

In the savanna woodlands of Kruger N. P., Impalas are the dominant prey item (68% of more than 2500 kills), although Cheetahs actually display a preference for Common Reedbucks *Redunca arundinum* in that region (Pienaar 1969). In Phinda G. R. in KwaZulu–Natal, where Cheetahs were reintroduced, the most common prey species taken was Nyala *Tragelaphus angasii* (the most abundant, medium-sized ungulate available), which constituted 39% of all kills, followed by Impala (34.5% of all kills) (Hunter 1998a). In the Kalahari, Springboks are the dominant prey (86.9% of kills; Mills 1984), while in Kafue N. P. in Zambia, Pukus *Kobus vardonii* were taken most frequently (Mitchell *et al.* 1965). In the Serengeti, Tanzania, Thomson's Gazelles were the most preferred prey (Kruuk & Turner 1967, Schaller 1968, Frame 1986, Caro 1994), while in Nairobi N. P., the three, favoured prey were Impalas (27% of 183 kills), Grant's Gazelles (25%) and Thomson's Gazelles (22%) (McLaughlin 1970). In the Sahara, the main prey includes Dorcas Gazelles *Gazella dorcas* and Dama Gazelles *Nanger dama*, bustards, ostriches, hares, hedgehogs, as well as camels and goats and sheep (Dragesco-Joffé 1993, Wacher *et al.* 2005).

Throughout its range, young animals are taken in preference to adults, especially in the case of larger species such as Common Wildebeests *Connochaetes taurinus*. For example, in Serengeti N. P., Thomson's Gazelle fawns constituted 53.7% of Cheetah kills, but only 5.9% of the gazelle population (FitzGibbon & Fanshawe 1989). Success rates hunting neonates are high (McLaughlin 1970, Schaller 1972, Caro 1994). In addition, Cheetahs select ungulate prey that are alone or in small groups, in high vegetation, less vigilant, on the edge of the herd, and far from nearest neighbours. Such individuals are often ♂♂, although Cheetahs are actually more successful at capturing single female Thomson Gazelles than single ♂♂ (FitzGibbon 1990). Males take larger prey than ♀♀ by virtue of their larger size and

by hunting in coalitions. At Phinda G. R., over 20% of prey killed by male pairs and trios weighed more than 100 kg, whereas only one kill (<1% of total) taken by ♀♀ weighed more than 100 kg (Hunter 1998a). Hunter (1998a) observed male coalitions twice take juvenile Giraffes. However, adult ♂♂ are not necessarily more successful when hunting in groups than as individuals (Caro 1994). Cheetahs are sometimes injured during hunts, though fatal injuries are rare. On very rare occasions, Cheetahs will scavenge or return to abandoned kills (Pienaar 1969, Caro 1982, 1994, Stander 1990); Hunter (1998a) recorded ♀♀ with large cubs return to abandoned kills on 12 occasions after leaving them overnight.

Cheetahs hunt by sight, and mainly by day, especially between 07:00 and 10:00h and 16:00 and 19:00h, which are the hours when competitors are less active (Schaller 1972, Cooper *et al.* 2007). In the Sahara, most hunting takes place during the cooler night-time hours, or shortly after dawn (Dragesco-Joffé 1993, Wacher *et al.* 2005); night-time hunting has also been recorded in Namibia (Standar 1990) and in the Serengeti (Schaller 1972). Five main hunting methods are employed (see Estes 1991): (i) crouch or sit as unsuspecting herd approaches; (ii) slow walk towards a herd in full view and break into a sprint from 60–70 m; (iii) start rush at 600 m if prey are oblivious or neonate ungulate prey stands up to nurse; (iv) approaching vigilant prey in semi-crouched stalk, freezing in mid-stride or dropping to a crouch if prey looks up, and interspersing these behaviours with trotting or sitting immobile until close enough to launch an attack; (v) flushing concealed prey from vegetation and pursuing it as soon as it runs off. On the Serengeti Plains, the last two mentioned methods are the main means of prey capture (FitzGibbon 1988). Cheetahs may take over two years to acquire some of these hunting methods, primarily relying on method (v) as juveniles.

Prey are pursued over short distances. Smaller prey are tripped or knocked over using a rapid swipe of the front paw. Medium- to large-sized prey is usually pulled off balance by hooking with the dew-claw and pulling backwards (see Londei 2000); larger prey may also be tackled by climbing onto the prey's haunches and toppling it. Large prey are suffocated or strangled by the Cheetah clamping the throat with its jaws, which takes time to achieve, with the Cheetah's large nasal passages allowing rapid inhalation to continue. Smaller prey are either grabbed by the muzzle, or killed with a bite to the skull or back of the neck. Prey are either eaten at the site of the kill, or dragged to nearby shelter. Cheetahs usually require time to recover following a chase, sometimes up to a full hour (Caro 1994). They feed rapidly, usually selecting the meat off the ventral surface first (although in 63% of more than 100 kills observed by L. T. B. Hunter [pers. comm.], Cheetahs began feeding on muscles of the hindlegs first), then the liver and the heart; however, bone consumption at kills has been recorded (Brain 1981, Phillips 1993). They are able to consume quite large quantities of food: in a feeding experiment, two Cheetahs consumed some 19 kg of food between them in a few hours of feeding (Phillips 1993).

Cheetahs make little attempt to defend their kills from larger predators and kleptoparasites such as Lions *Panthera leo* and Spotted Hyaenas *Crocuta crocuta*, and may lose up to 13% of their kills to kleptoparasites in Serengeti N. P. (Schaller 1972, Caro 1994). As a consequence, Cheetahs avoid hunting in areas where these predators are present (Durant 1998). Leopards *Panthera pardus*, African Wild Dogs *Lycaon pictus*, Brown Hyaenas *Hyaena brunnea* and even Striped

Cheetah *Acinonyx jubatus* external and myology views.

Cheetah *Acinonyx jubatus*. Far right: 12 heads with diverse facial expressions. The same 12 heads in outline (above left) and showing tonal contrast (centre).

Hyaenas *Hyaena hyaena*, Baboons *Papio* spp. and vultures have been recorded driving Cheetahs off their kills (J. S. Hunter *et al.* 2007a, b). There is one unusual record of a female Cheetah attempting to kill a subadult Ratel at Ngala Private G. R. in the Limpopo Province of South Africa; the tussle ended when a second Ratel, possibly the mother of the first, came to the rescue (Retallack 2005).

In Namibia, the Cheetah is an important predator of livestock on both commercial and communal farms: livestock depredation by Cheetahs on Namibian farmlands was calculated to account for at least 0.01 calves and 0.004 sheep per km², or 0.76 calves and 0.32 sheep annually on an averagely sized farm, and may be substantially more depending on estimates of Cheetah density (Marker 2003).

Social and Reproductive Behaviour All segments of the Cheetah population show variation in grouping patterns. Females live alone, unless they have dependent cubs (McLaughlin 1970, Frame 1984); ♂♂ live in small permanent coalitions of two or three (rarely four) animals throughout their lives, whereas others live alone. Most of these coalitions are composed entirely of littermates, but approximately 30% of Serengeti coalitions include an unrelated ♂ (Caro 1994). A ♂, or group of ♂♂, maintains close proximity to a single ♀, or to a mother and her cubs, when she is in oestrus. Such an association may last for as long as two days (although Hunter & Skinner [2003] observed ♂♂ associating with non-oestrous ♀♀ and their cubs for up to 18 days), and such associations may account for observations of larger documented group sizes (Graham 1966, Eaton 1970).

In the open plains habitats of Serengeti N. P., ♀♀ have enormous home-ranges of over 800 km² that follow the annual movements of Thomson's Gazelles (Durant *et al.* 1988, Caro 1994). Adult male Cheetahs, on the other hand, exhibit two distinct behavioural tactics. Resident or territorial ♂♂ hold and urine-mark small territories whereas non-resident (floater) ♂♂ roam over large

parts of the Serengeti Plains and rarely urine-mark. Non-residents are less relaxed than residents in that they sit up and lie alert more often; they exhibit signs of physiological stress, specifically elevated cortisol levels, and are in poor condition as determined from higher white blood cell counts, eosinophil levels, lower muscle mass and increased incidence of sarcoptic mange (Caro *et al.* 1989). Resident male territories are 37 km² (n = 22) on average whereas non-resident ranges are 777 km² (n = 9) on average, and overlap those of others. Males do not occupy territories continuously. All ♂♂ start out nomadic, but whereas some remain non-residents all their lives, others become territorial; yet others, first encountered as a resident, subsequently become nomads.

In contrast to the situation in Serengeti N. P., home-range sizes in woodland savannas vary from 24 km² in Matusadona N. P. in Zimbabwe to 320 km² in the Kalahari (Hunter 1998a, Mills 1998b, Purchase & du Toit 2000, Broomhall 2001). The nomadic nature of Springboks in the Kalahari (Mills 1998b), and the concentrated distribution of prey on grasslands in Matusadona N. P. (Purchase & du Toit 2000), likely influences home-range size of female Cheetahs in these areas. In Kruger N. P., where there are no migratory prey, home-range sizes were estimated at 126 km² for a three-male Cheetah coalition, 195 km² for a solitary ♂, and 150 km² and 171 km² for two female Cheetahs (Broomhall *et al.* 2003). Females used denser woodland habitat more frequently than ♂♂, as they seemed to be influenced by the distribution of their main prey, Impalas, which also preferred denser woodland habitat.

In opposition to the hypothesis that Cheetahs utilizing a migratory prey base have larger home-ranges than those using a sedentary one, very large home-ranges are reported in Namibia, where there also are no migratory prey, and where perturbation caused by extensive control is a factor: Stuart & Wilson (1988) mention 1500 km², not dissimilar to the study of Marker *et al.* (2008) who found that Namibian Cheetahs have a mean 95% kernel home-range of 1651 km² (± 1594 km²) over

calculations suggest that ♂♂ distribute themselves according to group size and territorial status in such a way that each encounters equivalent numbers of ♀♀ on the Serengeti Plains. In essence, for single ♂♂, reduced reproductive benefits of nomadism are balanced by not having to share matings with coalition partners. Conversely, there are also strong reasons for believing that nomad ♂♂ are disadvantaged in comparison with territory holders, such as being in poor condition, thus it is still not clear why some ♂♂ remain single (and nomadic) throughout their lives (Caro & Kelly 2001). Males form coalitions in other parts of the continent, such as in Namibia (Marker *et al.* 2003a) and KwaZulu–Natal (Hunter 1998a, b).

Cubs are born in the shelter of long grass, tall or thick vegetation, marshes, underbush, or among rocks or kopjes. Females eat the afterbirth. Mothers return to the lair to nurse cubs for 6–8 weeks, during which time they regularly carry cubs to new lairs (Frame & Frame 1980), before cubs accompany their mother on hunts from 3–4 months (Laurenson 1993). Mothers capture food for their cubs, and some of these prey items are then released again allowing cubs to pursue and subdue prey, which probably facilitates acquisition of hunting skills. Cubs engage in extensive locomotor, social and object play during development amounting to 3.4% of their day on average (Caro 1995). Although playful cubs sometimes spoil their mother's hunting attempts, overall effects on hunting success are thought to be minimal (Caro 1995). After leaving their mother, littermates remain as a sibling group mostly within their natal range for approximately six months, but ♀♀ split from the group at around time of first oestrus. Males disperse out of their natal range, probably to avoid inbreeding, while ♀♀ are the more philopatric sex, with their ranges overlapping those of their mothers by as much as 60% (Caro 1994). Infanticide has not been witnessed in Cheetahs (Hunter & Skinner 2003).

Cheetahs have few vocalizations. They growl during antagonistic interactions at kills, and when ♀♀ are approached too closely by ♂♂; spitting and hissing may accompany lunging during such encounters. Mothers and cubs yip, a high-pitched bleat, when trying to find each other (Caro 1994).

Reproduction and Population Structure Females are polyoestrus, and duration of the oestrous cycle is 13.6 ± 1.2 days

Cheetah *Acinonyx jubatus* cub.

(Brown *et al.* 1996; and see Bertschinger *et al.* 1984, Asa *et al.* 1992). Length of oestrus varies from 1 to 3 days (Bertschinger *et al.* 1984). Females breed throughout the year (Labuschagne 1979, Laurenson *et al.* 1992) and are induced ovulators (ovulation occurring after copulation; Wildt *et al.* 1981); non-mating induced ovulation appears rare (Brown *et al.* 1996). Young ♀♀ do not become sexually mature until 21–24 months old, and ♀♀ first give birth at approximately 2.4 years (Caro 1994, Kelly *et al.* 1998, Durant *et al.* 2004); ♀♀ are reported to be capable of reproduction at 13–16 months of age (Wrogemann 1975). Wild ♂♂ are capable of reproduction at approximately three years (Durant *et al.* 2004); captive ♂♂ have sired offspring in their third year of life, and all ♂♂ between 15 and 26 years in the study by Wildt *et al.* (1981) produced motile spermatozoa.

Gestation lasts approximately 93 days, and up to eight cubs are born in a litter, though six is normally the most that emerge from the lair in the wild (Caro 1994). Sex ratio does not differ from 1 : 1 at birth. In Serengeti N. P., cubs weigh 350 g at birth, though heavier weights are recorded from captivity (averaging 463 g; Wack *et al.* 1991), and are born altricial (Beekman *et al.* 1999). Young, up to the age of about three months, have a unique covering of long bluish-grey or smoky coloured hair, 70–80 mm in length, which conceals the tiny spots on the pelage underneath. Eyes open at Day 10–12, and the full set of milk teeth erupts by around six weeks; the permanent set is in place by about 8–9 months. Cubs in Serengeti N. P. grow at an average of 44.6 g/day in the lair (Laurenson 1995a, b), and were weaned at about four months, and independent between 13 and 20 months (average 17.1 months; Kelly *et al.* 1998), after which the mother begins to raise another litter (Schaller 1972). From data from animals measured in Namibia, ♂♂ and ♀♀ attain adult body mass after 49 months of age (Marker & Dickman 2003). Average inter-birth interval in Serengeti N. P. is 20.1 months (Kelly *et al.* 1998).

Serengeti ♀♀ continue to reproduce until 11.8 years of age, and can live as long as 13.6 years in the wild (Caro 1994, Kelly *et al.* 1998, Durant *et al.* 2004). Serengeti ♂♂ live for a maximum of 7.8 years, far shorter than ♀♀ (Durant *et al.* 2004; but see Oliver *et al.* 2011). Maximum longevity for a captive Cheetah has been given as 21 years, and in captivity a large number of animals have survived longer than 17 years (Marker-Kraus 1997); a captive ♀ of some 15 years of age still showed follicular activity (Wildt *et al.* 1981).

Mortality rates from emergence to independence may be high, partly due to high mortality between emergence and about age three months (Laurenson 1994, 1995c). Pienaar (1969) reported a 50% mortality rate in Kruger N. P., McLaughlin (1970) 43% in Nairobi N. P., and Hunter (1998a) 38% at Phinda G. R. Females will quickly resume oestrus and conceive again (on average, in 19 days) if a litter is lost prematurely; one ♀ mated and conceived two days after losing a litter (Laurenson *et al.* 1992).

In Serengeti N. P., average Cheetah litter-size at independence was 2.1 cubs; litter-size averaged 2.5 between 1969 and 1979 when Lion abundance was low on the Plains, but averaged 2.0 between 1980 and 1994 when Lion abundance increased by 60% (Kelly *et al.* 1998). Nevertheless, a population viability analysis shows that, in spite of increasing Lion density, on average, the Cheetah population in Serengeti N. P. is nearly self-replicating (i.e. $\lambda = 0.997$). Cheetah populations may be self-replicating because they move to areas where Lions are absent.

Certain matrilineal lines in Serengeti N. P. are far more successful than others (Kelly 2001, Pettorelli & Durant 2007), with five lineages contributing 45% of the Cheetah population. Why reproductively successful mothers produce reproductively successful daughters and granddaughters is unknown, but playbacks of Lion roars to Cheetahs demonstrate that the female Cheetahs that react most strongly to Lion roars by moving away from the speaker were those with the highest reproductive success (Durant 2000). Since Lion predation is so important in affecting reproductive success in this species, the finding raises the possibility that daughters inherit some aspects of their mothers' wariness or anti-predator tactics.

Predators, Parasites and Diseases Adult Cheetahs are relatively immune from predation although occasional cases of predation by Lions, Spotted Hyenas and Leopards have been reported. However, predation on cubs may be extremely high. In Serengeti N. P., 95% of cubs born fail to reach independence 14 months later, and 73% of these deaths are due to predation principally by Lions (Laurenson 1994). Cubs are sometimes killed when Lions take over a Cheetah kill (J. S. Hunter *et al.* 2007b) but they are also killed in their dens for unknown reasons; Cheetah mothers are unable to defend small cubs against Lions that are four times their weight. Groups of Cheetahs are less likely to be harassed by most predators than are single animals (Caro 1994).

There are no systematic surveys of diseases in wild Cheetah populations. In Namibia they have minimal to no disease (Munson *et al.* 2004a, 2005), although of seven telemetered Etosha Cheetahs, six died of anthrax (Lindeque *et al.* 1998; and see Jager *et al.* 1990). In Serengeti N. P., Cheetahs show high seroprevalence for feline coronavirus and herpesvirus (Evermann *et al.* 1993). Feline immunodeficiency virus is also present in high frequency (40%) in some Cheetah populations (e.g. Tanzania), but absent (0–2%) in others (e.g. Namibia) (Troyer *et al.* 2005). Lentivirus (Osofsky *et al.* 1996) and *Bartonella* (Molia *et al.* 2004) have also been reported in the wild. In captivity, infectious diseases are far more common: feline infectious peritonitis virus (FIPV)/feline enteric coronavirus and feline herpes virus are endemic. Indeed, an FIP outbreak dramatically reduced a captive collection in 1982 and 1983, but has not been a significant problem recently. In both the USA and South Africa, captive Cheetahs also suffer from gastritis associated with *Helicobacter* that account for up to 40% of adult mortality (Munson 1993, Terio *et al.* 2005). Chronic degenerative diseases, such as glomerulosclerosis, veno-occlusive disease and amyloidosis, are also major causes of mortality. Cheetahs under one year of age frequently die from pneumonia (Munson *et al.* 1999). Other diseases recorded in captivity include parvovirus (Steinel *et al.* 2000), spongiform encephalopathy (Kirkwood & Cunningham 1994), dermatitis (Munson *et al.* 2004b), leukoencephalopathy and hindlimb paralysis. Stress, as measured by elevated corticosteroid concentrations (Terio *et al.* 2004, Munson *et al.* 2005), and perhaps diet and low genetic variability, are both thought to be responsible for prevalence of degenerative disease in captive animals raising conservation and ethical concerns about keeping Cheetahs in captivity.

Marker & Dickman (2004) examined dental abnormalities in 208 wild cheetahs trapped on Namibian farmlands, and recorded three anomalies: erosion of the upper palate, crowding of lower incisors, and absence of one or both upper premolars. A little over 40% of Cheetahs showed evidence of deep palatine erosion (where the lower

molar penetrates the palatine mucosa), of which approximately 15% had perforated upper palates. Focal palatine erosion had previously only been recorded in captive Cheetahs (Fitch & Fagan 1982).

Penzhorn *et al.* (1998b; and see references therein) provided a detailed review of parasites recovered from both wild and captive Cheetahs at the time, including one rickettsia (*Eperythrozoon felis*, seen in blood smears from an animal in Nairobi N. P.), nine protozoa (including *Hepatozoon* sp., and *Theileria*-like piroplasms), 14 nematodes, four cestodes (including three species of *Taenia*), one trematode (*Pharyngostomum cordatum*), 21 ticks, two mites (*Notoedres cati* and *Sarcoptes scabiei*, the latter of which causes sarcoptic mange, an outbreak of which was recorded in the Masai Mara in Kenya), four flies (among which, lesions caused by *Stomoxys calcitrans* have been seen on the ears of Cheetahs at breeding centres in South Africa), four fleas and two lice (*Damalinia elongata*, usually associated with Impalas, and *Felicola* sp.). Some of these parasites normally are associated with the prey of Cheetahs, which presumably become infected while feeding.

Conservation IUCN Category: Vulnerable A2acd, C1 (*A. j. hecki* – Critically Endangered C2a(i), D; *A. j. venaticus* – Critically Endangered D). CITES: Appendix I. CMS: Appendix I (except populations in Botswana, Namibia and Zimbabwe).

An annual quota of 150 live animals or hunting trophies from Namibia, 50 from Zimbabwe and 5 from Botswana per annum was passed at 1992 CITES meeting. The international fur trade, prevalent in the 1960s, has all but halted, though domestic trade remains prevalent in some parts, such as north-east Africa.

Habitat encroachment and reduction in ungulate prey, stemming from cultivation and direct exploitation, are responsible for most of the massive reduction in range. Direct persecution still occurs in most areas where Cheetahs exist outside of protected areas, such as in Namibia, where the overwhelming majority of animals (more than 90%) live on farmland. In the past 20 years numbers in Namibia have declined from 6000 to ca. 2500 due to eradication and removal from farms because they are perceived as a threat to livestock (Marker *et al.* 2003b). Human-mediated mortality accounted for 79.4% (n = 50) of wild deaths reported, of which the majority involved prime adult animals, with a peak at around 5–6 years of age (Marker 2003, Marker *et al.* 2003b). None the less, between 1991 and 1999, annual tallies (informed by surveys) of Cheetahs killed by farmers significantly decreased, with an overall mean of 19 Cheetahs killed annually in an initial survey falling to 2.1 in the follow-up. These findings suggest that although Cheetahs on Namibian farmlands are still perceived as a problem, farmers' tolerance toward them might have improved. Management strategies that reduce livestock losses, such as the use of livestock guarding dogs, have proved successful and cost-effective at mitigating losses of livestock to Cheetahs outside protected areas (Marker 2003, Marker *et al.* 2003c).

The principal conservation tool for Cheetahs is enforced protection within fully protected areas such as national parks. However, mesopredators such as Cheetahs and African Wild Dogs suffer from competition with larger carnivores. For example, a stochastic model of the Serengeti Cheetah population demonstrates that Cheetah populations decline to extinction under high or average Lion abundances. That Cheetah juvenile survival is so strongly affected by Lion predation suggests that outside protected areas where Lions are hunted, Cheetahs

may have reasonably robust populations although evidence for this is controversial (Laurenson 1995c, Gros 1998). Important protected areas that represent strongholds for Cheetah populations include the Kgalagadi Transfrontier Park (South Africa, Botswana), Nxai Pan and Chobe National Parks, and Okavango Delta (Botswana), Etosha N. P. (Namibia), Liuwa Plains and Kafue National Parks (Zambia), Tsavo and Ruaha National Parks (Tanzania) and, of course, the Serengeti N. P. and Mara ecosystem (Tanzania, Kenya) (IUCN SSC 2008, 2009). In West Africa, the major remaining stronghold is the WAP protected areas complex between Benin, Niger and Burkina Faso (P. Chardonnet pers. comm.). An important population of desert-adapted Cheetah is still distributed widely through the Ahaggar National Park in Algeria (Hamdine *et al.* 2003, Wacher *et al.* 2005).

Allozyme work on wild and captive populations shows that the Cheetah lacks genetic variation in at least some portion of its genome; percentage polymorphism and average heterozygosity appear close to zero (O'Brien *et al.* 1983, Wayne *et al.* 1986). Reciprocal skin grafts between unrelated Cheetahs that fail to show rejection confirm absence of genetic variation (O'Brien *et al.* 1985). Nevertheless, mitochondrial DNA show more variation than previously supposed (Menotti-Raymond & O'Brien 1993), and more recent studies, including previously unsampled populations, have revealed higher genetic variation in the current global Cheetah population than previously described (Charruau *et al.* 2011). The causes of the genetic bottleneck are unknown but could possibly result from very low population sizes during the Pleistocene and breeding between relatives (Menotti-Raymond & O'Brien 1993, Hedrick 1996). In theory, genetic monomorphism raises two issues of conservation concern: (i) reduced juvenile survival because deleterious recessive alleles may not be masked by more dominant benign alleles if loci are not heterozygous, and (ii) populations are likely to be susceptible to disease because if a disease overcomes the immune system of one individual, it may overcome every member of the population. Both factors were thought to be involved in the Cheetahs' failure to breed well in captivity prior to the 1990s (O'Brien *et al.* 1985, Marker & O'Brien 1989), but chronic stress now seems far more probable (Munson *et al.* 2005; but see Wacher *et al.* 2011). In recent years, breeding success has improved (Marker & Grisham 1993) as problems with housing, maternal behaviour and feeding have been resolved suggesting poor management practice could have contributed to earlier problems (Wielebnowski 1996, Caro 2000). None the less, disease is viewed as a potential concern in both captivity and in the wild.

There are an estimated 1500 Cheetahs in captivity worldwide, maintained by importation of wild-caught animals (see Marker 2003).

Adult deaths in captivity account for 66% of mortalities in captivity and are principally due to renal failure and liver disease; juvenile mortality results from diverse causes but primarily pneumonia (Marker & Grisham 1993). Breeding is still limited to relatively few individuals so that effective population size is low (18.2% of the census population size). Causes of variation in captive breeding success include inbreeding (Wielebnowski 1996), inadequate social environment and housing (Wielebnowski *et al.* 2002), possible physiological problems associated with sperm abnormalities (Wildt *et al.* 1993), and disease (Munson 1993). In addition, individual temperament is an important predictor of reproduction with tense and fearful animals having low reproductive output (Wielebnowski 1999). Artificial insemination has been relatively successful and ♀♀ conceived through artificial insemination have also reproduced successfully. Furthermore sperm from Namibian Cheetahs has been used to produce litters in captivity. Sporadic reintroductions of captive-born individuals have been attempted in areas of South Africa but have largely failed due to inability to hunt wild ungulates and predation from Lions; in contrast, wild-to-wild translocations of Cheetahs in South Africa and Namibia have successfully re-established populations (Hofmeyr & Van Dyk 1998, Hunter 1998a, b).

GENUS *Felis*

Small Cats

Felis Linnaeus, 1758. Syst. Nat., 10th edn, I: 41.

The genus *Felis* has, in the past, embraced a large part of the living felids, often only to the exclusion of the genera *Acinonyx* and *Panthera* (Simpson 1945, McKenna & Bell 1997). Such an arrangement, however, is not well supported by primary systematic studies (see Felidae for

further discussion), and following the most recent molecular analyses this genus is now restricted to members of the domestic cat lineage and includes some of the smallest species of the family: Black-footed Cat *Felis nigripes*, Sand Cat *Felis margarita*, Wildcat *Felis silvestris*, Swamp

or Jungle Cat *Felis chaus* and Chinese Desert Cat *Felis bieti* (Wozencraft 1993, 2005). However, *Felis bieti* has been reduced from a separate species to a subspecies of *Felis silvestris*, using mtDNA studies (Driscoll *et al.* 2007), having diverged about 0.23 mya from the European wildcats (*F. s. silvestris*). All wild species are distributed in the Old World and all occur on the African continent. Only one species, the Black-footed Cat, is endemic to Africa, the other species having wide distributions extending into Asia and Europe or just occurring on the fringes of north-east Africa. They inhabit all habitats, except for closed tropical forest.

Members of the genus are small or medium-sized felids (HB varies from 360–1120 mm, body mass 1–13 kg), displaying the classic felid body shape, with a strong elongate body, short to medium length legs, tail 38–60% of HB length, and small rounded paws with 4–5 functional toes (Haltcnorth 1953). The dental formula is $I^{3/3}, C^{1/1}, P^{3/2}, M^{1/1} = 30$. All but the Swamp Cat have relatively large and broad heads. The skull is lightly built compared with other Felidae lineages with slight zygomatic arches and large orbits and a large inflated skull capsule (Heptner & Sludskii 1972). The upper profile seen from the side is convex. A sagittal crest, if present, is only weakly expressed. The auditory bullae are strongly inflated especially in the Sand Cat and Black-footed Cat. The ears are narrowed towards the point, which is sometimes pencilled with a short tuft (Pocock 1951). The backsides of the ears are always uniformly coloured yellow-reddish, sometimes with black edge, but never with a conspicuous white spot. Shoulders are lower than sacral region. The forelegs have at least one stripe, the brachial, below the elbow on the inner side and the hindlegs are striped at least externally above the hocks. The tail may be banded above throughout and is always strongly striped in its distal half, and may have a black tip. The pelage of all African species is relatively short, with dense hair. The ground colour of the coat is brownish-buff to grey, and either of uniform colour or heavily marked. If spots are present there

is marked fusion on the flanks behind the shoulders, to form vertical stripes characteristic for *Felis* (Pocock 1951). Melanism is only rarely reported in the wild, as in the Swamp Cat in Pakistan (Roberts 1977).

Felis species are carnivores that usually prey on mammals and birds that are smaller than themselves (Sunquist & Sunquist 2002). Despite their relatively early scientific description, there is still little known about the ecology and social structure of several species. They are mostly solitary with their social organization generally following the typical felid pattern of little intra-sexual overlap, with the range of a territorial ♂ typically overlapping the smaller ranges of one or more ♀♀.

The genus *Felis* has a weakly represented fossil record, compared with *Panthera* (Turner & Antón 1997). The most likely fossil ancestor, *Felis attica*, is found throughout the late Miocene in Eurasia (Beaumont 1961). Further possible fossil ancestors were *Felis lunensis* of the late Pliocene/early European Pleistocene (Kurtén 1965, 1968). The recent analysis of Johnson *et al.* (2006) has shown that the *Felis* lineage split as one of the two most recently derived groups from the Asian Leopard Cat lineage, some 6.2 mya and is therefore the most recently evolved, and also the smallest in body sizes, of all felid lineages. The domestic cat lineage originated in Eurasia and then migrated to Africa probably in the late Pleistocene (Yamaguchi *et al.* 2004b, Johnson *et al.* 2006). The oldest African fossils pertaining to the genus *Felis* are from Kanapoi, Kenya, dated to ca. 4.1 mya (Werdelin 2003b). The genus appears sporadically in the African fossil record from that time onwards. Through climatic and geographic isolation events populations were cut off from each other by water, deserts and mountains and evolved also through adaptation to arid and mesic ecological conditions into the different species of *Felis*.

Alexander Sliwa

Felis chaus SWAMP CAT (JUNGLE CAT)

Fr. Chat des marais (Chat des jungle); Ger. Rohrkatze, Sumpfluchs

Felis chaus Schreber, 1777. Die Säugethiere 2 (13): pl. 110.B [1777]; text, 3 (24): 414 [1777]. 'wohnt in den sumpfigen mit Schilf bewachsenen oder bewaldeten Gegenden der Steppen um das Kaspische Meer, und die in selbiges fallenden Flüsse.

Auf der Nordseite des Terekflusses und der Festung Kislar ... desto häufiger aber bei der Mündung der Kur ... '.

Listed in Honacki *et al.* (1982) as 'U.S.S.R., Dagestan, Terek River, N. of the Caucasus'.

Swamp Cat *Felis chaus*.

Taxonomy The Swamp Cat was originally placed in a separate genus (*Catolynx*) due to its resemblance to the Eurasian Lynx *Lynx lynx*, but was later reassigned to the genus *Felis*. It has not yet been decisively decided whether the Swamp Cat played a role in the development of the domestic cat, with the Wildcat *Felis silvestris* typically considered as the progenitor of the domestic felid (Collier & O'Brien 1985, Driscoll *et al.* 2007). Although there is apparently no real evidence of this species ever having been fully domesticated, it is known that the Swamp Cat was tamed and trained by the ancient Egyptians to hunt wildfowl or to catch rodents, and they were also mummified and placed in tombs (Morrison-Scott 1952). Six subspecies are usually recognized (mainly reflecting morphological differences), but only one is currently listed from Africa, *F. c. nilotica*, in Egypt (Smithers 1975). Synonyms (Africa only): *nilotica*, *rüppelii*. Chromosome number: $2n = 38$ (Wurster-Hill & Gray 1973, C. Driscoll pers. comm.).

Lateral view of skull of Swamp Cat *Felis chaus*.

Description Large-bodied, long-legged cat with shortish, banded tail and large, pointed ears. Face long and slim. Long ears are rounded and set close together on the crown; backs reddish-buff with distinctive black apical tuft of hair (up to 15 mm in length). Muzzle and throat usually white or ochre; area around the eyes whitish with a dark line running from corner of eye down each side of nose. Pupil elliptical and iris yellow. The homogeneous unspotted coat can be sandy-brown, reddish, or grey in colour. Inside of forelegs bears 4–5 prominent black rings, and some individuals have faint stripes on the outside of the forelegs. Fur rough in the summer coat and individual hairs are dark tipped. Belly fur pale cream and comparatively long and soft in the winter coat. Melanistic individuals occur regularly in Pakistan and India (Roberts 1977, Chakraborty *et al.* 1988). Tail comparatively short, about one-third of body length (38% in Egypt; Osborn & Helmy 1980). Distal third of tail bears 2–3 blackish rings terminating in a black tip. Males larger than ♀♀. There are four pairs of nipples.

Rostrum and cranium somewhat elongate, and frontal and postorbital swellings are prominent. Postorbital width slightly more than rostral width. Anterior end of zygomatic process attenuate, and mastoid process large and protruding (Osborn & Helmy 1980).

Geographic Variation See Taxonomy.

Similar Species

Felis silvestris. In Egypt, found along margins of the Delta and the Nile Valley, including the Fayoum, in the Mediterranean coastal desert to Mersa Matruh, and in the Western Desert (Hoath 2003). Smaller, with body markings more conspicuous; cheek stripe present, and lacrimal stripe less prominent; tail longer; skull less elongate, and postorbital swellings absent; anterior end of zygomatic process rounded.

F. margarita. In Egypt, known only from the Sinai and rocky deserts of E Egypt. Lighter colour, with more conspicuous body markings; broader ears; pads of feet covered with hair; relatively longer tail; relatively longer nasals and larger bullae.

Distribution On the African continent, the Swamp Cat occurs only in Egypt, in the Nile Delta, and along the western Mediterranean coastal desert to Mersa Matruh. They are present in the Nile Valley south to Aswan, and in El Faiyum, Farafara, Dakhla and Kharga oases (Osborn & Helmy 1980, Hoath 2003). Meinertzhagen (1934) makes reference to this species from the Hoggar of Algeria, based on a skin purchased in Arak (and see Heim de Balsac 1936); however, Pocock (1944) identified this specimen as a Wildcat, and there is no

Felis chaus

evidence for the existence of this species in Algeria (Kowalski & Rzebik-Kowalska 1991).

Extraliminally, the Swamp Cat has a relatively wide distribution, ranging from Egypt eastwards throughout the Middle East from Israel to Asia Minor, Iraq, Iran, Afghanistan, Pakistan, India, Nepal, Sri Lanka, Myanmar, to mainland South-East Asia (Sunquist & Sunquist 2002).

Habitat The preferred habitat includes tangled stands of reeds and bushes, riverine swamps and tall grass. In Egypt, it is found in low cultivated or marshy ground, reed-beds, fields of sugarcane, bean fields or any similar thick cover (Osborn & Helmy 1980). They have been recorded around settlements in the El Faiyum. It usually avoids open spaces, and is commonly found below 1000 m altitude, although it ascends mountains up to 2400 m in the Himalaya (Sunquist & Sunquist 2002).

Abundance No available information for Egypt, although the Swamp Cat is the most common of the wild felids in Egypt. They appear fairly adaptable, but are only patchily distributed in suitable habitats (M. Saleh pers. comm.).

Adaptations The Swamp Cat is a very good swimmer, and can hunt in water. Its rough fur dries fast. It is also a very good tree climber. Its keen sense of hearing helps it locate its prey, particularly rodents. These cats often rest up in disused burrows of other species, such as porcupines and foxes, sometimes arranging a nest of dry reeds on the surface of the ground, under bushes or among reeds (Novikov 1956, Kitchener 1991, Alderton 1993, L. Glas pers. obs.); during the day they also rest up in dense cover or in rock crevices and tree cavities. They are primarily nocturnal, although cats have been observed hunting during daytime (when the weather is cool).

Foraging and Food Prey consists mainly of small mammals (rodents, gerbils and hares), birds (from the size of larks to various

waterfowl), and occasionally amphibians, reptiles and insects. Flower (1932) states that they would eagerly kill and eat live snakes of the genera *Coluber* and *Psammophis*. In Egypt, one cat collected from near Alexandria had its stomach full of fish (Osborn & Helmy 1980). Bonhote (1909) mentions that one killed an almost full-grown sheep, and 'after dragging it to the edge of the enclosure, devoured nearly a whole fore-quarter.' Flower (1932) found that average daily consumption of raw horse-meat was 0.49 kg per cat, and the maximum amount of meat that a cat would eat at one sitting was 1.87 kg.

Dietary studies from elsewhere in the species' range reveal similar dietary preferences (e.g. Ognev 1935, Ishunin 1965, Roberts 1977, Khan & Beg 1986, Mukherjee *et al.* 2004), and confirm that they are powerful enough to kill prey such as subadult gazelles. However, they are also known to supplement their diets with fruits; in Tajikistan, the fruits of the Russian olive made up 17% of the diet (Novikov 1956).

Swamp Cats will sit motionless, attentively listening for the sounds of their prey, and then leap vertically high in the air, landing and catching the prey. Similar leaps are also used to catch birds. When hunting in the water they seize the prey in their mouth, keeping their head in the water (Novikov 1956, Kitchener 1991, Alderton 1993, L. Glas pers. obs.).

Social and Reproductive Behaviour Swamp Cats are poorly studied, and there is limited information available on their social organization. They are solitary, and studies in Israel have shown that male territories overlap several female territories (L. Glas pers. obs.). The ♂ is vocal during oestrus, and will stalk a potential mate from a distance until she is ready to accept his attentions (Alderton 1993, L. Glas pers. obs.). The kittens are kept in a hidden reed-bed den, lined with fur and grass. Dens are concealed and located in inaccessible areas (Novikov 1956, Alderton 1993).

Reproduction and Population Structure Female Swamp Cats enter oestrus from Jan to Mar. Oestrus lasts five days (Sunquist & Sunquist 2002). In Egypt, the young are born from mid-Dec to Apr (Flower 1932, Osborn & Helmy 1980). Gestation period is 63–68 days (Sunquist & Sunquist 2002), and litter-size is 1–4 (usually 2–3), although Flower (1932) mentions a litter of six born in the Giza Zoological Gardens in mid-Apr. Birth-weight of neonates was 43–55 g in the wild (Heptner & Sludskii 1972), although captive kittens have been recorded with weights up to 160 g (Schauenberg 1979). Eyes first open at 10–13 days. The kittens differ significantly in appearance from adults as they have very distinctive black markings

on their coats. They are weaned around 15 weeks old (Schauenberg 1979). Both sexes reach sexual maturity at the age of about one year (Mendelssohn & Yom-Tov 1987), although other records put this much later at as much as 36 months of age (Eaton 1984). In captivity the Swamp Cat can live 15–20 years (Mendelssohn & Yom-Tov 1987, Weigl 2005), but in the wild longevity is probably less.

Predators, Parasites and Diseases Kittens are likely to fall prey to Golden Jackals *Canis aureus* and Leopards *Panthera pardus*. Recorded parasites in Egyptian animals include trematodes of the genus *Heterophyes* (Wells & Randall 1956) and the tick *Haemaphysalis leachi* (Hoogstraal 1958).

Conservation IUCN Category: Least Concern. CITES: Appendix II.

According to Hoath (2003), although protected by Egyptian law, the species is still persecuted in Egypt, with trapping recorded along the coast of the Delta, and pelts found on sale in the market at Kerdassa and the Khan al-Khalili. In other parts of its range, its generalist diet and adaptability, and ability to survive in a variety of habitats, make it the most common of the small felids (Sunquist & Sunquist 2002).

Fr. Chat de Sables; Ger. Sandkatze

Felis margarita Loche, 1858. Revue Mag. Zool. Paris (2) 10: 49, p l. 1. 'environs de Négonca (Sahara)' [Algeria].

Taxonomy There are four recognized subspecies, including *F. m. harrisoni* from the Arabian Peninsula, *F. m. scheffeli* from the Nushki Desert of Pakistan (Hemmer 1974b) and *F. m. thinobia* from the sand deserts of Turkmenistan, Uzbekistan, Kazakhstan and possibly N Iran and NE Afghanistan; only the nominate form, *F. m. margarita*, occurs in Africa (Schauenberg 1974). The forms *airensis* and *meinertzhageni* were described from single specimens and were later considered

synonymous with the nominate form (Schauenberg 1974, Hemmer *et al.* 1976; but see Smithers 1975). The subspecies *F. m. thinobia*, called the Barchan Cat, was temporarily recognized as a separate species (Ognev 1926, Weigl 1961), but was later classified as a subspecies of the Sand Cat (Heptner & Sludskii 1972). Synonyms: *airensis*, *harrisoni*, *marginata*, *margarita*, *marquerittei*, *meinertzhageni*, *scheffeli*, *thinobia*. Chromosome number: 2n = 38 (Jotterand 1971).

Sand Cat *Felis margarita*.

Description A small cat, with size and build smaller than the Wildcat *Felis silvestris* (but ears outstandingly larger). Head flat and broad; ears broad and set low down on the sides of the head without apical tufts. Eyes yellow amber, greenish to yellow-bluish. Nose pad black. Vibrissae white, the supralabial group attaining about 80 mm. Pelage soft and dense, in winter up to 55 mm on the back, with abundant soft woolly underfur, giving the cat a solid appearance despite its small size. The colouration is strikingly pallid; the general tint of the back is pale sandy-isabelline to golden-sandy, finely speckled with black over the shoulders and with silvery-grey on the upper flanks. A poorly differentiated spinal band is present. Crown of the head pale sandy and marked with very faint ill-defined striations. Three to five dark, narrow, always obscure and sometimes indistinguishable, longitudinal lines on the back of the neck (Rosevear 1974). Face appears broad due to well-developed side-burns. Backs of the ears are rufous-tawny, each with an extensive apical black spot, extending for 15–25 mm about half the length of the external margin. Face is marked with a dark reddish-fulvous stripe from the anterior edge of each eye backwards, across the cheeks. Chest and belly are white, with an indistinct line of demarcation on lower flanks and very faint buffy wash on lower throat. Limbs white internally; externally marked by at least two pronounced black elbow-bar 'bracelets', extending round to the internal aspect. The outsides of the hindlimbs have from two to five dark, mostly brown-black, half-rings (Weigel 1961). The pattern of the flanks is composed of seven or eight indistinct reddish-brown vertical stripes, broken up into spots and lightly washed with black in places (Harrison & Bates 1991). The limbs are of medium length, with the paws broader than in the Wildcat; the palms and soles are distinctive, being covered with a dense mat of fine, long (15–30 mm, Heptner & Sludskii 1972), dark-brown to black wavy hair, completely concealing the pads. Front paw carries five digits, with the thumb carrying the sharp dew-claw higher up on the wrist; the ivory coloured claws touching the ground are somewhat blunt. Hind paw carries only four digits

Lateral view of skull of Sand Cat *Felis margarita*.

and claws are more blunt than those of the front paw. Tail is half the body length, tipped with black and has a varying number of subterminal tail rings (typically six in *F. m. margarita*). The baculum is very small, not exceeding 3 mm (Schauenberg 1974). Males on average larger and heavier than ♀♀. Four pairs of nipples.

Skull distinctive. Orbits large, more spherical and forward-facing than in the Wildcat and the interorbital region a little broader. Rostrum short and broad, with nasals almost parallel-sided throughout a great part of their length, only tapering abruptly posteriorly. Zygomatic arches wide and outwardly bowed. Sagittal crest strongly developed over the posterior braincase and lambdoid crests also pronounced and rather squarely truncated behind. Auditory bullae exceptionally large, in all directions peculiarly inflated (Harrison & Bates 1991), leaving only a space of 4–5 mm between them. Auditory orifice, like the bullae, also exceptionally large, complementing the broad external ears (Rosevear 1974).

Geographic Variation Sand Cats become gradually larger from west to east, with the smallest subspecies *F. m. margarita* in Africa (Schauenberg 1974). Probably the ancestral form most closely resembled *F. m. margarita*; from this a radiation of more specialized forms arose, with *F. m. thinobia* and *F. m. scheffeli* acquiring a more intensely eremial/psammophilic pattern of skin and *F. m. harrisoni* of skull (Hemmer *et al.* 1976). In *F. m. margarita*, specimens from Algeria and Niger tend to be brighter in colour and have more distinct markings than other recognized subspecies (Schauenberg 1974). Five specimens obtained from the N Sinai were assigned to the nominate form (Saleh & Basuony 1998) due to pelage colouration, but were intermediate in skull characters between the nominate form and *F. m. harrisoni* (Hemmer *et al.* 1976).

Similar Species

Felis silvestris. Wide, but discontinuous, distribution in North Africa.

Larger and darker, with longer legs, a relatively smaller and narrower head and more vertically oriented ears; plantar and digital pads not concealed by thick mat of long hair.

F. chaus. Restricted to vicinity of Nile R. and Mediterranean zone of Egypt. Overall sandy-brown pelage, without distinctive markings; reddish-brown hair on ear backs with short, black tufts of hair at tips.

Distribution In North Africa, the Sand Cat occurs marginally in W Morocco (Panouse 1957, Cuzin 2003) including Western Sahara

Felis margarita

(Valverde 1957, Hemmer *et al.* 1976, F. Cuzin pers. comm.), Algeria (De Smet 1988, Kowalski & Rzebik-Kowalska 1991), and from the Sinai to the rocky deserts of E Egypt (Mendelssohn, in Hemmer 1974c, Osborn & Helmy 1980, Goodman & Helmy 1986, Saleh & Basuony 1998, Hoath 2003). There are no confirmed records from Tunisia (Lataste 1887, and Blanc 1935, in LeBerre 1990), Libya (Hufnagl 1972) or Egypt, west of the Nile R. (Goodman & Helmy 1986, M. Saleh pers. comm.), but this distributional gap may close with future survey work.

There are both specimens and reliable sightings from Niger (Pocock 1938, Rosevear 1974, Schauenberg 1974, Dragesco-Joffé 1993, J. Newby & T. Wachter pers. comm.), and they are supposed to occur in the Majabat al Koubra (Lamarche 1980) in Mauritania. Since they are recorded from the Adrar Souttouf Mts in Western Sahara (Hemmer *et al.* 1976), they may well occur in adjacent parts of Mauritania. Sand Cats are thought to be present, although there are no confirmed records available, in Senegal, Mali, Chad (where spoor have been found; J. Newby & T. Wachter pers. comm.) and Sudan.

A presumed subfossil record from Tenerife, Canary Is. (Sarrion Montañana 1985) was later reassigned as a domestic cat (Hutterer 1990).

Extraliminally, the Sand Cat occurs in the Arabian Peninsula, Israel, Jordan, N Iran, Turkmenistan, Uzbekistan and the Baluchistan province in Pakistan (Harrison & Bates 1991, Sunquist & Sunquist 2002). A recent record for Syria is the first for this country (Serra *et al.* 2007).

Habitat A desert specialist inhabiting undulating stabilized dune areas, wadi beds and steppe with sparse grass and shrub cover (generally being absent from heavier vegetated valleys). Also found in shifting sand dunes and in rocky deserts ('hammada') (Abbadi 1991, Saleh & Basuony 1998) and coastal plains (M. Saleh pers. comm.). One cat was even seen sitting on a branch of a mangrove tree 2 m above ground (M. Saleh pers. comm.). Occurs to altitudes of about 2000 m.

Abundance Difficult to census and thus often reported as rare. Only density estimates come from a telemetry study in S Israel (Abbadi 1991, 1993), where 11 cats were caught in the study area of 15 × 25 km (375 km²) (M. Abbadi pers. comm.). In low-quality habitat, such as shifting sand dunes, densities may be very low.

Adaptations The palms and soles are covered by a dense mat of fine, long, wavy dark hair of about 1 cm length, completely concealing the pads. These tufts of hair may facilitate walking across shifting sands helping to spread the weight as it moves (Harrison 1968) and to make it more silent, or to protect the soles from hot ground. The claws are not very sharp, due to the lack of sharpening surfaces and the Sand Cat's digging habits – impressions are often visible in the spoor (Dragesco-Joffé 1993).

The ears are large, widely set apart and low on the sides of the head, flattening the Sand Cat's profile when hunting in open areas. This may aid detection of movements of subterranean prey and protect the inner ears from wind-blown sand (Kingdon 1990). The auditory bullae are exceptionally well developed, to increase hearing abilities in areas with little vegetation cover. While the area of the external ear's pinna flange is similar to that of the domestic cat, the dimensions of the ear canal are about twice those of the domestic cat, as is the volume of the middle air space (Huang *et al.* 2002). There is structural and functional evidence that Sand Cats have hearing sensitivity considerably greater than domestic cats for frequencies below 2 kHz. The placement of the Sand Cat's pinna flanges towards the side of the head together with the relatively long ear canals could increase the interaural time differences and thereby improve their accuracy in pinpointing the location of sound resources. This would be of habitat-specific survival value for pinpointing prey animals and danger from predators. The Sand Cat is considered the northern representative of the Black-footed Cat *Felis nigripes*, whose body and head is of similar shape. Sight is acute to allow for orientation during crepuscular and nocturnal hunting. The sand-coloured pelage is typical camouflage for sand-dwelling (eremial) species.

Dens are in disused fox *Vulpes* spp. warrens, and also in rodent and Desert Hedgehog *Paraechinus aethiopicus* burrows enlarged by the Sand Cats (Schauenberg 1974, Le Berre 1990). Several Sand Cats used burrows interchangeably (Abbadi 1993). The *thinobia* subspecies lives in shallow burrows in the sand, constructed amongst the roots of saltbushes or *Caligonum* plants (Heptner & Sludskii 1972). Sand Cats may also use the same burrows excavated by the Fennec Fox *Vulpes zerda*, which is ecologically similar (Dragesco-Joffé 1993). The latter author measured a den 150 cm in length, going down in a straight line 60 cm deep with a tunnel diameter of 15 cm. Le Berre (1990) described the den as 15–20 cm in diameter, 150 cm long, descending at an angle of 30–45°, generally with a single entrance. Scats are covered with sand.

Foraging and Food Carnivorous, feeding mainly on small desert rodents, including spiny mice (*Acomys* spp.), jirds (*Meriones* spp.), gerbils (*Gerbillus* spp.) and jerboas (*Jaculus* spp. and *Allactaga tetradactyla*), but also young of Cape Hare *Lepus capensis*. It will also hunt small birds like Greater Hoopoe Lark *Alaemon alaudipes*, Desert Lark *Ammomanes deserti*, and consume reptiles such as Desert Monitor *Varanus griseus*, fringe-toed lizards *Acanthodactylus* spp., Sandfish

Scincus scincus, short-fingered gecko *Stenodactylus* spp., and horned and sand vipers of the genus *Cerastes*, and insects (De Smet 1988, Abbadi 1993, Dragesco-Joffé 1993). They are capable of rapid digging to extract the latter prey items (Schauenberg 1974). Sand Cats may cover kills with sand and return later to feed. Sand Cats are independent of drinking water as they are capable of satisfying their moisture requirements from their prey, but drink readily if it is available.

Sand Cats are nocturnal, although during the winter they may be active during the day (Heptner 1970, Dragesco-Joffé 1993). Ambient temperatures may range from -25°C to 58°C . Sand Cats in the Aravah Valley, Israel, were active throughout the night and a ♂ hunted and travelled on average 5.4 km during nine nights (Abbadi 1993).

Social and Reproductive Behaviour Sand Cats are solitary, although during the reproductive season pairs share the same burrows (Schauenberg 1974). One ♂ in the Aravah Valley of Israel had a home-range of 16 km² (Abbadi 1993); the ranges of ♂♂ overlap. Home-range size is likely to vary between regions according to resources available to the animals, and possibly competition from other sympatric carnivores such as Red Fox *Vulpes vulpes* and Wildcat, which consume similar prey.

Males utter a distinctive sharp call, like a small dog (Hemmer 1974c). In captivity both sexes called upon first introduction (Mellen 1989). When it is surprised by a human observer the animal's reflex is to crouch immediately behind the nearest tuft of vegetation, chin on the sand, completely motionless. Some individuals are surprisingly placid when encountered (Goodman & Helmy 1986, Dragesco-Joffé 1993), and indeed they tame easily.

Reproduction and Population Structure In the Sahara, mating takes place from Nov to Feb. One ♀ had an oestrous cycle of 46 days, and oestrus lasts five days (Sunkuist & Sunkuist 2002). Gestation ranges from 59 to 67 days (Mellen 1989) and, in Niger, the young are born from Jan to Apr (Dragesco-Joffé 1993). Litter-size ranges from 2–8, but the norm is three. Birth mass has been given as 39 g (Scheffel 1974) and 50 g (Dragesco-Joffé 1993); four stillborn captive kittens weighed a mean of 72 g (range 70–75 g; G. Olbricht pers. comm.) and four surviving kittens averaged 71 g (range 56–84 g; K. Clark pers. comm.). Young grow rapidly: their eyes open at 15 days, they take solid food at five weeks, and may become independent possibly as early as four months (Dragesco-Joffé 1993). Sexual maturity is at 9–14 months (Mellen 1989, Dragesco-Joffé 1993, A. Sliwa pers. obs.). Captives may live up to 14 years (Sausman 2000, Weigl 2005).

Predators, Parasites and Diseases Kittens are probably vulnerable to predation from Red Fox and Eurasian Eagle-owls *Bubo bubo*. Adults fall victim to Golden Jackals *Canis aureus*, especially when they hunt in pairs (Dragesco-Joffé 1993), and probably domestic dogs. Eight species of helminth worms, four species of fleas and one species of tick were found on several individuals of *F. m. thinobia* in the former USSR (Heptner & Sludskii 1972). Little is known about

disease, but captive cats are highly susceptible to respiratory tract infections (Sausman 1997).

Conservation IUCN Category: Near Threatened. CITES: Appendix II.

On the African continent, Sand Cats are recorded from several protected areas, including Tassili n' Ajjer and Ahaggar National Parks (Algeria), and Air and Tenere National Reserve (Niger). The main threats include the expansion of human settlement, and the introduction of feral and domestic dogs and cats (which serve both as direct competitors and predators, as well as vectors for disease transmission) (Nowell & Jackson 1996). They may be killed in traps laid out by inhabitants of oases targeting foxes and jackals or in retaliation for killing their chickens (De Smet 1988, Dragesco-Joffé 1993). Most Sand Cats presently in captivity are *harrisoni* or represent hybrids (*harrisoni* × *sheffeli*) (Auckland 2001).

Measurements

F. m. margarita

HB (♂♂): 420, 455 mm, n = 2

HB (♀♀): 390, 420 mm, n = 2

T (♂♂): 270, 270 mm, n = 2

T (♀♀): 235, 245 mm, n = 2

HF c.u. (♂♂): 110, 112 mm, n = 2

HF c.u. (♀♀): 100, 105 mm, n = 2

E (♂): 70 mm, n = 1

E (♀): 52 mm, n = 1

WT (♀): 2.06 kg, n = 1

Algeria, Niger (Schauenberg 1974, Rosevear 1974)

F. m. margarita/harrisoni

HB (♂): 479 mm, n = 1

HB (♀♀): 463 (432–484) mm, n = 4

T (♂): 249 mm, n = 1

T (♀♀): 223 (221–229) mm, n = 4

HF c.u. (♂): 111 mm, n = 1

HF c.u. (♀♀): 103 (101–106) mm, n = 4

E (♂): 61 mm, n = 1

E (♀♀): 57 (54–59) mm, n = 4

Sinai, Egypt (Saleh & Basuony 1998)

F. m. harrisoni

HB (♂♂): 454 (440–452) mm, n = 3

T (♂♂): 270 (250–300) mm, n = 3

HF c.u. (♂♂): 110 (110–110) mm, n = 3

E (♂♂): 63 (57–68) mm, n = 3

Oman, U.A.E. & Saudi Arabia (Harrison & Bates 1991)

Felis nigripes BLACK-FOOTED CAT

Fr. Chat à pieds noir; Ger. Schwarzfußkatze

Felis nigripes Burchell, 1824. Travels in the Interior of Southern Africa, 2: 592. Burchell (1824: 509) implied the country of the 'Bachapins', presumably in the capital, 'the town of Litákun (Letárkoon) ... 27° 6' 44 [S] ... 24° 39' 27 [E]' [South Africa].

Black-footed Cat *Felis nigripes*.

Taxonomy Two subspecies have been described: the nominate form and *F. n. thomasi* (Meester *et al.* 1986). Smithers (1971) doubted the validity of the characters separating the two, and the current author believes they represent a geographical cline from the smaller, paler northern *F. n. nigripes*, with more bleached ground colour and less distinctive striping, to the larger more vividly coloured *F. n. thomasi* with jet black bands and spots in the Eastern Cape of South Africa described by Shortridge (1931). Specimens with characteristics of both subspecies are found close to Kimberley, C South Africa, where these distinctions break down (A. Sliwa pers. obs.). *Felis nigripes* may be polymorphic in the centre of its range and only differentiates into distinct ecotypes at the outer limits of its range. Synonyms: *thomasi*. Chromosome number: $2n = 38$ (Kráľ & Zima 1980).

Description The smallest felid in Africa. Stocky with broad head and large, widely spaced, rounded ears. Nose very small and varies from red to black in colour. Eyes coloured dark yellow to light greenish. Margins of eyes, ears and mouth white. Two black cheek stripes run from the corner of eyes and from below eyes to edge of face. Four black bands on nape of neck, two running along the back and on to the shoulder. Body colour varies from cinnamon-buff to tawny or off-white, hairs being 25–30 mm long. The soft fur grows longer and denser during winter. Bold black or rust-tinged bands or rings on shoulders and high on legs, up to five on back legs and two on front, and distinct spots of the same colour on the body. Throat has two or three black to reddish stripes, either solid or broken up. Underparts pale buff or white. Tail short (<40% length of the body and head) and narrowly black-tipped; backs of ears are the same colour as body (Skinner & Chimimba 2005). Hair on undersides of front paws and back legs black. Front paw carries five digits, with thumb or dew-claw higher up on wrist, each carrying a sharp claw. Hind paw carries only four digits and claws are somewhat more blunt. Body measurements suggest differences between the sexes, but these may be difficult or impossible to determine when seen at a distance, especially in the field. There are three pairs of nipples.

Lateral view of skull of Black-footed Cat *Felis nigripes*.

Skull is high and rounded, with a flatter section on top from the level of the eye orbits to the middle of the braincase, where it slopes off abruptly to the supraoccipital crest. Rostrum is very short and broad. Zygomatic arches are 75% of total skull length at their widest. Auditory bullae are exceptionally large, total length being 25% of total skull length and width at the widest point, 18% (Skinner & Chimimba 2005). Outer, upper incisors only very slightly larger than the remainder; canines very sharp and flattened on their inner sides. Upper second premolars are tiny, the fourth sectorial. Molars tiny.

Geographic Variation

F. n. nigripes: Kalahari of Botswana, Namibia, and Northern Cape (South Africa). Lighter in colour, being tawny or, in some specimens, off-white; the bands running from the nape of the neck are often broken into short stripes or spots; spots brownish-black or tawny; generally has a more bleached or washed out appearance than the southern specimens.

F. n. thomasi. Karoo of C and S South Africa. Background colour cinnamon-buff; the bands from the neck are often strongly developed and, originating from the forehead, the two central ones extend unbroken to the base of the tail; three distinctive throat rings, which are black, narrowly edged with rufous; the hairs of the spots and bars are satiny-black.

Similar Species

Felis silvestris. Sympatric. Almost threefold larger, with much longer legs and tail, and no clear spotting; reddish to rusty-brown tint to the hair on back of ears. Unlikely to be confused with Black-footed Cat, but also has black under feet.

Distribution Endemic to southern Africa. Black-footed Cats range from NE Namibia and SW Botswana, southwards through the Northern Cape and the Free State (Lynch 1983) of South Africa and over much of the interior to parts of the west coast of Namaqualand (Stuart 1981). Rautenbach (1982) took animals in North West Province and further east in what is now Gauteng, and it is likely that they occur eastwards in Mpumalanga, although they have yet to be recorded

from Swaziland or Mozambique. In South Africa they occur furthest south-east at the junction of the Fish and Kat Rivers (L. Wingate pers. comm.). They have a marginal occurrence into KwaZulu-Natal (Rowe-Rowe 1992a). During the latter part of the twentieth century it is quite possible that they may have expanded eastward with increasing desertification, i.e. due to livestock overgrazing, as confirmed by a recent record close to Warmbaths in the Limpopo Province, South Africa (Power 2000) and even further north-east in Ezemvelo Reserve on the highveld (J. Power pers. comm.) and close to Marble Hall (Skinner & Chimimba 2005). So far there is no confirmed record for Lesotho (Lynch 1994) and although they are likely absent from much of this country, especially the Lesotho highlands, they may occur in the lowlands adjacent to the Free State, South Africa (N. Avenant pers. comm.). They occur marginally into NW Zimbabwe (Hwange N. P.; V. Wilson pers. comm.) and, although not listed by Crawford-Cabral (1989a), almost certainly in SE Angola, since there is a specimen right across the border from Namibia in Cuando Cubango province (M. Griffin pers. comm.).

Habitat A specialist of open, short grass areas with an abundance of small rodents and ground-roosting birds. Inhabits dry, open savanna, grasslands and Karoo semi-desert with sparse shrub and tree cover and a mean annual rainfall of between 100 and 500 mm at altitudes of 0–2000 m. The presence of epigeal termitaria and burrowing rodents like the Southern African Springhare *Pedetes capensis* may be beneficial to the species. Absent from the driest and sandiest parts of the Namib and Kalahari Deserts.

Abundance Due to their shy and secretive nature, Black-footed Cats are very difficult to census, but are generally considered uncommon to rare throughout their range. The only density estimates come from C South Africa, near Kimberley, where ten adult cats roamed an area of 60 km² (Sliwa 2004). In low-quality habitat densities are probably very much lower.

Adaptations Its small size allows the Black-footed Cat to hunt and rest in open arid areas. Near Kimberley, South Africa, it uses and takes refuge in dens excavated by the Southern African Springhare. One study recorded 98% of 184 resting places used as being in abandoned springhare burrows (A. Sliwa pers. obs.). In some areas it frequently uses hollowed out, unused termite mounds (termitaria), hence the common name ‘anthill-tiger’ (the Afrikaans ‘miershoop tier’). Its auditory bullae are exceptionally well developed, benefiting hearing abilities in areas with little vegetation cover. Hearing is its most important sense. Sight is acute to allow for orientation during crepuscular and nocturnal hunting. It is considered to be the southern representative of the Sand Cat, *Felis margarita*, which has a body and head of similar shape. Black-footed Cats are nocturnal and crepuscular.

Foraging and Food Opportunistic carnivore, taking everything it can overpower. There are possibly strong regional, and certainly seasonal and sex-specific, differences in diet. Males kill on average larger prey while the smaller and more agile ♀♀ are more successful in catching small birds. In summer ♀♀ feed mainly on rodents while in winter a higher proportion of larger (>100 g) birds and mammals are taken, while ♂♂ show less seasonal variation in proportions of prey classes taken (Sliwa 2006). In seven stomachs collected in Botswana by Smithers (1971), muroid rodents were found in four, spiders in three and sengi, reptile, insect and bird remains in one each. A total of 43 vertebrate prey species were identified at the Kimberley study site (Sliwa 1994a, b, 2006, Olbricht & Sliwa 1997, 2006). There were 14 species of mammals comprising 72% of the total prey mass consumed, 21 species of birds (26%) with eggs of various species taken as well, and eight species of amphibians and reptiles. A minimum of ten invertebrate species was eaten, some as small as the alates of harvester termites. The most frequently taken prey species was the Large-eared Mouse *Malacothrix typica*, and average prey size was 24.1 ± 47.4 g (S.D.; $n = 1725$ prey captures) (Sliwa 2006). The largest prey they have been recorded taking successfully is Cape Hare *Lepus capensis*. They have also been recorded attempting to take resting Springbok *Antidorcas marsupialis* lambs, attempts that always failed when the lamb stood up (Sliwa 1994a).

Three different hunting styles have been identified. With the ‘fast-hunt’ technique, the cat moves in swift bounds at a speed of 1–2 km/h trying to flush prey from cover using the element of surprise and relying mostly on eyesight. The ‘slow-hunt’ involves a slow stalk, winding snake-like between the grass tufts, trying not to move any grass stalks in the process. The cat moves its head from side to side, looking and listening carefully, its ears moving constantly, alert to any movements or sounds. The average speed for this style is 0.5–0.8 km/h. When locating prey the cat stalks to within 1–2 m and tries to determine its exact position, catching it in a final rush. About 70% of the night is spent hunting. The ‘sit-down’ hunt involves the cat positioning itself at a rodent den system and waiting with drawn up front paws for up to two hours. The final rush consists of one, or several, fast jumps out of the crouch. Using this technique the cat moves at 0.1–0.4 km/h. Birds are sometimes snatched from the air.

Small mammals are killed with a neck bite and swallowed head first (Sliwa 1994a). Larger *Tatera* gerbils’ heads are sometimes bitten off, the stomach and intestines removed, and then the rest of the body is swallowed whole. Sometimes even the contents of the intestines are squeezed out by pulling them through the cat’s incisor

teeth and then swallowed. Cape Hares were killed by either a neck bite or by biting the forehead, and then left to die while kicking, while a Black Bustard *Eupodotis afra* was grabbed by the wing or neck and never released. Feeding started on the head, followed by the neck and back and only later the breast muscles were eaten. Little plucking takes place, as is the case with smaller birds (such as larks). Only the wing tips with primaries are always chewed off, sometimes the tail feathers, but the rest of the bird is eaten complete. Snakes were tired out by fast blows to their heads and then killed with a swift neck bite, then swallowed whole from the head first. Eggs are taken gently between the cat's jaws then cracked open to lap up the contents (Sliwa 1994a).

Black-footed Cats hunt throughout the night in all weather conditions and temperatures, ranging from -10°C to 35°C , with only brief resting periods. Hunting success is very high with about one vertebrate prey animal caught every 50 minutes and 10–14 rodents or small birds caught in a night. This represents about 250–300 g of food, about 20% of the cat's body weight, but record intakes can reach 450 g per night (Sliwa 1994a, b). Excess food is cached, usually in shallow Aardvark *Orycteropus afer* diggings or inside weathered, hollow termite mounds. Cats scavenge readily (even from antelope carcasses) (Sliwa 1994a). They are independent of water, but will drink occasionally when it is available, although this has never been seen in healthy cats in the wild (A. Sliwa pers. obs.). Black-footed Cats are occasionally shadowed by Marsh Owls *Asio capensis*, which catch birds that are flushed (Sliwa 1994c). Travelling distance is between 4.4 and 15 km (mean = 8.4 ± 2.1 km) per night as measured by a vehicle's odometer (Sliwa *et al.* 2010). When moving during daylight hours, they are mobbed by birds such as larks and Southern Ant-eating Chats *Myrmecocichla formicivora*.

Social and Reproductive Behaviour Black-footed Cats are solitary, except for ♀♀ with dependent kittens, and during mating. Males have larger annual home-ranges (20.7 km^2 ; $n = 5$) than ♀♀ (10.0 km^2 , $n = 7$) (Sliwa 2004). Male ranges overlap those of 1–4 ♀♀. Intra-sexual overlap varies from 12.9% for three ♂♂ to 40.4% for five ♀♀. Home-range size is likely to vary between regions according to resources available to the individuals.

Black-footed Cats communicate through olfaction predominantly using urine spray-marking. The frequency of spray-marking by a ♀ fluctuates strongly during the year, depending on the stage of her reproductive cycle. Marking frequency is high before mating, low when pregnant and ceases completely when rearing kittens (Molteno *et al.* 1998). Male scent-marking is most intensive prior to mating, when there are as many as 585 sprays per night (Sliwa *et al.* 2010). Scent-rubbing, and possibly claw-raking, may have some signalling function. Faeces are rarely covered and they do not use middens. Vocal communication, a loud meowing sound, repeated up to ten times in quick succession, is heard especially from ♂♂ looking for ♀♀ during the mating season. Females occasionally call loudly in oestrus. Soft calls are used when ♂♂ court ♀♀ and when ♀♀ call their kittens (Sliwa *et al.* 2010). Females with kittens have special alarm calls. During these calls the ears are depressed.

During winter up to ten copulations occur during oestrus (Sliwa *et al.* 2010). The resident ♂ guards the ♀ and chases intruding ♂♂, and fights ensue between competing ♂♂. Kittens are born in hollow termitaria, or springhare burrows (Olbricht & Sliwa 1997).

The mother leaves her kittens for several hours at night from the day of birth and resumes her hunting schedule after four days. She returns infrequently during the night to suckle the young (Sliwa 1995). Kittens are moved frequently after the first week. The mother carries prey items to the den to feed them and teaches the kittens to hunt using live prey (A. Sliwa pers. obs.). Kittens are independent after 3–4 months, but remain within the range of their mother for extended periods (A. Sliwa pers. obs.).

Reproduction and Population Structure Gestation is 63–68 days (Leyhausen & Tonkin 1966, Schürer 1988), and up to two litters are born per year from spring to autumn, coinciding with the rains and greater availability of food (Olbricht & Sliwa 1997). Litter-size is 1–4, but usually two, and birth-weight is 60–90 g (mean 77 ± 11 g, $n = 10$). Eyes open at 3–10 days, deciduous teeth erupt at 14–21 days and kittens take solid food within 30 days (Olbricht & Sliwa 1995). They are weaned in two months, and permanent teeth erupt at 148–158 days. Sexual maturity (in captivity) is seven months for ♀♀ and nine months for ♂♂ (Olbricht & Sliwa 1997). Females have an oestrous cycle of ca. 12 days (J. Herrick pers. comm.) and oestrus lasts about 36 hours (Leyhausen & Tonkin 1966).

The adult sex ratio in the wild was 4 ♂♂ to 6 ♀♀ or 1 : 1.5 (Sliwa 2004). Birth sex ratio is 1.16 : 1 in captivity (Olbricht & Sliwa 1997). Captive cats may live up to 16 years (Sliwa & Schürer 2000), although data from the wild indicate two ♀♀ were at least four years old and a ♂ about six years old before they died (A. Sliwa pers. obs.). Mortality of kittens is not known from the wild, although one kitten of a litter of two died in a hailstorm (A. Sliwa pers. obs.).

Predators, Parasites and Diseases Young, or sick, cats and kittens are vulnerable to predation by Black-backed Jackals *Canis mesomelas* and Caracals *Caracal caracal*. However, recently there were two cases of intraguild killing by Caracals and Black-backed Jackals of two adult radio-marked cats (B. Wilson & J. Kamler pers. comm.), as well as regular harassment of adult Black-footed Cats by Black-backed Jackals (Olbricht & Sliwa 1997, A. Sliwa pers. obs.). The presence and abundance of Black-footed Cats may be adversely affected by the density of meso-carnivores like Black-backed Jackals and Caracals as well as close competitors like the Wildcat *Felis silvestris*, which may explain the absence or rarity of the species in otherwise suitable habitat and protected areas (Sliwa *et al.* 2010). Kittens and possibly adults have been recorded falling victim to large nocturnal raptors such as eagle-owls (*Bubo* spp.). Cats also fall victim to domestic dogs, which are used to chase or dig out jackals during problem-animal control operations (Sliwa 1995). Little is known about disease, but both wild (A. Sliwa pers. obs.) and captive cats have succumbed to kidney failure (secondary AA amyloidosis) (Olbricht & Sliwa 1997), indicated by high urea concentrations and creatinin values in the blood (Sliwa & Schürer 2002).

In a study of cats caught for radio-collaring, fleas (*Pulex* sp.) and ticks (*Ixodes*) were common ectoparasites (A. Lawrenz pers. comm., A. Sliwa pers. obs.). Horak *et al.* (2010) recorded *Haemaphysalis zumpti* from five animals in the Northern Cape. Adult stages of *Toxascaris leonina* and the eggs of *Ancylostoma tubaeforme* and *Sarcocystes bovis* were found in faeces. Blood parasites of the complex *Babesia* have been recorded in the red blood cells of various individuals (A. Lawrenz pers. comm., A. Sliwa pers. obs.).

Conservation IUCN Category: Vulnerable C2a(i). CITES: Appendix I.

Black-footed Cats are present in several protected areas across their range in southern Africa, including Etosha N. P. (Namibia), Makgadikgadi Pan (Botswana), Hwange N. P. (Zimbabwe), albeit in low densities, and several reserves in South Africa, including Addo Elephant N. P. and Willem Pretorius G. R. Although not yet confirmed from the South African side of the Kgalagadi Transfrontier Park, there is a record from the Botswana side (Smithers 1971).

Threats to Black-footed Cats include the expansion of human settlement and arable agriculture, use of poison, desertification, overgrazing and bush encroachment. They may be susceptible to poisons used during locus-control campaigns. Farmers setting 'coyote-getters' and poisoning of carcasses during control operations targeting other predators may also affect Black-footed Cats since they readily scavenge (Visser 1978, Stuart & Wilson 1988, Sliwa 1994a, b). Night calling and shooting aimed at Black-backed Jackals as well as the use of free-roaming hunting dogs for predator control also impacts Black-footed Cats in the C Karoo (C. Stuart & T. Stuart pers. comm.).

Felis silvestris WILDCAT

Fr. Chat ganté (Chat sauvage d'Afrique); Ger. Falbkatz

Felis silvestris Schreber, 1777. Die Säugethiere 2 (15): pl. 107 [1775]; text 3 (23): 397 [1777] Type locality not given.

Fixed by Haltenorth (1953) as 'vielleicht Nordfrankreich'. Listed by Pocock (1951) as Germany.

Wildcat *Felis silvestris*.

Taxonomy A problematic species from the taxonomic viewpoint, primarily due to differing views on the relationship of the African Wildcat to the European Wildcat, for many years considered two separate species, *Felis lybica* and *Felis silvestris*, respectively. Pocock (1951), in his massive synthesis of the species, held them to be

taxonomically distinct, while admitting a close relationship. On the other hand, Haltenorth (1953) considered *lybica* not as a separate species, but as a race of *silvestris*. Subsequent published classifications have either supported the idea of treating the two as conspecific (e.g. Ellerman *et al.* 1953, Haltenorth 1957, Corbet 1978, Wozencraft 1989a, 1993, 2005, Corbet & Hill 1991, Bronner *et al.* 2003) or assigned African representatives to *F. lybica* (Ellerman & Morrison-Scott 1951, Rosevear 1974, Smithers 1975, Ansell 1978, Swanepoel *et al.* 1980, Meester *et al.* 1986), usually not without reference to the domestic cat. A multivariate analysis of craniometric characters in the African Wildcat, European Wildcat and the domestic cat was unequivocal in considering *lybica* as conspecific with *silvestris* (Ragni & Randi 1986; but see Puzachenko 1996), and molecular studies have corroborated this viewpoint (Randi & Ragni 1991, Essop *et al.* 1997, Johnson & O'Brien 1997; but see Wiseman *et al.* 2000).

Nowell & Jackson (1996) recognized four groups of *F. silvestris*, following Weigel (1961) and Hemmer (1978): the forest cats (*silvestris* group) of Europe, the Caucasus and Asia Minor; the steppe cats (*ornata* group) of south and central Asia; the tawny cats (*lybica* group) of Africa and the Middle East; and the domestic cat (which several authors – most recently, Wozencraft [2005] – have treated as separate from the wildcat). In an attempt to investigate relationships among domestic cats, their indigenous wild progenitors, and

Lateral, palatal and dorsal views of skull of Wildcat *Felis silvestris*.

related species of the genus *Felis*, Driscoll *et al.* (2007) undertook a detailed genetic assessment and found that *F. s. silvestris* (European Wildcat), *F. s. lybica* (Near Eastern Wildcat), *F. s. ornata* (Central Asian Wildcat), *F. s. cafra* (Southern African Wildcat) and *F. s. bieti* (Chinese Desert Cat, usually considered a distinct species) each represents a distinctive subspecies of *Felis silvestris*. Wildcats from North Africa were attributable to *F. s. lybica*, but the boundaries between this form and the southern African *F. s. cafra* require further elucidation. The correct spelling of the specific name is *silvestris*, not *sylvestris*.

Synonyms (Africa only): *brockmani*, *bubastis*, *caligata*, *cafra*, *caffra*, *caligata*, *cristata*, *cyrenarum*, *foxi*, *griselda*, *guttata*, *haussa*, *hybrida*, *lowei*, *lybiensis*, *lybica*, *libyca*, *lynesi*, *maniculata* (Temminck, 1824 and Cretschmar, 1826), *mauritana*, *mellandi*, *namaquana*, *nandae*, *obscura*, *ocreata*, *pulchella*, *pyrrhus*, *rubida*, *rupellii*, *rusticana*, *sarda*, *savanicola*, *taitae*, *ugandae*, *vernayi*, *xanthella*. Chromosome number: $2n = 38$ (Jotterand 1971, Wurster-Hill & Gray 1973).

Description Similar in size and general appearance to domestic cat but tends to be heavier and longer in the leg. Can be difficult to distinguish the two in the field. A characteristic feature of the Wildcat is the reddish to rusty-brown tint to the hair on the backs of the subtriangularly pointed ears, which has been documented throughout its extensive African range (Rosevear 1974, Dragesco-Joffé 1993, Skinner & Chimimba 2005). Overall pelage colour ranges from dark grey, tawny-brown, reddish to sandy-yellow, marked with faint to fairly bold tabby spots, stripes and blotches. In general, populations in drier areas

are usually paler than those from higher rainfall regions. In the C Saharan mountains (Tassili) very dark cats have been observed (De Smet 1988). There is a wide zone of intergradation of colour in areas where different subspecies/colour forms come together. The length of the coat is extremely variable, and Pocock (1951) cites extremes of 22–44 mm on the flanks and 34–55 mm for the spinal crest. Tail tapers towards the tip, has variable dark ringing (normally two rings), is dark to black-tipped, and approximately 50–60% of the length of the head and body. Dark to black rings are often present on the legs, of variable intensity and distribution. The chin and throat are white and the underparts paler than the upper and often a fawn to reddish tinge. Undersurfaces of front and hindfeet very dark and most commonly black. The feet are entirely hairy below, except for the pads. Males are on average larger and heavier than ♀♀. Three pairs of nipples.

The skull is high, arched and comparatively lightly built, and with a short muzzle. The zygoma is rather thick and heavily constructed, thus providing substantial attachment for masseter muscles; there is also considerable space for powerful temporalis muscles. The supraoccipital crest is wide and strong. The postorbital processes do not join, although there may be a cartilagenous junction (Skinner & Chimimba 2005). Rosevear (1974) mentions aberrations in the typical dental formula: in some specimens, the upper second premolar is lacking on one or both sides having been shed and the alveolus closed over, an occurrence that apparently can be observed in process in some skulls.

Geographic Variation Differences in pelage colouration and patterning of museum skins has led to a proliferation of subspecies, most invalid. Pocock (1951) recognized 32 subspecies across the range of the species, of which 16 were African (one of them, *bubastis*, apparently extinct). Smithers (1975) recognized ten subspecies for the continent, and some 14 subspecies were listed in the *lybica* group by Nowell & Jackson (1996). The recognition of so many subspecies is doubtful, and based largely on minor differences in the pelage colouration and patterning of museum skins. For example, Dorst (1950) found a wide range of colour from red to grey in a series of 15 skins from a restricted collecting area just north of Lomé (Togo). The series also demonstrated the considerable range of size in a small population. Indeed, although there is variation in size within any Wildcat population there would appear to be few, if any, significant differences on the regional level. Rosevear (1974) gives head and body length ranges from 400 to 600 mm and weights of 4.5 to 5.5 kg for West Africa, with a possible low adult weight of 2.7 kg. Kingdon (1977) gives a head and body length range of 470–660 mm and weights of 3.0–6.5 kg for East Africa. In neither case is the number of specimens used to calculate these ranges given. The measurements for the former Cape Province (South Africa) presented in this account (see Measurements) also fall within this range.

A high degree of intergradation is evident between described forms, as evidenced in populations from southern Africa ascribed to the forms *cafra* and *griselda*. Differentiation is reportedly based on the darker colour of the former (from the better-watered southern and eastern areas) with the lighter sandier colour of the latter (from the drier western part of southern Africa). However, where their distributional ranges approach each other, it is almost impossible to assign the specimens to one subspecies or another. The issue is further complicated by the fact that this felid readily hybridizes with the domestic cat. The occurrence of hybridization seems to be uneven

across the species' range; in many areas, hybrids are common, and in some areas true Wildcats are at the best rare (as can be evidenced in some museum collections; C. Driscoll pers. comm.).

Similar Species

Felis nigripes. Sympatric in southern parts of range. About half the size and distinctly marked with dark to black spots and bars on body; tail and legs always distinctly ringed with dark brown or black; proportionally large head; backs of ears same as ground colour of body.

F. margarita. Sympatric in arid areas of North Africa. The smallest cat in Saharan belt restricted to sand desert; broad face with large, rounded ears; pelage more or less uniformly pale sandy-buff, with indistinct darker markings, dark edges to backs of ears; underparts white to off-white.

F. chaus. Restricted to vicinity of Nile R. and Mediterranean zone of Egypt. Larger (up to 12 kg), with overall sandy-brown pelage, without distinctive markings; reddish-brown hair on ear backs with short, black tufts of hair at tips.

Distribution Wildcats occur wholly, or in part, in nearly all African countries (Nowell & Jackson 1996). This extremely wide distributional range is accompanied by a very broad habitat tolerance, the species being apparently absent only from closed tropical forest. Although thinly distributed in true deserts such as the Sahara, Wildcats do occur, especially in association with hill and mountain country, such as the Hoggar. In North Africa they occur discontinuously from Morocco through Algeria, Tunisia, Libya and into Egypt. The species has an extensive distribution across the savannas of West Africa from Mauritania on the Atlantic seaboard, eastwards to the Horn of Africa, Sudan and Ethiopia; southwards, Wildcats are present in all East and southern African countries.

Extraliminally, Wildcats occur in the mountain ranges and on the desert fringes of the Arabian Peninsula, along the eastern border of

the Mediterranean Sea, then eastwards through Iran, Iraq, Pakistan, E Afghanistan and into W India. They also still occur throughout large parts of Europe, including N Scotland and the Mediterranean island of Sicily, and eastwards in Turkey, the Caucasus and from the Caspian Sea to S Mongolia and NW China (Sunquist & Sunquist 2002).

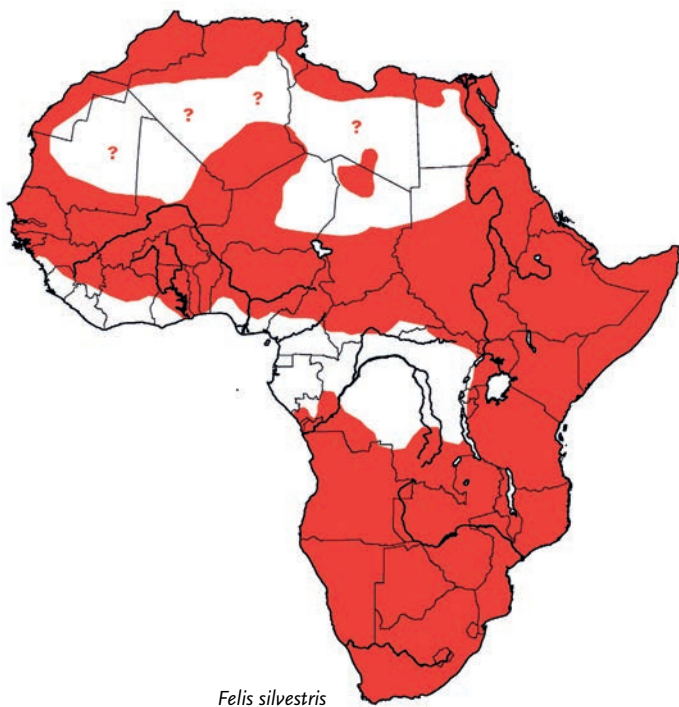

Habitat Very broad habitat tolerance, ranging from sea level to 2600 m in the Moroccan High Atlas (Cuzin 2003) and up to altitudes of more than 3800 m in the mountains of Kenya and Ethiopia (Young & Evans 1993, Yalden *et al.* 1996), but apparently absent from lowland tropical forest and open sand desert. Their distribution on a continental basis reportedly follows the 100 mm rainfall isohyet quite closely, below which they normally do not occur except where river courses serve as avenues into otherwise drier terrain, or where isolated mountains receive a slightly higher rainfall than the surrounding country (Skinner & Chimimba 2005).

Occurs around the fringes of the Sahara and in the massifs of Hoggar, Air and Tibesti in the central zone of that desert (De Smet 1988, Kowalski & Rzebik-Kowalska 1991). In the arid western and central areas of South Africa they are commonly associated with hill ranges and isolated rock outcroppings, penetrating the surrounding plains mainly along dry water-courses (C. Stuart & T. Stuart pers. obs.). Shows strong association with a variety of woodland types over much of its African range (Smithers 1971, Kingdon 1977). Throughout their range, adequate cover is required to rest up in during the day. Cover takes the form of rocky hillsides, reed-beds, riverine underbrush or stands of tall grass, holes or burrows excavated by other species, the exposed roots of trees, holes in termite mounds, and, in open semi-desert country such as the Kalahari, isolated stands of *Acacia* scrub or other bushes (Smithers 1971, Sliwa *et al.* 2010). The species is commonly found in and around cultivated areas and often in association with human settlements. In agriculturally developed areas, they use the shelter of standing crops such as maize and other high-standing grain crops.

Abundance Generally common despite human persecution, and high densities may be reached in suitable areas. In the broken hill country of the lower Orange R. basin of South Africa it is estimated that there is approximately one cat per 2 km² (C. Stuart & T. Stuart pers. obs.) while in East Africa density was estimated at 1/6–7 km² (Hendrichs 1972). Occurs at low densities in deserts such as the Nubian, Sahara and Namib. They are easily overlooked even when common, and difficult to trap.

Adaptations The thick and stoutly built zygoma provide substantial anchorage for the masseter muscles and are quite widely bowed to allow sufficient space for the well-developed temporalis muscles. The carnassial shear acts as an efficient cutting blade for slicing up prey. Cutting edges of the first lower molar lie at angles to each other and serve to hold prey firmly. Canines are somewhat flattened, sharp and quite long, adapted to delivering a killing bite by entering the neck vertebrae of their prey, prising them apart until the spinal chord is severed. The bullae are large and well developed, reflecting the keen sense of hearing (Skinner & Chimimba 2005). Terrestrial, but may climb trees.

Foraging and Food Detailed studies of diet have been made only in southern Africa (Smithers 1971, Stuart 1977, 1981, Rowe-

Felis silvestris

further than a few metres. The mother spent most of her time at the den and made short hunting trips. Initially, she hunted for herself and returned to the den to suckle the kittens. Later, the mother stayed away for longer periods, leaving the kittens in dense vegetation or in close proximity to trees. As the kittens approached five weeks of age she carried live prey back to them. The kittens played and practised their hunting skills on the stunned prey and either ate it or left the dead prey for the mother, who ate it or covered the remains. Males appeared to play no role in raising the young, although they visited ♀♀ with kittens. Kittens remained with the mother for 2–4 months after which they dispersed (Sliwa *et al.* 2010). Kittens from a previous litter have been observed playing with younger siblings (Herbst & Mills 2005).

Reproduction and Population Structure Breeding over much of its sub-Saharan range may occur throughout the year, but there are distinct peaks, and most births are recorded during warm summer months. In southern Africa births are mainly recorded from Sep to Mar (Skinner & Chimimba 2005) and in the Sahara and the Mediterranean coastal plain from Jan to Mar, the cooler months (De Smet 1988, Dragesco-Joffé 1993). In Kenya newborn young have been recorded in Mar (Allen & Lawrence 1937) and W Uganda in Dec (Kingdon 1977). One to five kittens (average 3; Smithers 1971, Sliwa *et al.* 2010) are born after a gestation period of 56–65 days (Green 1991).

Kittens are born blind, eyes opening at between 10 and 14 days, and accompany the mother hunting between the age of one and three months. Young mature rapidly and are independent at five months, allowing ♀♀ to have two litters in a year if conditions are optimal. Herbst & Mills (2005) recorded four litters in succession of three, two, two and three, although only a single kitten survived to five months in each case. Age at sexual maturity is 11 months. A wild-born Wildcat was about 19 years old when she died in captivity (Weigl 2005).

A captive-reared Wildcat crossed with a Serval *Leptailurus serval* producing several litters over a period of three years that reached maturity; in each case, the kittens were premature (Skinner & Chimimba 2005).

Predators, Parasites and Diseases Likely predators include larger carnivores, such as Lions *Panthera leo*, Leopards *P. pardus* and Spotted Hyaenas *Crocuta crocuta*, and raptors. On one occasion in the Kalahari, a male Ratel *Mellivora capensis* went into a Wildcat den, and a kitten escaped and was chased and caught above ground; another male Ratel was seen with a half-eaten adult although it was not seen how it was caught (C. Begg & K. Begg pers. comm.). In the same area, a Caracal *Caracal caracal* was seen with a half-eaten adult (M. Herbst pers. comm.). Sliwa *et al.* (2010) note that Giant Eagle Owl *Bubo lacteus* twice tried to grab a large adult male African Wildcat on the back, while the cat was crossing a clearing in the river bed. The owl was unable to lift the cat and the cat escaped into thick vegetation.

Parasites recorded from South Africa include fleas (*Ctenophalides connatus*, *Ctenocephalides felis*), ticks (*Haemaphysalis colesbergensis*, *H. zumpti*, *Ixodes rubicundus*, *I. pilosus*, *Rhipicephalus warburtoni*) and cestodes (*Diplopylidium acanthotetra*, *Joyeuxiella fuhrmanni*, *Mesocostoides lineatus*, *Taenia pisiformis* and *T. taeniaeformis*) (Horak *et al.* 1987, 2000, 2004, 2010). Johnson & Lester (1929) reported a specimen from West Africa infected with *Trypanosoma brucei*. Wildcats are susceptible to the same diseases as domestic cats, and feline panleukopenia may be a limiting factor in some areas (Mendelssohn 1989).

Conservation IUCN Category: Least Concern. CITES: Appendix II.

Found in most major, and many minor, conservation areas within its extensive range, the Wildcat is not threatened in the classical sense, although the threat of hybridization is real. Over wide areas of its range the Wildcat comes into contact with domestic and feral cats with which it readily interbreeds. Feral cats have been recorded far from human habitation, including arid areas such as the Kalahari, the Saharan Hoggar (De Smet 1988) and the deserts of Arabia. The main reported impacts of potential hybridization are from southern Africa (Stuart 1981, Wiseman *et al.* 2000, Skinner & Chimimba 2005) and North Africa (Hufnagl 1972, Kingdon 1977), although for southern Africa, at least, it is thought that the situation will not lead to species extinction in the foreseeable future (Wiseman *et al.* 2000). Especially in South Africa the Wildcat also is deliberately and incidentally targeted during ‘problem animal’ control exercises in sheep farming areas but this seems to have little impact on populations (C. Stuart & T. Stuart pers. obs.). Cunningham & Zondi (1991) report that there is a demand for the species in traditional medicine in KwaZulu–Natal (South Africa).

The Wildcat is frequently and accurately pictured in Egyptian temples and elsewhere, and it is generally held that cats were first domesticated in Ancient Egypt, at the latest by the twentieth to nineteenth centuries BC (Malek 1993). Ancient Egyptian ceremonies were held in Bubastis where cats were held sacred to the goddess of the hunt, of love and pleasure, Bast. Vast numbers of cats were mummified to please the goddess. An indication of this is of a shipment of mummified cats weighing 19 tons that was sent to England at the start of the twentieth century to be turned into fertilizer! However, several finds from Cyprus suggest that the origins of cat domestication were earlier, including the discovery of a cat buried in association with a human from the site of Shillourokambos, demonstrating that a close relationship had developed by 9500 years ago (Vigne *et al.* 2004). Recent genetic work suggests that cats were domesticated in the Near East (Driscoll *et al.* 2007). The Wildcat may have been attracted to human habitation by an abundance of small rodents that infested the grain stores of farmers and over time became habituated to man and his surroundings.

Family VIVERRIDAE

GENETS, LINSANGS, CIVETS

Viverridae Gray, 1821. London Med. Repos. 1821: 301.

| Genettinae | | |
|--------------------------------|---------------|--------|
| <i>Genetta</i> (14 species) | Genets | p. 214 |
| <i>Poiana</i> (2 species) | Linsangs | p. 251 |
| Viverrinae | | |
| <i>Civettictis</i> (1 species) | African Civet | p. 225 |

The Viverridae are distributed throughout the African and the Asiatic continents, with one species, the Common Genet *Genetta genetta*, also occurring in the Mediterranean ring. According to the classification presented by Wozencraft (2005), the family includes 15 extant genera and 35 species, although the systematics are debated. Its members occupy a large variety of habitats, from rainforest to woodland and more open milieus such as bushland, savanna and grassland. Some species may adapt to arid (*Genetta genetta*) and mountainous regions.

The Viverridae are small- to medium-sized carnivores, with head and body length ranging from 330 mm (*Poiana*) to 950 mm (*Civettictis*), and weight from 0.6 to 20 kg. Pelage is variable with striped, spotted or uniform patterns and the tail is either ringed or uniform. The body is long with short legs and a long tail, prehensile only in the genus *Arctictis*. The head is elongated with a pointed muzzle bearing long and mobile vibrissae. The feet and hands are variable, ranging from digitigrade to plantigrade paws with retractile, semi-retractile or non-retractile claws, and five toes in most of the genera. The sole of the feet bears wide and long metatarsal pads in the Paradoxurinae (palm civets), whereas the metatarsal pads are narrow in the Genettinae (genets), or very reduced (*Civettictis*) or absent (*Viverra*, *Viverricula*) in the Viverrinae (Veron 1999). Females have one to three pairs of nipples and males have a baculum. Most species have scent glands in the perineal region secreting a musky fluid. Sexual dimorphism is generally minimal.

The dental formula for the family is $I^{3/3}, C^{1/1}, P^{4/3-4}, M^{1-2/2} = 38-40$. The canines are elongated and straight, and the carnassials are developed in most species. The auditory bulla is characterized by a long, ovoid, well-inflated caudal entotympanic that forms a septum with the posterior wall of the ectotympanic (Hunt 1974). The viverrid bulla differs from those of most living feliforms in that the caudal entotympanic migrates anteriorly during ontogeny, which is similar to felids but with a caudal entotympanic more completely overgrowing the ectotympanic chamber of the bulla (Hunt 1987, Hunt & Tedford 1993).

Most of the viverrids are opportunistic omnivores with vertebrates (especially rodents) as the main source of prey. However, diet specializations occur in the Banded Palm Civet *Hemigalus derbyanus* (Hemigalinae) on invertebrates, in the palm civets on fruits, and in the semi-aquatic species (the Aquatic Genet *Genetta piscivora* and the Otter Civet *Cynogale bennettii*) on crustaceans and fishes. Their way of life ranges from wholly terrestrial (civets), semi-terrestrial (genets and Banded Palm Civets), to mostly arboreal (palm civets) or semi-aquatic (Otter Civet and Aquatic Genet). They are active at night and they usually spend the day in hollow trees, on large branches, in crevices or in burrows excavated by other animals (Nowak 1999).

African Civet *Civettictis civetta*.

They are generally solitary but occasionally associate in pairs. The viverrids have a variety of visual, olfactory and auditory means of communication (Wemmer 1977, Nowak 1999). Locus-specific defecation is characteristic of some species of Viverridae (*Genetta*, *Civettictis*) (Wemmer 1977, Roeder 1980).

The first viverrids are found in the early Oligocene (34–30 mya) in Europe and Asia. The first possible African viverrids are from the early Miocene (20–18 mya), but the identifications are based on dental material only and not on the auditory bulla, the ontogenetic growth pattern and final adult form of which has been considered diagnostic of the family (but see Gaubert & Veron 2003). The first modern auditory region relatable to the Viverridae is found in *Herpestides* (23–21 mya, Aquitanian of France; Hunt 1991). The first African viverrid with a modern-type auditory bulla is *Kanuites* from the Middle Miocene (Dehghani & Werdelin 2008), while the earliest members of the modern clades *Civettictis*, *Viverra* and *Genetta* appear in the Late Miocene or early Pliocene (Werdelin & Peigné 2010). Most striking is the presence in the Plio-Pleistocene African record of several viverrids, belonging to the genera *Viverra*, *Sahelictis* and *Pseudocivetta* that were of considerably greater body size than any living viverrid.

Using a fossil cross-validation method, Gaubert & Cordeiro-Estrela (2006) dated the emergence of Viverridae in the late Eocene–early Oligocene, with a split between the subfamilies Hemigalinae, Paradoxurinae and Viverrinae occurring in the late Oligocene–early Miocene; the terrestrial civets and the separation between (i) *Civettictis* and *Viverra*, and (ii) *Poiana* and *Genetta* were estimated to appear during the Middle Miocene. Ancestral area reconstructions recovered the Asian origin of Viverridae, Viverrinae, terrestrial civets and the clade (*Civettictis*, *Viverra*). Gaubert & Cordeiro-Estrela (2006) also identified two independent migration events from Asia to Africa, during the Middle Miocene (*Civettictis*) and between the

Myology of African Civet *Civettictis civetta*.

Skeleton of African Civet *Civettictis civetta*.

Tentative phylogenetic tree for African Viverridae (after Gaubert & Veron 2003).

late Oligocene and Middle Miocene (genets and oyans), most likely occurring via the Arabian microplate.

The Viverridae are included in the Feliformia as the sister-group of Hyaenidae (Herpestidae, Malagasy taxa) (Veron & Catzeflis 1993, Gaubert & Veron 2003, Yoder *et al.* 2003, Gaubert & Cordeiro-Estrela 2006, Eizirik *et al.* 2010). The monophyly of the Viverridae, as traditionally defined, has been questioned by many authors through both morphological and molecular studies (Hunt 1987, Wozencraft 1989b, Veron & Catzeflis 1993, Veron 1995, Flynn & Nedbal 1998, Veron & Heard 2000). As a consequence, *Nandinia* has been separated in the monotypic family Nandiniidae (Hunt 1987, Hunt & Tedford 1993, McKenna & Bell 1997, Flynn & Nedbal 1998; and see Nandiniidae profile), and the Malagasy taxa (*Cryptoprocta*, *Fossa*, *Eupleres* + Malagasy ‘mongooses’) represent the family Eupleridae, as sister-group to the Herpestidae (Yoder *et al.* 2003, Gaubert *et al.*

2005a; and see Wozencraft 2005). The Oriental Linsangs (*Prionodon*) also are now excluded from the Viverridae because they are sister-group of the Felidae (Gaubert & Veron 2003) and are included in the family Prionodontidae.

On the basis of molecular phylogenetic branching, morphological divergence and times of divergence, Gaubert & Cordeiro-Estrela (2006) proposed differentiating the remaining members of the Viverridae into two subfamilies: the Viverrinae *sensu stricto* (terrestrial civets of the genera *Civettictis*, *Viverra*, *Viverricula*) and the Genettinae (the genets and linsangs, represented by the genera *Genetta* and *Poiana*), with the clade (Viverrinae, Genettinae) forming the sister-group of the Asian clade (Hemigalinae, Paradoxurinae). Following this arrangement, two subfamilies comprising one and 16 species, respectively, occur in Africa: the Viverrinae, including *Civettictis* (monospecific), and the Genettinae, comprising *Genetta* (14 species, including former genus *Osbornictis*; after Gaubert *et al.* 2005b) and *Poiana* (two species). *Poiana* is strictly restricted to rainforest, while *Civettictis* and *Genetta* occur in both open and closed habitats. The African taxa are predominantly terrestrial, and most of them have an unspecialized post-cranial anatomy and dentition.

The Small Indian Civet *Viverricula indica*, which is widespread in South and South-East Asia, was introduced to Zanzibar and Pemba (Pakenham 1984) and to Mafia islands (see Kock & Stanley 2009), as well as Madagascar, the Comoros and Socotra. The species may have been introduced by Javanese traders as early as the twelfth century for extraction of the anal gland secretion that was used as perfume. Although clear tracks of this species were recorded in SE Zanzibar by Stuart & Stuart (1998c), it was not recorded at all during a camera-trapping survey (Goldman & Winther-Hansen 2003).

Philippe Gaubert & Géraldine Veron

Subfamily GENETTINAE – Genets, Linsangs

Genettinae Gray, 1864. Proc. Zool. Soc. Lond. 1864: 515.

Use of subfamily name follows Principle of Coordination of the International Commission on Zoological Nomenclature.

This subfamily was defined by Gaubert & Cordeiro-Estrela (2006), on the basis of both morphological grounds and molecular phylogenetics, to include the genera *Genetta* (type genus) and *Poiana*. The Genettinae have been subject to continuing taxonomic controversy over their numbers of species, especially within the genus *Genetta* (see Crawford-Cabral 1981a, Schlawe 1981, Wozencraft 1993, 2005, Gaubert *et al.* 2004b). In addition, *Poiana richardsonii* is either split into two distinct species, *P. richardsonii* and *P. leightoni*, or considered polytypic (see Beaufort 1965, Crawford-Cabral 1993b). Recent molecular phylogenetic analyses also include the Aquatic Genet (formerly *Osbornictis piscivora*) within *Genetta* (Gaubert & Veron 2003, Gaubert *et al.* 2004c), which is the approach followed here. The current treatment recognizes two genera in Africa: *Genetta* (14 species) are small to medium sized, with long tails, metatarsal pads well developed, and light dentition; and *Poiana* (two species), which are small sized, with very short fur, no distinct mid-dorsal line, and light dentition that lacks M2.

In general, the Genettinae are small and slender viverrids, with maxima of ca. 50 cm for head and body length and 3 kg in weight. The tail is longer and may equal the length of the body. Limbs are short compared with body length; members have short metacarpals and plantigrade forefeet, but long metatarsals with digitigrade hindfeet and slender but well-developed metatarsal pads (Taylor 1988). Semi-digitigrade feet (posterior feet digitigrade and anterior feet plantigrade) distinguish them from plantigrade Asiatic subfamilies (Paradoxurinae and Hemigalinae) and the digitigrade Viverrinae. The coat is spotted and the tail is clearly annulated with alternating bright and dark rings; the Aquatic Genet is an exception among Genettinae with its uniform brown-rufous coat colour. The facial mask has bright supra-orbital, and supra- and sub-labial pairs of spots. A well-marked and dark mid-dorsal line is usually present, often extending on the tail. The perineal glands are well developed (absent in *Poiana*), with a shallow interglandular pouch for musk storage in ♀♀.

The caudal entotympanic bone is weakly inflated, showing a globular shape; the paroccipital process covers the distal part of the bullae and is round and short without posterior prolongation. The dentition is weak

and sharp, with a reduced talonid in M1 and a well-marked lingual cusp in P3. The dentition of the Aquatic Genet is adapted to fish-eating.

General biology and adaptations are as in Viverridae (see family profile). The members of the group adapt to almost all terrestrial habitats throughout their range, with the exception of extremely arid regions and high-altitude mountain habitats. Foraging mainly occurs on the ground, although some species spend a large part of their time in trees and/or use them as refuges (*Poiana* and some genet species). *Genetta* and *Poiana* seem to have a more carnivorous diet than the omnivorous African Civet *Civettictis civetta* (subfamily Viverrinae), although many genet species are very opportunistic and adapt their diet according to seasonal and habitat variations. Births often coincide with the wet season (Jan–Mar), which might be correlated with the

peak of food abundance at this time. However, several species are reported to give birth throughout the year, and some species are known to have two litters in a year.

The earliest confirmed *Genetta* (an unnamed species) is early Pliocene (4 mya from Kanapoi in Kenya) (Werdelin & Manthi 2012). *Poiana* has no fossil records. Hunt (1996) suggested a possible phenomenon of *in situ* evolution in Africa following migrations from Eurasia, leading to diversification before taxa spread throughout the continent. The divergence between the genera *Genetta* and *Poiana* is estimated to have taken place at around 11 mya (Gaubert & Cordeiro-Estrela 2006).

Philippe Gaubert

GENUS *Genetta*

Genets

Genetta Cuvier, 1816. Le Règne animal 1: 156.

Servaline Genet *Genetta servalina* myology.

The origin of '*Genetta*' as a name is obscure. Borror (in Larivière & Calzada 2001) derived the name from the Greek prefix 'Gen', meaning 'bear' and the New Latin suffix 'etta', meaning 'small'. On the other hand, Lavauden (1926) suggested that '*genetta*' could be a derivative form of the French name for 'broom', i.e. 'genêt', the animal having been traditionally called 'broom cat' in German 'Geneth Katz', (nowadays rendered as 'Ginsterkatze' with similar affinities in the Portuguese name 'gato-ginete'; J. Crawford-Cabral, pers. comm.). Rosevear (1974) stated that it came from an Arabian word 'jarnait', which turned into 'genette' in Old French and was finally latinized into '*genetta*'. However, no evidence has been found about the use of such a word in Arab-speaking countries. *Genetta genetta* is 'namss' in Classic Arabic, 'el-zerdi' in Arabic dialects, and the Berber word is 'chbirdhou' (Algeria; W. Hamdine pers. comm.).

The taxonomy of the genus *Genetta* has been the focus of considerable debate. Inter-specific boundaries have sometimes been difficult to assess on the basis of morphological characters, especially due to the great variation in coat patterns and relatively low variability in skull characteristics. Wozencraft (1993) listed nine species grouped under three subgenera, namely: *G. johnstoni* (*Paragenetta*), *G. thierryi* and *G. abyssinica* (*Pseudogenetta*), *G. angolensis*, *G. genetta*, *G. maculata*, *G. servalina*, *G. tigrina* and *G. victoriae* (*Genetta*). However, other authors have recognized a larger number of species (e.g. Wenzel & Haltenorth 1972, Rosevear 1974, Crawford-Cabral 1981a, Schlawe 1981, Gaubert

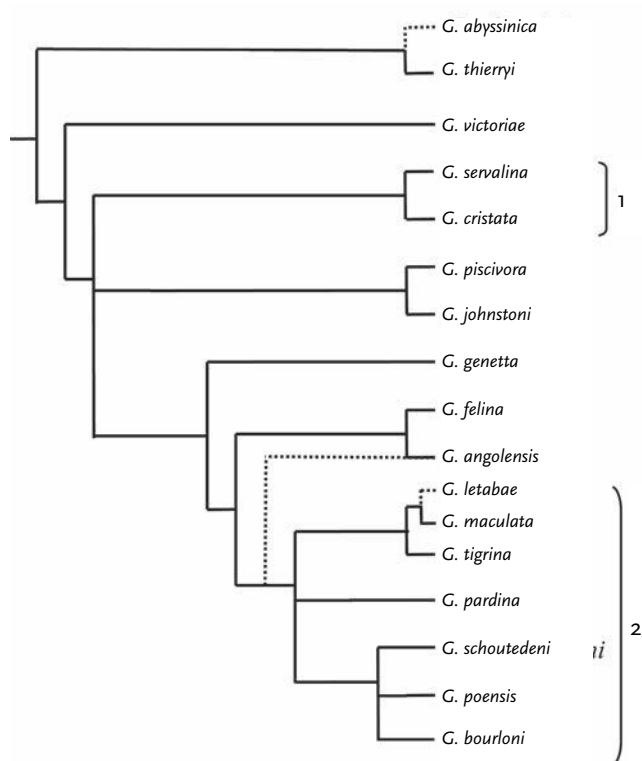

2003a, Gaubert *et al.* 2005b, Wozencraft 2005). This incongruence is primarily due to different opinions about the taxonomy of the morphologically similar large-spotted genets (see Table 7). Crawford-Cabral (1981a) suggested that populations of the large-spotted genets be divided into three geographical entities (which might correspond to valid species): *G. pardina*, west of the Volta R.; *G. 'rubiginosa'* (herein *G. maculata*, *sensu* Gaubert *et al.* 2003a, b), east of the Volta R.; and *G. tigrina*, along the coast of South Africa. This nomenclature only partly accords with Coetsee (1977), Kingdon (1977) and Wozencraft (1993). However, craniometrical analyses (Crawford-Cabral & Pacheco 1992), morphological observations (Schlawe 1981, Powell & Van Rompaey 1998, Gaubert 2003a, Gaubert *et al.* 2001, 2002b, 2005b), and analyses combining DNA and morphology (Gaubert *et al.* 2004b, 2005b), confirm the species status of these three taxa.

Although new methodologies have shed some light on species delimitations and phylogeny, the status of some taxa belonging to the large-spotted genet complex still need further clarification. For example, *G. maculata* appears to constitute a super-species comprising several valid species (Crawford-Cabral 1981a, Crawford-Cabral & Pacheco 1992, Crawford-Cabral & Fernandes 1999, 2001), such as the form *G. letabae* from south-east Africa (Gaubert *et al.* 2004a, 2005b). Further, recent investigations have also revealed that several forest 'forms' (*poensis*, *schoutedeni* and the newly described *bourloni*) constitute a distinct lineage of valid species (Gaubert 2003a, Gaubert *et al.* 2004b), although the status of the form *schoutedeni* requires further investigation and is not treated separately here.

Although the monophyly of the genus *Genetta* has been questioned by Gaubert *et al.* (2002b) on morphological grounds, DNA evidence (Gaubert & Veron 2003, Gaubert *et al.* 2004b, c) supports the inclusion of *G. johnstoni* with the other genets. Molecular analysis also supports the inclusion of the Aquatic Genet (formerly included in the genus *Osbornictis*) within the *Genetta* clade (Gaubert & Veron 2003, Gaubert *et al.* 2004c). The phylogenetic affinities of the Aquatic Genet have long been disputed. Gregory & Hellman (1939) considered the species to be a derived genet, and Wozencraft (1993) regarded it as the sister-taxon of *Genetta*. The new molecular evidence agrees with the morphological observations of Verheyen (1962) and Stains (1983), who felt that the

Table 7. Number of species and name usage in the main classifications of genus *Genetta* throughout ca. 150 years, with a focus on the taxonomy of the large-spotted genet complex.

| | Total number of species | Number of species and name usage within the large-spotted genet complex |
|------------------------------|---|---|
| Gray 1864 | 5 species – no subgenera | 2 species; <i>G. tigrina</i> ('South Africa; [...] Natal and East Africa; [...] Mozambique; [...] Abyssinia') and <i>G. pardina</i> ('Fernando Po; [...] Guinea; [...] Gaboon; [...] West Africa; [...] Interior of Senegal'; <i>G. poensis</i> and <i>G. genetoides</i> are junior synonyms)
Many erroneous synonymies with non Large-spotted Genets, including <i>G. maculata</i> with <i>G. vulgaris</i> (= <i>G. genetta</i>) |
| Matschie 1902 | 25 species – no subgenera | 10 species; <i>G. tigrina</i> (southern coast of South Africa), <i>G. rubiginosa</i> (Caconda, Angola; but erroneous attribution of type-locality), <i>G. schraderi</i> (Salomona, Eritrea), <i>G. zambesiana</i> (Mozambique), <i>G. gleimi</i> (Loanda, Angola), <i>G. stuhlmanni</i> (Uganda), <i>G. fieldiana</i> (Gabon), <i>G. dubia</i> (West Africa), <i>G. genetoides</i> (Ghana) and <i>G. pardina</i> (N Cameroon, Togo; <i>G. poensis</i> is a junior synonym) |
| Allen 1939 | 6 species – no subgenera | 2 species; <i>G. tigrina</i> (from Senegal to Ethiopia and Cape of Good Hope) and <i>G. maculata</i> (West Africa; <i>G. pardina</i> , <i>G. poensis</i> and <i>G. genetoides</i> are junior synonyms)
Many erroneous synonymies with non Large-spotted Genets |
| Coetzee 1977 | 7 species – subgenera
<i>Pseudogenetta</i> , <i>Paragenetta</i>
and <i>Genetta</i> | 1 species; <i>G. tigrina</i> 'sensu lato' (treated as a superspecies; includes <i>tigrina</i> – southern coast of South Africa – <i>rubiginosa</i> – from West Africa to Ethiopia and Natal – and <i>mossambica</i> – N Mozambique and S Tanzania) |
| Crawford-Cabral 1981a | 11 species, plus at least six taxa with debated status – subgenera <i>Pseudogenetta</i> , <i>Paragenetta</i> and <i>Genetta</i> | 5 species; <i>G. tigrina</i> (southern coast of South Africa; provisionally includes <i>G. methi</i> as a subspecies), <i>G. rubiginosa</i> ('from the Volta River eastwards to Abyssinia and southern Somalia and southwards to Zululand'), <i>Genetta</i> sp., aff. <i>G. rubiginosa</i> (S Sudan and SW Central African Republic; possibly corresponding to <i>G. aequatorialis</i> , but taxonomic status unclear), <i>G. pardina</i> (from Senegal to Volta River; <i>G. poensis</i> questionably considered a subspecies) |
| Schlawe 1981 | 10 species – no subgenera | 2 species; <i>G. tigrina</i> (southern coast of South Africa) and <i>G. maculata</i> (considered a polytypic species, with <i>G. pardina</i> , <i>G. poensis</i> and <i>G. genetoides</i> as junior synonyms and <i>G. rubiginosa</i> not valid) |
| Wozencraft 1993 | 9 species – subgenera
<i>Pseudogenetta</i> , <i>Paragenetta</i>
and <i>Genetta</i> | two species; <i>G. tigrina</i> (southern coast of Republic of South Africa) and <i>G. maculata</i> (all sub-Saharan Africa; <i>G. pardina</i> , <i>G. rubiginosa</i> , <i>G. poensis</i> and <i>G. genetoides</i> are junior synonyms) |
| Gaubert, Taylor & Veron 2005 | 17 species – no subgenera | 7 species; <i>G. tigrina</i> and <i>G. pardina</i> (same as Crawford-Cabral, 1981), <i>G. maculata</i> (from the Volta River to northern fringe of southern Africa), <i>G. letabae</i> (Mozambique to South Africa), <i>G. poensis</i> (West and central African rainforests), <i>G. burloni</i> (Upper Guinean Block) and possibly <i>G. schoutedeni</i> (central Africa; taxonomic status uncertain) |
| Wozencraft 2005 | 14 species – no subgenera | 5 species; <i>G. tigrina</i> , <i>G. pardina</i> , <i>G. poensis</i> , <i>G. burloni</i> and <i>G. maculata</i> (same as Gaubert <i>et al.</i> 2005a); <i>G. schoutedeni</i> considered <i>incertae sedis</i> |

morphological differences between *Osobornictis* and *Genetta* – in this case, skull and calcaneum characteristics – were too minor to justify generic status for the Aquatic Genet. Given the phylogenetic position of the Aquatic Genet within the genet phyletic tree, Gaubert (2004c) proposed that *Osobornictis* should be considered a junior synonym of *Genetta* (and see Wozencraft 2005).

According to the most recent phylogeny, *G. thierryi* is the most basal species and emerged ca. 8.5 mya (Gaubert & Veron 2003, Gaubert & Begg 2007). A paraphyletic group of rainforest species (*G. victoriae*, *G. johnstoni*, *G. piscivora* and *G. servalina*–*G. cristata*) then diverged during the late Miocene–early Pliocene (Gaubert & Begg 2007). Finally, *G. genetta* appears paraphyletic, since it is the sister-species of a clade grouping *G. angolensis*, *G. felina* (here included in *G. genetta*) and the large-spotted genets (*G. pardina*, *G. burloni*, *G. poensis*, *G. schoutedeni*, *G. maculata*, *G. tigrina*). The phylogenetic position of species in the aforementioned clade remains debated (Gaubert *et al.* 2004b, Gaubert

Tentative phylogenetic tree of the genets (adapted from Gaubert *et al.* 2004b, Gaubert & Begg 2007; *G. letabae*, *G. schoutedeni* and *G. felina* are not recognized here). Dashed branch leading to *G. abyssinica* and *G. letabae* represent assumptions based on morphological grounds (see Gaubert *et al.* 2002b, 2005c), whereas the alternative branching (plain and dashed lines) for *G. angolensis* reflects conflicting phylogenetic hypotheses (Gaubert *et al.* 2004b, Gaubert & Begg 2007). '1' represents the 'servaline genets' clade, and '2' includes the species of the 'large-spotted genet' complex.

& Begg 2007). Molecular studies have suggested that the large-spotted genets evolved from a recent common ancestor at the boundary of the late Pliocene–early Pleistocene (Gaubert & Begg 2007).

The genets are distributed throughout all sub-Saharan Africa, with one species (*Genetta genetta*) also occurring in the Arabian Peninsula, Maghreb and SW Europe (introduced in the latter region; see Morales 1994, Amigues 1999, Gaubert *et al.* 2009b, 2011). They occur in a wide range of habitats, from dense rainforest to open habitats, and may adapt to a diverse range of niches, including river streams (*G. piscivora*), arid regions (*G. genetta*), high-altitude plateaus and mountains (*G. abyssinica*, *G. maculata*, *G. servalina*) and human-disturbed environments (*G. genetta*, *G. maculata*, *G. pardina*). Remarkably, extant species of genets occupy most of the terrestrial habitats available in Africa. Although the genet morphotype has been conserved throughout the evolution of the genus, one important exception is the very derived, semi-aquatic Aquatic Genet (see below). Given the relatively recent time of divergence of this species (early–middle Pliocene; Gaubert & Begg 2007), accelerated morphological evolution seems likely. Johnston's Genet *Genetta johnstoni*, which arises at the same period and exhibits modified skull and dentition, supposedly adapted to insectivory (Lamotte & Tranier 1983), may also manifest accelerated evolution of morphological traits.

Genets are small- to medium-sized viverrids (HB roughly ranges from 420 to 570 mm) with a relatively long tail (ca. 70–100 % of HB). Coat pattern is distinctly spotted, with a dark mid-dorsal line, except in the Aquatic Genet, which has a uniform brown-rufous coat pattern. Coat patterns have been reported to play a role in individual recognition within genets (Wemmer 1977, Roeder 1984a). Drastic change in the phenotype of the Aquatic Genet, possibly adapted to hiding while fishing along stream borders, might involve modifications in recognition behaviour. Genet facial masks are characteristic, with upper labial, sub- and upper-orbital bright spots contrasting with the dark face. Limbs have semi-digitigrade paws, metatarsal pads are slender but well developed, and claws are felid-like but semi-retractile (Veron 1999, Gaubert *et al.* 2001). Skull characteristics are similar to those of *Poiana*. However, the general shape of the skull is more elongated and the interorbital constriction much more marked in *Genetta*. As additional diagnostic characters, the lingual cusp in P^3 is present (except in *G. tigrina* and *G. maculata* where it is reduced, and *G. piscivora* where it is absent), and the dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$, with a light and sharp dentition. Two species exhibit divergent dental characteristics adapted to particular feeding habits: *G. piscivora*, characterized by sharp-edged teeth adapted to piscivory, and *G. johnstoni*, which bears a weak dentition (especially jugal teeth) with proodontal inferior incisors that suggest an insectivorous diet.

Genets are opportunistic mesopredators mainly foraging on the ground, although the Aquatic Genet represents an exceptional case of specialization in hunting (Kingdon 1997). Although species differ markedly in how terrestrial they are, they all use trees as refuges and/or resting places. They also use latrines, possibly for territorial and communicational purposes. Latrines found in closed habitats do not form little hummocks unlike those from open places, but are, instead, more dispersed. Traces of scent-marking activity are found near latrines. Scent-marking relies on glandular secretions from perineal and anal glands presumably to communicate information pertaining to sexual, territorial, or social behaviour. Scent is deposited either through normal quadrupedal squatting, or the animal stands, with its head down and resting on its forefeet, in a reversed upright position. When fighting or stressed, genets may emit a musky scent from anal glands (Wemmer 1977). The number of nipples varies from one to two pairs and this difference may be correlated with habitats inasmuch as the rainforest-dwelling species *G. johnstoni*, *G. victoriae* and *G. servalina* bear only one pair of nipples. Fertile hybridizations have been recorded from captivity (between *G. genetta* and *G. pardina* or *G. maculata*; Gray 1972) and have been detected in the wild between (1) *G. maculata* and *G. tigrina* and (2) *G. tigrina* and *G. genetta* in South Africa (Gaubert *et al.* 2005b).

Fourteen species, including the Aquatic Genet *G. piscivora*, are described in this work, which takes account of several authors' opinions (Crawford-Cabral 1981a, Schlawe 1981, Heard & Van Rompaey 1990, Crawford-Cabral & Pacheco 1992, Wozencraft 1993, 2005, Gaubert 2003a, Gaubert *et al.* 2004a, b, 2005b, Gaubert & Begg 2007). Although the genets, as defined here, include a species characterized by high morphological divergence and niche adaptation (the Aquatic Genet), the genus *Genetta* is maintained without the traditional subgenera because: (1) some phylogenetic relationships within the genus are not well supported enough to accurately discriminate between the lineages; (2) the geological period during which major speciation events are thought to have occurred is relatively recent (Pliocene); and (3) a common genet morphotype (except in *G. piscivora*) has been generally conserved, including plesiomorphic lineages. Species can be distinguished by spot pattern, mid-dorsal line/crest, tail annulation, and colouration patterns on limbs. Gaubert *et al.* (2008) produced an interactive, web-based identification key for genets (and linsangs) that provides an updated diagnostic tool on the taxonomy of the genus *Genetta*.

Philippe Gaubert

Genetta abyssinica ETHIOPIAN GENET

Fr. Genette d'Abyssinie; Ger. Streifengenette.

Genetta abyssinica (Rüppell, 1836). Neue Wirbelt. Fauna Abyssin. Gehörig. Säugeth. 1: 33, pl. 11. 'In Abyssinien, wo es sehr häufig vorkommt, führt es beiden Landeseingebornen zu Gondar'; restricted to Gondar (12° 36' N, 37° 28' E), Ethiopia, by Schlawe (1981).

Taxonomy Described from a complete adult male specimen. Traditionally included in subgenus *Pseudogenetta* (see Crawford-Cabral 1980–81) with the similar Hausa Genet *G. thierryi* (but see genus profile). The sister-species relationship with the Hausa Genet was confirmed by morphological cladistic analysis (Gaubert 2002b).

Considered a primitive genet by Crawford-Cabral (1980–81) on the basis of its shared characters with the African Linsangs (*Poiana* spp.), such as having the central depression of the forefoot hairless and a smaller and less specialized skull. Synonyms: none. Chromosome number: not known.

Ethiopian Genet *Genetta abyssinica*.

Description One of the two smallest genet species (the other being the Hausa Genet). Sexes similar in colour and size. Dark facial mask well marked, contrasted by a pair of supra- and sub-ocular white spots. Forehead grey, with a thin dark vertical line on the muzzle. Ear slightly rounded. Hair short and straight. Pelage soft, with dorsal spots merged in two or three dark lines on each side of the mid-dorsal line. Ground colouration pale creamy-grey (lowland) to dirty yellow (highland plateaux of Ethiopia), with a widening of the dorsal spots and dark rings of the tail in forms from high altitudes (Diaz Behrens & Van Rompaey 2002); the general darkening of pelage in specimens from high plateaux is likely to be associated with higher annual rainfalls (Diaz Behrens & Van Rompaey 2002). Throat, chest and ventral pelage pale grey. Nuchal stripes well defined. Spots of both sides of the neck coalesced with spots of the shoulder, forming a pair of large dark stripes. Mid-dorsal line not contrasting with the rest of the dorsal markings, often starting from the neck between the pair of nuchal stripes and split longitudinally by a line of pale hairs (at least from the shoulder). Spots of the flank, thigh and shoulder rounded and not following a line. Hindlimbs and forelimbs pale grey with dark spots. Line bordering the outer side of the forefoot pads and inner side of the hindfoot pads brown. Forefeet and hindfeet unspotted and pale grey. Central depression of the forefoot hairless. Tail narrow and annulated with seven to nine pale rings to the tip (the tail tuft being black). As in the Hausa Genet, pale rings broken by dark hairs along the mid-dorsal line axis. The skull is reduced in size. The caudal entotympanic bone is rounded and weakly inflated in comparison with the ectotympanic bone (bullae).

Geographic Variation None recorded.

Similar Species

Genetta genetta. Sympatric. Taller; presence of dorsal crest; thick tail with long hairs, tuft whitish.

G. maculata. Sympatric. Taller; large dorsal spots squared or rounded and not coalesced; tip of the tail with a large dark ring.

Distribution Endemic to Africa. The collection-based work of Schlawe (1980) and the review by Yalden *et al.* (1996) restricted the species' range to high plateaux and dry lowlands of Ethiopia, N Somalia, Eritrea, Djibouti and SE Sudan. Records are scarce and patchily distributed: Annesley Bay (Zula–Massawa region, Eritrea), Bulhar (W

Genetta abyssinica

of Berbera, Somalia), Senaar (Sudan), Gondar, Awash and Simien Mountains National Parks, L. Metahara, Mt Albasso (Arsi province), Galu and Addis Ababa (Ethiopia) and Djibouti. The presence of the species was recently confirmed in the Abune Yosef massif, Ethiopia (Diaz Behrens & Van Rompaey 2002). A road-killed specimen from near Awash N. P. deposited in the Zoological Natural History Museum in Addis Ababa University, Ethiopia, initially identified as being this species (Balakrishnan & Bekele 2008) was subsequently shown to be a Common Genet *Genetta genetta* (Gaubert *et al.* 2009a). Künzel *et al.* (2000) stated that the existence of this genet in Djibouti was uncertain, although A. Laurent (pers. comm.) considered the species still present in the country.

Habitat Although the habitat requirements of this species are not well known, it appears to have a wide altitudinal and ecological range, from coastal plains and open dry lowlands to high plateaux (Yalden *et al.* 1996), with altitudes sometimes exceeding 3000 m (e.g. Mt Albasso: 3400 m). Diaz Behrens & Van Rompaey (2002) found evidence for, and directly observed, living specimens in montane heather moorlands and afroalpine grasslands up to 3750 m in the Abune Yosef massif, in the northern Highlands of Ethiopia. This is the first record of Ethiopian Genets in a forested habitat, namely the montane dry forest of Abi Jakula (dominant species include Tree Heath *Erica arborea*, Curry Bush *Hypericum revolutum* and Abyssinian Rose *Rosa abyssinica*). According to Haltenorth & Diller (1980), the Ethiopian Genet is sometimes found near urban areas, but this statement seems at odds with the fact that they are so poorly known.

Abundance The current population status of this species is unknown, but they are evidently rare. Rüppell (1835) found them to be rarer than the Common Genet *Genetta genetta* in Ethiopia, and Yalden *et al.* (1996) considered them 'remarkably uncommon'. Currently known from only a few museum specimens (Diaz Behrens & Van Rompaey [2002] listed 16 specimens).

Adaptations Mainly nocturnal, although Diaz Behrens & Van Rompaey (2002) reported diurnal activity, which they suggested was a response to the activity patterns of rodent prey at high altitudes.

Foraging and Food Little is known, but a comparative examination of scats collected from afroalpine latrines and savanna woodlands has suggested mainly carnivorous tendencies, with rodents (e.g. species of the genera *Arvicanthis* and *Lophuromys*), complemented by birds (passerines), insects (Coleoptera) and seeds. At higher altitudes, with a more impoverished fauna and flora, the relative percentage of insects varied, suggesting opportunistic consumption; likewise, fruits are rare but seeds resembling domestic lentils imply possible foraging in cultivated areas. On the other hand, in low-altitude savanna-woodland areas, scats contained more fruits and insect remains (Diaz Behrens & Van Rompaey 2002).

Social and Reproductive Behaviour Limited observations in the wild suggest a solitary life-style. Latrines are used as in genets inhabiting open habitats. Diaz Behrens & Van Rompaey (2002) indicated that each latrine contained about 30 droppings and was found on rocky edges and in rocky holes. Gotch (1979) suggested that it could be domesticated and was perhaps the original 'cat' of ancient Egypt, but probably confused the Ethiopian Genet with the Common Genet.

Reproduction and Population Structure Unknown, but likely to have similar, small litters as in other genet species. One specimen in captivity apparently lived to nearly 14 years of age (Weigl 2005), though the identity of this specimen is not confirmed.

Predators, Parasites and Diseases Nothing known. Probably susceptible to predation from the same predators as the Common Genet and Large-spotted Genet *G. maculata*. Stiles & Baker (1935) reported tapeworms *Dipylidium gervaisi* in intestines and *Hymenolepis*

liguloides as ectoparasites of the species.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Yalden *et al.* (1996) mentioned habitat loss due to felling and cultivation in *Acacia* woodland and thornbush as a threat, together with pressures of herds of domestic stock in both arid lowlands and high plateaux. A recent niche modelling-based study suggested that the suitable range of the Abyssinian Genet was now highly fragmented by large mosaics of croplands (Papes & Gaubert 2007). In Ethiopia, only three National Parks are likely to support populations of the Ethiopian Genet: Yangudi-Rassa, Awash and Simien Mountains. To date only three Ethiopian Genets have ever been kept in captivity (at Frankfurt zoo from 1949 to 1958, and mentioned in Schreiber *et al.* 1989). After DNA analysis (cytochrome *b*) a specimen previously listed in ISIS and housed at the Miller Park Zoo (USA) proved to belong to the Pardine Genet *G. pardina*.

Measurements

Genetta abyssinica

HB: 408, 430 mm, n = 2

T: 380, 403 mm, n = 2

GLS: 81.3 (76.6–89.6), n = 6

GWS: 41.5 (38.8–46.4), n = 6

Body measurements: Djibouti and Ethiopia (museum specimens: BMNH and MNHN)

Skull measurements: museum specimens (BMNH, FMNH, NHMB, NMNH, SMF)

Haltenorth & Diller (1980) give weight as 1.3–2.0 kg

Genetta angolensis MIOMBO GENET

Fr. Genette d'Angola; Ger. Bürstengenette

Genetta angolensis Bocage, 1882. J. Sci. Math. Phys. Nat. Lisboa, ser. 1, 9 (33): 29. Caconda, Angola (13°47' S; 15°08' E).

Miombo Genet *Genetta angolensis*.

Taxonomy The type material of the Miombo Genet, consisting of three adult specimens (one mounted and two stuffed skins) kept in the Lisbon Museum (Museu Bocage), was burned in a fire in

1978. Photographs of these specimens are all that remain. The type locality 'Calucimba' as given by some previous authors is actually the native name of this species, and indeed of all genets, in Angola. The specimens were sent from Caconda to Bocage. The collector, Mr Anchieta, had his headquarters in this town, and most probably all zoological specimens he sent from there were collected on the surroundings of Caconda or brought by natives from nearby.

Synonyms: *hintoni*, *mossambica* (but see below). Of the two synonyms, *hintoni* was once regarded as a subspecies of the Common Genet *Genetta genetta* (e.g. Ellerman *et al.* 1953), but is now considered conspecific with *angolensis*. The second supposed synonym, *mossambica*, has been a source of taxonomic confusion. Originally described by Matschie in 1902, Moreau *et al.* (1946) fixed the type locality as 'Mossimboa (11°38' S, P. E. A)' (i.e. Portuguese East Africa, or Northern Mozambique). Later, Roberts (1914, 1951) identified three specimens in the Transvaal Museum collected in

Boror (Mozambique, between Lingungu and Lualua rivers in Zambezia Province) as *G. mossambica*. Crawford-Cabral (1980–81) considered *mossambica* a possible subspecies of *G. angolensis*, in spite of some differences in the skull, a treatment followed by others (e.g. Schlawe 1980, 1981, Wozencraft 1993). However, a study by Crawford-Cabral & Pacheco (1992) found that the specimens from Boror, identified by Roberts as *mossambica*, fell within the phenotypic profile of the large-spotted genet complex, and may constitute a separate species (Crawford-Cabral & Fernandes 2001). Consequently, the specimens from Boror have not been discussed in the present profile, but are provisionally allocated to the large-spotted genet complex (see section on Taxonomy under Large-spotted Genet *G. maculata*). The form described as *gleimi* is here also ascribed to the Large-spotted Genet. Finally, doubts about the validity of the name *mossambica* itself remain because the type specimen of the latter has since been identified as a potential hybrid between Large-spotted Genet and Miombo Genet (Gaubert *et al.* 2005b, c). The phylogenetic position of *G. angolensis* within *Genetta* and the monophyly of the species remain uncertain (Gaubert *et al.* 2004b, Gaubert & Begg 2007). Chromosome number: not known.

Description The Miombo Genet is medium sized, about the size of the Common Genet, but appearing bulkier, with a shorter, bushy tail (ca. 80–90% of HB) and relatively long feet (ca. 19% of HB). Hair very long, at least 30 mm on middle of tail, more than 40 mm on mid-dorsal line and up to 70 mm on rump. There is a great deal of individual variation in ground-colour and markings (stripes and spots), with ground-colour varying from light ochraceous to brownish or greyish tones or even to black. Melanic and half-melanic individuals are rather common (about 20% of the specimens in some museum series). Underparts creamy white to dirty white in non-melanic specimens. Stripes and spots vary from different hues of brown to black, except that the mid-dorsal stripe is always intensely black.

Muzzle black, chest and throat blackish, sub-ocular patch whitish. In parallel, two nuchal stripes run from the nape to the shoulders where they diverge and enlarge towards the elbows (although not so conspicuously marked as in other species). Below them, a pair of thinner stripes and small spots scatter on the shoulders and sides of the neck. Between the nuchal stripes another pair of thinner, parallel stripes runs down the neck and extends along about one-fourth of the mid-dorsal line, where the stripes vanish or break up into a first row of flank spots. A long-haired mid-dorsal stripe extends only over the terminal three-quarters of the mid-dorsum. Usually it is flanked on each side by four rows of oblong to squared spots, elliptically disposed, and, below, by a few small scattered spots. Tail black-tipped, with seven to nine black rings narrower than the intervening white spaces but becoming wider from the middle of the tail to the tip; the intervening white spaces graduate to a brownish tinge on the dorsal mid-line. Forelegs black, with pure white hairs on the upper surface of the extremities (metacarpals) and along a stripe to half-way up the legs. Hindlegs black, with only the upper surface of the extremities (metatarsals) marked with pure white, the black colouration extending to the thighs as a pair of stockings. Two pairs of nipples. In the skull, the caudal entotympanic bone is not ventrally inflated.

Geographic Variation Any geographic variation in this species seems to be obscured by the large amount of individual variation.

Palatal and dorsal views of skull of Miombo Genet *Genetta angolensis*.

Animals from the Angolan Plateau (C Angola) could constitute a nominate form attributable to *angolensis*. Likewise, animals from Shaba (SE DR Congo) and W Zambia (north of the Zambezi R.) could correspond with *hintoni*. However, specimens from Zambia and SE DR Congo do not seem to differ from those from Angola. The population in S and E Tanzania and the extreme north of Mozambique, between the coast and L. Nyasa, could be tentatively regarded as a separate subspecies. However, because of doubts about the validity over the name *mossambica* (Gaubert *et al.* 2005b, c; and see Taxonomy), no name is available for this eastern population.

Similar Species

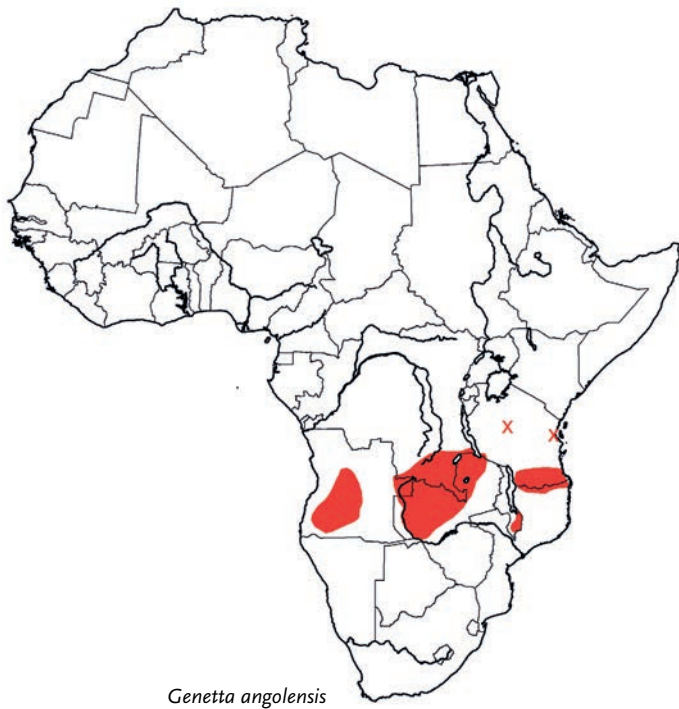

Genetta maculata. Sympatric. Hair much shorter, not exceeding 40 mm on the mid-dorsal stripe (even in *soror* Schwarz, a form characterized by relatively long and soft fur).

G. genetta. Only sympatric over parts of the range; paler ground-colour; smaller spots; longer, white-tipped tail, with a larger number of caudal rings.

Distribution Endemic to Africa. The Miombo Genet is recorded from Angola, DR Congo, N Mozambique, Tanzania and Zambia, and appears to have a disjunct range with two large gaps in its distribution, one in E Angola, the other between the Muchinga Escarpment (Zambia) and L. Malawi. The northernmost record is a skin in the Berlin Museum from 'Turu' (Singida area, C Tanzania) mentioned by Schlawe (1980). This identification was regarded as questionable by Schlawe himself, but has since been confirmed by P. Gaubert (pers. comm.). The species has also been recorded from Mandera, in NE Tanzania (Schlawe 1980), and from the Shire Highlands and Namwara, in S Malawi (Ansell 1985, Ansell & Dowsett 1988). Wozencraft (2005) lists Zimbabwe as a range country, but this cannot be substantiated.

Habitat As the common name suggests, a species of open miombo (*Brachystegia*) woodland interspersed with savannas, mainly from areas with ferrallitic soils and relatively high, but seasonal rainfall (more than 1000 mm per annum).

Abundance Although poorly known, the species was reported to be locally common on an open plain in the Luando Strict N.

R. (C Angola, north of Cuanza R.), characterized by *Cryptosepalum curtisiorum* and termitaria.

Adaptations The dentition, specifically the incisors, appears to show an adaptation for grasping, which suggests a high incidence of arthropods in the diet (Crawford-Cabral 1981b).

Foraging and Food Terrestrial and nocturnal, seen foraging on the ground at night. Stomach contents of a specimen from the Kafue N. P., Zambia, contained remains of grasshoppers, traces of chitinous insect remains, unidentified fruit and some grass (Ansell 1969), which lends support to the suggestion above that arthropods may be a favoured prey.

Social and Reproductive Behaviour There is a paucity of information relating to all aspects of the Miombo Genet's ecology and behaviour. Based on nocturnal observations of these animals, Crawford-Cabral (1967) suggested that they remain hidden during the day in old Aardvark *Orycteropus afer* burrows.

Reproduction and Population Structure No breeding records are currently available.

Predators, Parasites and Diseases Large carnivores and eagle owls are likely predators, and they are probably susceptible to many carnivore parasites and diseases but, currently, none has been specifically identified.

Conservation IUCN Category: Least Concern. CITES: Not listed.

At least as far as Angola is concerned, there are no apparent reasons why this species should be considered threatened. Its habitat has only

seen minor change and there is little hunting. None the less, there remains a need for further study of this poorly known species.

Genetta burloni BOURLON'S GENET

Fr. Genette de Bourlon; Ger. Bourlon-Genette

Genetta burloni Gaubert, 2003. Mammalia 67 (1): 95. 'GUINEA, Sérédou, Cercle de Macenta'.Bourlon's Genet *Genetta burloni*.*Genetta burloni*

Taxonomy Named in honour of Philippe Bourlon, keeper at the Vincennes Zoo, Paris, who lost his life in the course of his duties. The species belongs to what was commonly referred to as the large-spotted genet 'forest forms' of West Africa (with *poensis*, and the forms *schoutedeni* and *genettoides*; see Pocock 1908, Rosevear 1974, Crawford-Cabral 1980–81, Schlawe 1981 and Gaubert 2003a). Crawford-Cabral (1980–81), on the basis of a craniometrical study, isolated two specimens that he considered as potentially representing a species distinct from both Pardine Genet *G. pardina* and King Genet *G. poensis*. He suggested as a possible name *dubia*, but waited for further comparisons with type material. Gaubert (2003a), in a taxonomic revision of the forest forms based on discrete morphological characters, concluded that specimens attributable to this new species – including the material from Crawford-Cabral (1980–81) – had no available name, and thus erected *burloni*. Described from a complete specimen (skin and skull), its species status was further confirmed by DNA-based phylogenetic investigation (Gaubert *et al.* 2004b), and accepted by Wozencraft (2005). Synonyms none. Chromosome number: not known.

Description Similar to the Pardine Genet, but ground colouration 'dirtier', and spots completely dark and partly coalesced at the rump. Facial mask well marked, with a thin dark vertical line on the muzzle. Sub- and supra-ocular white spots contrasting with the dark muzzle. Ear broad-based and slightly rounded. Pelage relatively short and rough. Ground colouration generally pale yellowish-grey. Throat, chest and ventral pelage whitish-yellow to grey. Nuchal stripes well defined. Mid-dorsal line wide and dark without long crest hairs, beginning after the shoulder. Dorsal spots elongated and squared, completely dark and partly coalesced at the rump. Hindlimbs and

forelimbs dark and well spotted. Upper parts of the forefeet spotted; upper parts of the hindfeet unspotted. Underparts of feet dark. Tail thickly furred but hair relatively short, almost half completely dark, and annulated with five to seven pale rings. Sexes similar in colour and size.

The skull shows very large posterior extension of frontal bones, almost completely overlapping the dorsal region of interorbital constriction, and caudal entotympanic bone inflated.

Geographic Variation None recorded.

Similar Species

Genetta pardina. Sympatric. Dorsal spots not coalesced; tail annulated almost to the tip, which is covered by a large dark ring.

G. johnstoni. Sympatric. Dorsal spots rufous-red and coalesced; tail annulated with pale rings to the tip.

G. poensis. Sympatric. Dorsal spots greatly fused in various parts of body; nuchal stripes not clearly delimited.

Poiana leightoni. Sympatric. Smaller; ears large and rounded; spots smaller and dark, no mid-dorsal line.

Distribution Endemic to Africa. Collection localities suggest a distribution restricted to the Upper Guinean rainforests, including Sierra Leone (Tekea), Liberia (Fisherman Lake, New Camp, Monrovia, Bopulu, Grand Gedeh and Sinoe Counties), Guinea (Sérédou, Zياما Forest, Mt Nimba; also collected from Dieké forest; M. Colyn pers. comm.) and Côte d'Ivoire (Man; purchased specimen; and near Danane cuve) (Gaubert 2003a). A specimen in the Field Museum of

Natural History (FMNH54687), attributable to Bourlon's Genet, was collected from Oda in Ghana in 1946, but the true origin of this animal is in question.

Habitat Collection localities suggest restriction to rainforest (Gaubert 2003a).

Abundance The population status of this species in the wild is unknown. It is known from 29 museum specimens, several having been recovered from bushmeat markets in SE Guinea as recently as 2003.

Remarks There is no information available on the biology of this species. The coalesced spotted coat patterns suggest adaptation to more humid and closed habitats.

Conservation IUCN Category: Near Threatened. CITES: Not listed.

Several of the collecting localities in Guinea are Classified Forests (including Ziama and Diécké), and the species is also recorded from Mt Nimba. A field mission in 2001 in Taï N. P., adjacent to the species' current known range, failed to confirm the presence of the species, although other viverrids were sighted, including the rare Johnston's Genet *Genetta johnstoni* (see Gaubert *et al.* 2002a). Given its likely

restriction to rainforest, it is probably being affected by ongoing habitat loss in the region, although rates of forest loss in Liberia are nowhere near as high as, for example, in neighbouring Côte d'Ivoire (Christie *et al.* 2007). Hunting pressure is also probable, as skins were sighted in the bushmeat market of Man, Côte d'Ivoire (P. Gaubert & C. Crémère pers. obs.). This is a very poorly known species, and is urgently in need of survey work in order to assess the status of this species in the wild.

Philippe Gaubert

Genetta cristata CRESTED GENET

Fr. Genette servaline à crête; Ger. Hauben-Ginsterkatze

Genetta cristata Hayman, in Sanborn 1940. Trans. Zool. Soc. Lond. 24: 686. Okoiyong, Mamfe Division, Cameroons (Nigeria, 05° 45' N, 08° 25' E).

Crested Genet *Genetta cristata*.

Taxonomy Monotypic. Originally described as a subspecies of the Servaline Genet *G. servalina* and recognized as such by Coetzee (1977) and Wozencraft (1993). Considered a distinct species by Rosevear (1974), Crawford-Cabral (1980–81) and Van Rompaey & Colyn (1998) on the basis of pelage characteristics and skull measurements. Studies involving morphology and molecular phylogenetics have confirmed its species status (Gaubert *et al.* 2004b, 2005b, 2006; and see Wozencraft 2005). Rosevear (1974) described *G. bini* from one skin collected from the Ohsu F. R., some 65 km north-west of Benin City, W Nigeria. The skin differs from typical *G. cristata* skins in the absence of a nuchal crest and in the size, shape and number of spots. Schlawe (1981) and Wozencraft (1993) consider it as synonymous with the Large-spotted Genet *G. maculata*. Powell & Van Rompaey (1998) considered it as a junior synonym of *G. cristata* as followed herein and by Gaubert (2003a) and Wozencraft (2005). Synonyms: *bini*. Chromosome number: not known.

Description Small, slender, long-legged genet with an elongated face and silky pelage. Ground-colour somewhat variable from grey over pale to rich ochraceous. Whole underside greyish with irregular, small, randomly spaced spots on the chest and throat; ventral pelage between hindlegs without spots. Hair covering the scrotum dark brown. Thin nuchal crest present composed of short hairs that run in the opposite direction to the surrounding hairs; discontinuous mid-dorsal line, with relatively long hairs, from just behind the shoulders to the base of the tail. Both nuchal crest and mid-dorsal line form an

erectile crest when the animal is excited. Body covered with numerous close-set, dark brown to black spots, which may form longitudinal rows, especially near the spine. Fore- and hindlegs spotted on the inner surface for two-thirds of their length. Fore- and hindfeet dark brown to black; there is often a distinct, pale, greyish patch over the metatarsal region above. Tail long, cylindrical with eight to ten dark rings, about three times as wide as the intervening light-coloured rings, and the tip grey. One pair of nipples. In the skull, the caudal entotympanic bone is ventrally inflated.

Geographic Variation Known to be present on both sides of the Niger R., but no geographic differences are currently known.

Similar Species

Genetta maculata. Sympatric. Spots larger, fewer, symmetrically arranged; black-tipped tail.

G. servalina. It is possible that this species may be sympatric and hybridize in Cameroon, Gabon and Congo (Gaubert *et al.* 2006). No nuchal or mid-dorsal crest.

Nandinia binotata. Sympatric. Heavier; more brownish coloured; two light-coloured shoulder spots; soles of fore- and hindfeet naked to wrist or ankle; tail not distinctly ringed.

Poiana richardsonii. Sympatric in Cameroon only. Smaller, more slender; spots smaller; lighter coloured.

Distribution Endemic to Africa. Confined to the lower Guinean rainforest of Nigeria and Cameroon. This species is recorded as ranging from the Niger R. eastwards probably to the Sanaga R. (Heard & Van Rompaey 1990, Powell 1995, Powell & Van Rompaey 1998). There are records of the species from west of the Niger Delta, including the type of *bini* from Ohosu F. R., and specimens from Odi (C. B. Powell pers. comm.), Tungbo (05° 07' N, 06° 10' E) (Powell & Van Rompaey 1998) and near Patani (05° 13' N, 06° 11' E) (Angelici & Luiselli 2005). Although the region between the Niger Delta and the Cross R. is

heavily populated with many villages interspersed by patches of forests and cultivated land, records do exist: one was recently bought at the roadside near Azumini (04° 57' N, 07° 29' E) (Angelici & Luiselli 2005). Gaubert *et al.* (2006) give records of the species that show it ranging more than 500 km south of the Sanaga R. to S Cameroon, Gabon and N Congo, as well as 180 km west of the type locality of the form *bini* in Nigeria between Oni and Epe (but these are not mapped here).

Habitat Inhabits scrub, low tangled vegetation and bare ground below trees in high deciduous forest. Occasionally, also present in secondary and montane forest up to more than 1000 m above sea level (Sanderson 1940, Heard & Van Rompaey 1990). In the Niger Delta, throughout the heavily forested parts, including the marsh forest zone but not the mangrove zone. In the largely deforested zone east of the Orashi R., there is no recent record but local hunters claimed the species was still present in 1997 (Powell & Van Rompaey 1998). Angelici & Luiselli (2005) found that the presence of Crested Genet was statistically correlated to the presence of primary dry forest and bush-mango plantations inside the forest, and to a lesser extent secondary dry forest, and primary flooded forest, but negatively influenced by the presence of suburban areas, pineapple plantations, bushlands and oil palm plantations.

Abundance In the Niger Delta area the Crested Genet seems common where it occurs (Powell 1995). There is no information on the abundance of the Crested Genet in its distribution area east of the Cross R.

Adaptations Crepuscular, and considered definitely terrestrial by Sanderson (1940), but probably semi-arboreal as most genet species (Heard & Van Rompaey 1990); captive specimens are agile climbers spending most of their time in high places.

Foraging and Food Examination of the stomachs of 11 specimens showed that insect remains were dominant in the diet (51.4%), with mammals accounting for 20%, reptiles 8.6% and vegetable matter 5.7% (Angelici & Luiselli 2005). Two semi-captive young pursued and ate small insects, frogs and lizards, the latter of which were a favourite prey (Heard & Van Rompaey 1990).

Social and Reproductive Behaviour Nothing is known about adult behaviour in the wild. Two young semi-captives groomed each other and slept, explored and hunted together. They defecated in one place and the older one appeared to scent-mark with perineal glands whilst urinating, slowly moving his pelvis from side to side. Both rolled and rubbed themselves in smells and substances to which they were attracted. They were quiet animals and did not vocalize often. Both had at least three easily recognizable vocalizations in addition to a purr and a growl: a long meow; a short squeak; and a combination of a short sneeze/cough/grunt with which they greeted each other after being apart and which they sometimes used to maintain contact when not in sight of each other (Heard & Van Rompaey 1990).

Reproduction and Population Structure One-week-old litters were recorded late Aug and mid-Oct in the Oban area of SE Nigeria (Heard & Van Rompaey 1990). Two embryos in a ♀ collected in Dec in the Niger Delta, Nigeria (C. B. Powell in litt.).

Predators, Parasites and Diseases Unknown, though probably similar to other genets.

Conservation IUCN Category: Vulnerable A2cd. CITES: Not listed.

Field surveys are needed to identify the exact distribution, habitat and conservation requirements of the species, especially since the Cross River State forests are rapidly being converted into farms or wastelands and the Niger Delta is exploited as an oil-production area. Indeed, there currently are no protected areas established in the Niger Delta. The Crested Genet is also believed to suffer from high hunting pressure, and in the Niger Delta (Nigeria) is a target of the bushmeat market (Angelici *et al.* 1999c).

Measurements

Genetta cristata

HB: 540 (495–622) mm, n = 13

T: 431 (431–432) mm, n = 3

E: 86, 95 mm, n = 2

GLS: 94.6 (87.5–99.2) mm, n = 14

GWS: 45.2 (42.7–48.9) mm, n = 14

Throughout range (museum specimens: BMNH, MRAC, SBP and ZMB)

Key References Angelici & Luiselli 2005; Heard & Van Rompaey 1990; Rosevear 1974; Sanderson 1940.

Genetta genetta COMMON GENET (SMALL-SPOTTED GENET)

Fr. Genette commune; Ger. Ginsterkatze (Gemeinegenette, Kleinfleckgenette)

Genetta genetta (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 45.

Spain [restricted to El Pardo, near Madrid (40° 32' N, 3° 46' W) by Cabrera (1914)].

Common Genet *Genetta genetta*.

Taxonomy High intra-specific variability within this species makes clear distinctions between populations difficult to assess. The main taxonomic groupings usually include genets from: (1) Europe and Maghreb (*genetta*); (2) West to East Africa, south of the Sahara (*senegalensis*); and (3) southern Africa (*felina*) (with *senegalensis* and *felina* sometimes being merged into one population under *felina*). Such groups have either been considered valid species (Roberts 1951, Cabral 1966, Schlawe 1981, Honacki *et al.* 1982) or subspecies (Wenzel & Haltenorth 1972, Rosevear 1974, Coetzee 1977, Crawford-Cabral 1980–81, Meester *et al.* 1986, Wozencraft 1993). In addition, the forms *dongolana* and *neumanni* have sometimes been designated distinct populations from East Africa (Crawford-Cabral 1980–81, Wozencraft 1984, Kingdon 1997). Crawford-Cabral (1980–81) recognized two groups (East + South Africa, and West Africa + Maghreb + Europe) and six subspecies in Africa, but suggested that the Common Genet may

be just one polytypic species. However, Wozencraft (1984) distinguished four separated populations from West Africa, East Africa, southern Africa and around the Mediterranean.

A recent molecular phylogeny suggests that the species is paraphyletic, with a southern African clade attributed to the species *felina* (note that *Genetta felina* is not treated here as distinct, but see Gaubert *et al.* 2004b, 2005c). *Genetta genetta* appears to be the sister taxon of the large-spotted genet clade (Gaubert *et al.* 2004b). In addition, three groups were identified within the restricted *G. genetta* clade: (1) West Africa–southern Africa; (2) Arabian Peninsula; and (3) Europe–Maghreb (populations from East Africa were not sampled) (Gaubert *et al.* 2009b). The species is estimated to have diverged during the middle to late Pliocene (Gaubert & Begg 2007).

Major synonyms: *afra*, *bella*, *dongolana*, *felina*, *grantii*, *hararensis*, *neumanni*, *pulchra*, *senegalensis*, *vulgaris* (see Wozencraft 2005 and Gaubert *et al.* 2005c for complete list). Chromosome number: 2n = 54 (nFa = 92) (Matthey 1964, Gaubert *et al.* 2004a) for specimens from France. A karyotyped specimen published by Wurster & Benirschke (1968) under the name *G. genetta neumanni* with a diploid chromosome number 2n = 52 (nFa = 96) is likely to belong to the Large-spotted Genet *G. maculata* (Gaubert *et al.* 2004a).

Description A medium-sized genet, with long hairs and elongated and coalesced thin dorsal spots merging in longitudinal lines. Facial mask relatively marked, with a thin dark vertical line on the muzzle. Sub- and supra-ocular white spots contrast with the dark muzzle. Pelage relatively long and soft. Ground colouration from whitish-grey to pale yellow-rufous. Throat, chest and ventral pelage whitish or pale yellowish-grey to grey. Nuchal stripes well defined. Mid-dorsal line thin and dark with long erectile crest hairs (up to 75 mm) beginning after the shoulder. Hairs of the scapula with a globular medulla containing no air spaces. Hindlimbs and forelimbs same colour as the ground colouration and spotted. Hindlimbs with

outer side and back covered in dark hairs, this colouration extending onto the underpart of the hindfeet and bordering the toes. Upper part of forefoot and hindfoot lightly spotted. Underpart of forefoot dark. Tail relatively long (ca. 95–97% of HB) with long hairs (up to 60 mm) and annulated with 8–10 pale rings. Margins of the rings often not clearly distinguishable due to the overlapping long guard hairs of the preceding ring. Tip of the tail whitish. In two-month-old individuals, pattern of spots similar to adult but coalesced spots of the back tending to form several longitudinal lines. Two pairs of nipples. Skull is of medium size, with a large sagittal crest and weakly marked interorbital constriction (oligostenomic skull; Crawford-Cabral 1980–81). The caudal entotympanic bone is not ventrally inflated.

Geographic Variation It is sometimes difficult to find discriminative and fixed morphological characters between populations and the following is a tentative list of regional variants that have been judged to be subspecies by a variety of authors.

- G. g. genetta*: SW Europe, Morocco, Algeria, Tunisia and Cyrenaica (Lybia). Hair long; ground colouration ash-grey to pale yellowish-grey; spots of the back thin and black, same colour as mid-dorsal line.
- G. g. grantii*: SW Arabian Peninsula (Saudi Arabia and Yemen), Oman. Hair short; ground colouration pale whitish-grey; spots of the back thin and pale orange-brown, contrasting with the black mid-dorsal line.
- G. g. senegalensis*: West Africa. Hair short; ground colouration off-white (Senegal) to pale whitish-grey and light beige; spots of the back large and spaced-out, a rufous-brown contrasting with the black mid-dorsal line. The extreme pelage pattern and colour variability of specimens from Dahomey Gap to Cameroon make a range restriction to W of Volta R. more sensible.
- G. g. dongolana*: populations from East, north-east and central Africa are tentatively placed under the same subspecies. Hair short; ground colouration pale yellowish-grey; spots of the back large and close-set, a rufous-brown contrasting with the black mid-dorsal line. Similar to the form *neumanni* (Tanzania) on the basis of spot patterns (but see Crawford-Cabral 1980–81).
- G. g. pulchra* (here taken to include *bella*; Crawford-Cabral 1980–81, J. Crawford-Cabral in litt.): southern Africa, north of Orange R. to SW Angola, W Zambia and NE Botswana.
- G. g. felina*: probably a distinct species (Gaubert *et al.* 2004b, 2005b). Southern African coast to Namibia, S Angola and W Zambia. Apparently sympatric with *pulchra* in Namibia, S Angola, W Zambia and NE South Africa (Gauteng) (see Gaubert *et al.* 2005b). Hair long, ground colouration bright ash-grey-white; hindfeet covered by a dark 'sock' and posterior part of forefeet completely dark.

All genets inhabiting regions with Mediterranean climate (Europe, Maghreb and southern coastal zone of South Africa) show a similar pelage pattern and colouration, i.e. long hairs, ash-grey to pale yellowish-grey background pelage and black spots, with a mid-dorsal line of the same colour. Other individuals, distributed throughout sub-Saharan Africa and the Arabian Peninsula (hot and dry climates), exhibit a distinct pelage pattern and colouration: short hairs, pale whitish-grey to light beige background pelage and spots rufous-brown

contrasting with the black mid-dorsal line. This colouration appears to reflect climatic conditions. Melanistic specimens occur throughout the Iberian Peninsula, but seem absent from the native range of the species (Gaubert & Mézan-Muxart 2010).

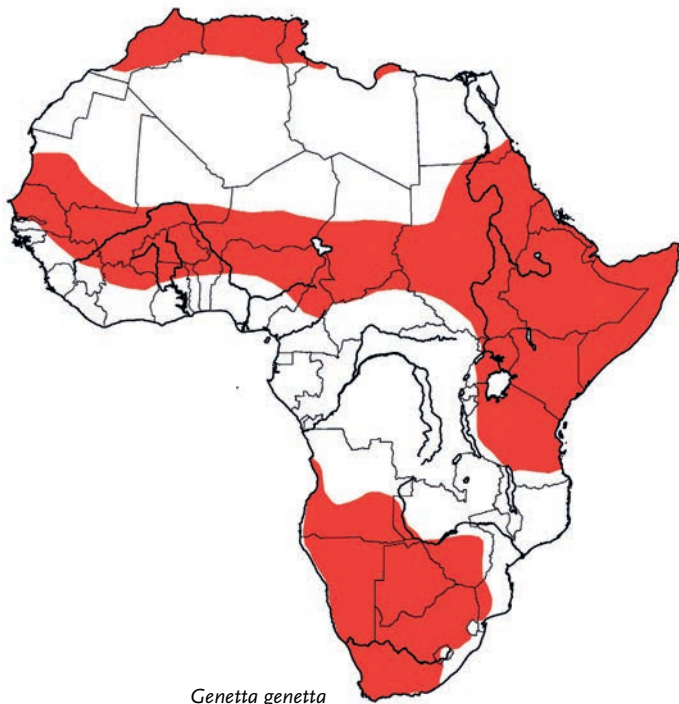

Similar Species

- Genetta thierryi*. Sympatric. Smaller; pelage short; no erectile sagittal crest; dorsal spots and dark rings of the tail rufous-brown; mid-dorsal line split longitudinally by a line of pale hairs.
- G. abyssinica*. Sympatric. Smaller; pelage short; no erectile sagittal crest; mid-dorsal line split longitudinally by a line of pale hairs.
- G. pardina*. Sympatric. Larger; pelage short; no erectile sagittal crest; dorsal spots squared or ovoid, large and not coalesced; tip of the tail black.
- G. maculata*. Sympatric. Pelage short; no erectile sagittal crest; dorsal spots squared or ovoid, larger and not coalesced; tip of the tail black.
- G. angolensis*. Sympatric. Ground colouration usually darker, especially on the legs; spots of the back squared and partially coalesced; tip of the tail black.
- G. tigrina*. Sympatric. Spots of the back squared, large and partially coalesced; tip of the tail black.

Distribution Widespread species, occurring on the northern Saharan fringe (Morocco, Algeria, Tunisia and Lybia), and then in open and dry savanna zones throughout sub-Saharan Africa (extending into parts of Guinea savanna), and drier habitats such as rocky areas, near-desert scrub (reaches Tentane at 19° 49' N, 12° 57' E, Mauritania), and coastal Sahara (Brito *et al.* 2010). Usually absent from rainforests, dense woodlands and woodland–moist savanna mosaics (e.g. miombo woodland in Angola).

In sub-Saharan Africa, the current distribution seems to consist of three large blocks, corresponding roughly to West Africa, East Africa and southern Africa. According to museum collections (Schlawe 1980, P. Gaubert pers. obs.), individuals were regularly collected between the western and eastern ranges (i.e. N Cameroon, S Chad and Sudan), suggesting a continuum between the two populations. The northern limit for both West and East populations ranges between 18 and 22° N. The eastern block has its southern limit reaching approximately 10° S (Schlawe 1980). Both field surveys and museum collections suggest a clear separation between the southern and eastern blocks, with no specimens known from Malawi, N Mozambique and much of Zambia. Populations from the southernmost region are recorded from S Angola and extreme W Zambia, and then southwards throughout Namibia, Botswana and Zimbabwe (except the northernmost and easternmost areas) to the South African coastline. To the east they are replaced by populations of the Large-spotted Genet *G. maculata*, reaching as far as W Lesotho (Lynch 1994), the western parts of the Eastern Cape and NW KwaZulu–Natal in South Africa (Rowe-Rowe 1992a), and SW Mozambique (Smithers & Lobão Tello 1976); they have not been recorded from Swaziland (Monadjem 1998).

Extraliminally, the Common Genet is present in forests and scrublands around the Mediterranean region of SW Europe (Spain, including the Balearic Islands of Mallorca, Ibiza and Cabrera, Portugal, and France, where it is now established in the south-eastern part of the country; Gaubert *et al.* 2008b), and patchily recorded

in the east and north-east European regions (the Alps of France, Switzerland and Italy, NE France, Belgium, the Netherlands and SW Germany; see Léger 1998; Delibes 1999b). Also occurs in hilly and mountainous coastal regions of Arabia, Yemen and Oman (Harrison & Bates 1991). Records of individuals reportedly from Palestine (Tristram 1866) proved to be false (Schlawe 1981, Kock 1983). It has been suggested that this species was introduced as a tamed animal into Spain from the Maghreb and then into S Europe, either through early commercial exchanges (Crawford-Cabral 1980–81, Amigues 1999) or later, at the time of the Moorish invasions. Recent studies have identified North Africa as the geographic source of the European populations, possibly restricted to N Algeria (Gaubert *et al.* 2009b, 2011); Andalusia (S Spain), Catalonia (NE Spain), and the Balearic Is. (Ibiza and Mallorca) were identified as the main ‘hotspots’ of introduction of the species into Europe. Remains found in the South Galala Plateau cave, Egypt, and illustrations on papyrus and in stone relief from the Nile Valley confirm a northern African range before and at the beginning of historical times (Osborn & Osbornova 1998). Known as sub-fossils in the early Pleistocene of Ethiopia and in the late Pleistocene of Barbary (Savage 1978).

Habitat Like other genet species, the Common Genet is usually associated with trees and bushes, but it can also be found in bushy and rocky treeless areas, usually where there is a definite dry season (Kingdon 1977). Its only habitat requirements seem to be available prey and the presence of woody or rocky shelters, and it does not appear to depend on a water supply (Kingdon 1977). The range of the species in Africa suggests that it avoids the most arid zones as well as tropical rainforests.

North of the Sahara, in Morocco, the Common Genet is found in *Quercus* spp. and other kinds of forests and in bushy areas, mainly in the mountains (Cabrera 1932; and up to 2700 m in the western High Atlas Mts, Cuzin 2003), but also in rocky ravines, preferably vegetated and in close proximity to water (Panouse 1957) into the

Sahara fringe, where it is common in oases and other productive areas (F. Cuzin pers. comm.). In Algeria it occurs from sea level, where it is found in riparian forests (Delibes *et al.* 1989), up to 2000 m in the Djurjura Mts, where the average annual rainfall reaches 1400 mm; here the species occupies all types of habitats, being most abundant in the old forests of *Quercus ilex* and *Cedrus atlantica* (De Smet & Hamdine 1988).

South of the Sahara, the species occurs in the wooded savannas of the Sahel, Sudan and, locally, the Guinea zones (Happold 1987) where it seems to prefer wooded areas, but also occupies rocks, broken termite mounds and disused dens of jackals and other species (Bigourdan & Prunier 1937). In East Africa it shows a clear preference for areas of high woody cover; in the Ethiopian Highlands, around 3000 m, a female genet showed a distinct preference for woodland (spending 84% of her time there), followed by bush, farmland and grassland (Admasu *et al.* 2004c). In the Serengeti N. P. in Tanzania, the number of genet sightings is significantly correlated with the number of trees and thickets (Waser 1980) and the species is commonly seen on escarpments, rocky outcrops and other hills (Kingdon 1977).

In Botswana, the species has been found in all major vegetation associations and in areas with mean rainfall from less than 200 mm to more than 700 mm; it occurs in the riverine forests of Okavango, the rocky kopjes of E Botswana and the open dry scrub savannas of C and SW Botswana (Smithers 1971). Habitat data were recorded for 100 individuals: 47 were captured in *Acacia* woodland or scrub, including riverine *Acacia*, 16 in Mopane *Colophospermum mopane* woodland or scrub, 12 in *Terminalia*–*Bauhinia* scrub, nine in unspecified riverine forests, nine in open grassland with scattered bushes and trees, and lower numbers in other habitats. In open habitats the species did not occur unless there was some adjacent cover of scrub or isolated patches of trees with underbush; this suggests that scrub cover or woodland is an essential habitat requirement (Smithers 1983). However, the Common Genet penetrates true desert along seasonal water-courses (e.g. Kuiseb and Swakop Rivers in the Namib Desert; C. Stuart & T. Stuart pers. comm.).

Taking a broad west–east transect across the southern African sub-region, the Common Genet is the only genet species occurring in the arid zones of Namibia, is widely distributed in Botswana and W Zimbabwe, but becomes less common eastwards, being replaced by some species of the large-spotted genet group in E Zimbabwe, most of Mozambique as well as KwaZulu–Natal and Swaziland. The Miombo Genet *G. angolensis* broadly replaces the Common Genet throughout the miombo country (J. Crawford-Cabral pers. comm.). This kind of partial replacement also occurs in other parts of Africa (Coetzee 1977, Kingdon 1977, Happold 1987).

Lateral view of skull of Common Genet *Genetta genetta*.

In Europe, the Common Genet is especially abundant in *Quercus* spp. forests, but it is also common in olive groves, *Olea europaea*, riparian copses, ash groves, *Fraxinus* spp. and scrublands, being rare or absent in open areas, marsh and cereal crops (review in Larivière & Calzada 2001). Cold temperatures could restrict the distribution of the Common Genet in C Spain (Virgós *et al.* 2001). In SW Arabia it is said to inhabit dry ravines in hills and mountains (Harrison 1968). The Common Genet is often found in proximity to people and human buildings (e.g. Admasu *et al.* 2004c).

Abundance One of the most common small carnivores, though detailed data on density are scarce. Genets seem to be very abundant in the Djurjura Mts of Algeria, where in 10 days De Smet & Hamdine (1988) captured eight different individuals (seven ♂♂, one ♀) in a few hectares. In Senegal, Sillero-Zubiri & Marino (1997) recorded a night-time frequency of 1.76 per 100 km. In the Kirawira area of Serengeti N. P. a density of 1.5 ± 0.37 individuals per km² was estimated (Waser 1980); previously, Hendrichs (1972) reported densities of about 0.5 individuals per km² in Serengeti N. P. In Europe, density in Doñana N. P., SW Spain, was 0.33 adults per km² and 0.67 animals per km², the latter figure including young individuals (Palomares & Delibes 1994).

Adaptations Long hairs of the black dorsal line and tail, reaching 70 mm or more, can be erected giving the animal an intimidating look; in this situation the enlarged black and white tail is displaced transverse to the antagonist (Gangloff & Ropartz 1972). Three pairs of contrasting white facial spots were thought to help young to orient themselves in relation to their mother (Roeder 1984b).

Sharp and curved semi-retractable claws and some characteristics of the limbs make genets capable of climbing but unable to dig (Taylor 1974, 1976). However, although Common Genets actively climb trees to forage on fruit and roosting birds and to escape predators (Taylor 1970a, Gangloff & Ropartz 1972), most of their activity is on the ground. The usual locomotion is walking and trotting, with the body held very close to the ground surface and the vertebral axis, including the tail, kept horizontal; the shoulders are kept lower than the base of the tail and the centre of gravity for the whole body is very low (Taylor 1970a). They often utilize roads, tracks and dry stream beds when travelling.

Resting places include hollow logs, holes in trees, underbush cover, piles of boulders etc.; in parts of their range, such as Namibia and Botswana, where there are no trees, they use holes in the ground or disused Aardvark *Orycteropus afer* and Southern African Springhare *Pedetes capensis* burrows. They make no attempt to modify holes in the ground to their requirements, nor do they carry in bedding material. Also, in Botswana, they use holes in calcareous cliffs (Smithers 1971), a habit also reported by Delibes (1974) in Spain.

Experimental tests reveal a high level of activity in total darkness, suggesting dependency on senses other than vision (Kavanau & Ramos 1975). However, in Serengeti N. P. they were seen foraging more often in bright moonlight (Waser 1980). One radio-marked lactating ♀ in Omo N. P., Ethiopia, was strictly nocturnal and active throughout the night, its average daily activity reaching 55% of the day (Ikeda *et al.* 1983) and in Botswana the earliest sightings were just after dark, at 19:00h, with records through until 02:00h (Smithers 1971). In Serengeti N. P., Common Genets were observed between

20:00h and 06:00h (n = 11; Hendrichs 1972). In Spain, the highest levels of activity occur after sunset and just before sunrise, the genets being active on average 26% of the 24-hour period (Palomares & Delibes 1994); dial activity coincides with that of the Long-tailed Field Mouse *Apodemus sylvaticus*, the main prey (Palomares & Delibes 2000).

Secretions of sebaceous glands from several regions of the body have a communication role (Roeder 1978a, 1980b, Roeder *et al.* 1989). Especially important are the perineal glands, opening in both sexes in a longitudinally oriented Y-shaped slit between the anus and the genitalia; their blackish secretion has a very persistent musky smell (Skinner & Chimimba 2005). The urine has a pungent smell and is used for marking and under stress.

Foraging and Food The Common Genet feeds mostly on small mammals, but is a generalist feeder that will also eat birds and eggs, reptiles, amphibians, fish, insects, other arthropods, fruits, mushrooms and garbage. It is known to raid poultry. In captivity, its daily energetic requirements were estimated between 150 and 280 Kcal/kg of body weight (Livet & Roeder 1987). The relative length of the intestine might be correlated with a more strictly carnivorous diet than in canids, but less than in felids (M. Delibes pers. obs.).

The main prey in northern parts of North Africa is the Long-tailed Field Mouse, a Palearctic rodent that, as already noted, is also the most common prey in SW Europe (Delibes 1974, Livet & Roeder 1987). However, arthropods reach frequencies of occurrence similar, or even higher, to those of small mammals in faeces collected in Morocco and Algeria, although the ingested biomass of arthropods is low. Birds are consumed as a complementary winter food in Morocco (Delibes *et al.* 1989) and Algeria (Hamdine *et al.* 1993). Reptiles and amphibians were generally scarce in North African genet diet, except during spring in some riverine places of Algeria (Delibes *et al.* 1989). Fruits, including figs, are consumed in the Djurjura region of Algeria (Hamdine *et al.* 1993) and in Moroccan Tafilalet's oasis (F. Cuzin pers. comm.). In Saharan fringes, where the Long-tailed Field Mouse is absent, remains of gerbils *Gerbillus* spp. are found in faeces (F. Cuzin pers. comm.). In East Africa, Waser (1980) observed Common Genets capturing skinks and large locusts and stalking frogs around temporary ponds in Serengeti N. P.; Hendrichs (1972) reported small mammals, reptiles, amphibians, fishes and insects as foods in the same area; in the Ethiopian Highlands genets were occasionally seen foraging in rubbish dumps (Admasu *et al.* 2004c).

In Botswana, Smithers (1971) examined 78 stomachs and found that murids were present in 54%, insects (72%; mainly grasshoppers, beetles, and termites), arachnids (36%; mainly scorpions and hunting spiders), reptiles (18%; snakes, skinks and geckos), birds (6%) and other food items with less frequency. Murid prey in this area included at least ten different species, of which Natal Multimammate Mouse *Mastomys natalensis*, *Mus* spp., Southern African Pouched Mouse *Saccostomus campestris*, Paeba Hairy-footed Gerbil *Gerbillurus paeba*, Common African Fat Mouse *Steatomys pratensis* and *Tatera* spp. had more or less similar importance. In Zimbabwe, an analysis of 29 stomachs (Smithers & Wilson 1979) gave somewhat similar results, although in this case the Natal Multimammate Mouse was the rodent species most frequently consumed. The remains of shrews, normally not palatable to small carnivores, were recovered from stomachs, and in the Botswana sample there was a record of the

Cape Pipistrelle *Pipistrellus capensis*. Wild fruits were represented in both samples, especially raisin bush berries, *Grewia* sp. In the Namib Desert, Stuart (1977) found small mammals in more than 90% of faeces analysed, and insects in about 60% ($n = 125$). Other dietary studies conducted in South Africa (Stuart 1981, Rautenbach 1982) report similar dietary preferences, and Stuart (1981) mentions that a batch of scats collected at De Hoop N. R. in the Western Cape contained the remains of crabs.

Most foraging takes place at night. When locating potential prey, Common Genets move slowly and stalk it in a cat-like fashion, finishing with a sudden pounce or rush (Waser 1980). The rate of prey capture by Common Genets in the East Africa savannas seems to be lower than other more insectivorous small carnivores (Waser 1980). Prey are grabbed with the claws of the forelimbs and bitten at any part of the body, but if they are not killed in a short time, the genet will throw itself on its side and grab the prey with the claws of all four limbs, trying to crush the head and neck with a few bites, in a felid-like fashion (Skinner & Chimimba 2005). Typically, small rodents and other vertebrates are bitten in two or three sections to be swallowed (Delibes 1974).

Social and Reproductive Behaviour Only four of 145 observations in Serengeti N. P. were of pairs separated by less than 100 m; the rest were of solitary individuals (Waser 1980). In SW Ethiopia two ♀♀ (an adult and an immature) foraged solitarily even though their home-ranges did overlap (Ikeda *et al.* 1983); another ♀ radio-tracked in the Ethiopian Highlands was exclusively solitary (Admasu *et al.* 2004c). However, genets in captivity accept the close presence of other individuals.

Communication between different individuals takes place mainly through olfactory and visual marks, but calls are important in the mother–offspring relationships (Livet & Roeder 1987). Olfactory marking by captive genets has been extensively studied (Roeder 1978a, b, 1980a, b, 1983a, b, Roeder *et al.* 1989, Roeder & Thierry 1994). Common Genets use secretions from their perineal glands (mainly ♀♀) and urine (mainly ♂♂), as well as flank and leg rubbing. Anogenital marking behaviour by ♂♂ is higher during the breeding season, while ♀♀ mark more often during the rest of the year. Flank rubbing has been associated with aggressive encounters. Scent-marks allow recognition of individuals and their social and reproductive status. Intimidatory aggressive–defensive behaviour (against conspecifics and potential predators) includes the erection of the long hairs of the tail and the black central dorsal crest, an arch-back stance (like a cat), and explosive hissing accompanied by a head-darting movement towards the antagonist, with the open mouth showing the teeth (Gangloff & Ropartz 1972, Livet & Roeder 1987).

Common Genets defecate in latrines placed on elevated points, mainly on rocks, but also on trees, bird nests, or even on the top of buildings (Roeder 1980b). A large number of faeces (more than 100) can be found in one latrine. Large-sized faeces (on average 15 cm long and 1.4 cm wide; Livet & Roeder 1987) make latrines conspicuous. They have a communicatory function, as faeces are impregnated with the secretion of anal glands. Several individuals use the same latrines, which seem to be more frequent at the border of the home-ranges (Palomares 1993c). Isolated, scattered faeces are also deposited.

Home-ranges are relatively small. In SW Ethiopia, a lactating ♀ radio-tracked during ten weeks used 0.62 km² and an immature ♀ radio-tracked during seven weeks used 0.34 km² (Ikeda *et al.* 1983).

In the Bale Mts, a radio-tracked ♀ used an area of 1.7 km² during 17 months, but its core area (50% of locations) was only 0.2 km² (Admasu *et al.* 2004c). In Serengeti N. P., Waser (1980) estimated through direct observations of marked individuals that ranges were smaller than 0.75 km². In the same area, a well-known individual ranged in about 0.50 km² (Hendrichs 1972). Home-range size seems to be larger in Europe. In S Spain the average size was 7.8 km² (Palomares & Delibes 1994) while in N Spain the home-range of three ♂♂ varied from 2.1 to 10.2 km² (Zuberogoitia *et al.* 2002) and in France an adult ♀ occupied 2 km² (Lodé *et al.* 1991). Some evidence suggests that significant overlaps in home-range occur (e.g. Waser 1980, De Smet & Hamdine 1988). A detailed study on a low-density population in SW Spain indicates that there is large intersexual, but low intrasexual, overlap (Palomares & Delibes 1994). Common Genets in SW Spain moved on average 2.8 km daily and changed their diurnal resting sites, which were placed in dense thickets and hollow trees. The average distance between consecutive diurnal resting sites was 0.73 km (Palomares & Delibes 1994).

Courtship and mating behaviour has been studied on captive animals (Roeder 1979). Between seven and ten days before mating the ♂ increases and the ♀ decreases their ano-urogenital marking activity. At the same time, the ♂ repeatedly sniffs the anogenital region and the flanks of the ♀, emitting a contact call as a repeated coughing. Copulations last two or three minutes and are repeated four or five times during the same night.

Roeder (1984b) and Roeder & Pallaud (1980) studied the ontogenetic development of communicatory and predatory behaviour in captive genets. Young suckle during almost four months, although they begin to consume solid food at the age of 45 days. When 12 weeks old they pursue and try to capture prey and at the age of 18 weeks they have developed all their hunting skills. During the four months of lactation the communication between the mother and the cubs is visual, acoustic and by direct olfactory contact. The use of perineal glands for marking begins very late and seems to mature only when the animals are 19 months old, probably at the time of sexual maturity.

Reproduction and Population Structure In West, East and southern Africa breeding seems to be associated with wet seasons, while it occurs in spring and autumn in the Mediterranean of North Africa and SW Europe (Haltenorth & Diller 1980). One adult ♀ Common Genet was lactating in SW Ethiopia by the end of Nov (Ikeda *et al.* 1983) and Ansell (1960a) recorded a pregnant ♀ in Zambia in Feb. Most gravid ♀♀ were detected in Botswana from Oct to Feb, although the breeding season could be extended through subsequent months (Smithers 1971). Elsewhere in southern Africa, pregnant ♀♀ have been taken in Sep, Oct and Jan (Stuart 1981, Rautenbach 1982).

In Europe, captive and free-living genets can breed almost at any season, but mainly from Apr to Jun and secondarily from Sep to Nov (Delibes 1974, Roeder 1979, Aymerich 1982). Male genets have no clear seasonal testicular activity (Souloumiac & Audy 1979) and ♀♀ can become receptive again if they lose kittens, having two or even three litters in a year (Rosevear 1974, Livet & Roeder 1987). However, there are no reports of free-living ♀♀ successfully breeding twice a year.

Females reach sexual maturity when two years old (Krapp & Delibes 1993). Gestation period is 10–11 weeks (Roeder 1979).

Litters have been found in hollow trees, and the burrows of other animals, in Africa (e.g. Stevenson-Hamilton 1947, Shortridge 1934, Smithers 1971) as well as in Europe (Delibes 1974). Litter-size is 1–4, with a mode of 2 (Livet & Roeder 1987, Krapp & Delibes 1993). Average litter-size in southern Africa was 2.6 ($n = 11$) and two out of the 11 gravid ♀♀ carried four fetuses with implantation 2R : 2L (Smithers 1983). Young at birth are covered with hair, have closed ears and eyes, and weigh 60–85 g (Roeder 1979). They grow slowly: about 300 g when one month old, 450 g at two months, 900 g at four months and 1500 g at eight months (hand-reared young by M. Delibes). Captives have lived to more than 20 years (Jones 1982, Weigl 2005).

There is a paucity of data on population structure and dynamics. In Europe, sex ratio at birth is about 1 : 1 (26 ♂♂ and 24 ♀♀ in 22 litters), but more adult ♂♂ than ♀♀ (1.35 : 1, $n = 648$) were captured (Krapp & Delibes 1993). A sample of individuals measured in Botswana suggested that ♂♂ were captured three times as frequently as ♀♀ (Smithers 1971).

Predators, Parasites and Diseases Servals *Leptailurus serval*, Caracals *Caracal caracal*, Leopards *Panthera pardus*, Ratels *Mellivora capensis* and large owls have been quoted as predators of the Common Genet in Africa (Haltenorth & Diller 1980). Caro & Stoner (2003) have suggested that genets should be vulnerable to inter-specific killing by a large number of other African carnivores.

Common Genets have been recorded as parasitized by the ticks *Haemaphysalis (Rhiphystoma) moreli*, *H. silacea*, *H. spinulosa*, *H. zumpti*, *Amblyomma hebraeum* and *Ixodes pilosus* in sub-Saharan Africa (Camicas *et al.* 1972, Horak *et al.* 1987, 2000) and a flea *Ctenocephalides felis damarensis* in S Angola (Ribeiro 1974). At least three species of hookworms (nematodes, helminths), *Ancylostoma tubaeforme*, *A. genettae* and *A. braziliense*, have been recorded in Somalia (Macchioni 1995, Iori & Lanfranchi 1996), as has *A. caninum* in South Africa and Senegal (quoted in Macchioni 1995). In Africa and Europe, a substantial number of other parasitic helminths and various ticks, fleas and lice have been found on Common Genets (reviewed in Larivière & Calzada 2001). Admasu *et al.* (2004c) emphasize that the ability of genets to live close to humans and their domestic animals could have implications for the transmissions of disease at the domestic–wildlife interface.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Common Genets have a wide distribution on the African continent and extraliminally, have a very broad habitat tolerance, and are present in numerous protected areas. They are occasionally eaten by people in some localities, and the skin and body parts are used for medicinal and decorative purposes while skins may be used for the manufacture of karosses in southern Africa. In Djibouti, Künzel *et al.* (2000) reported genets being for sale in Djibouti city and Ali Sabieh.

Genetta johnstoni JOHNSTON'S GENET

Fr. Genette de Johnston; Ger. Liberiagenette.

Genetta johnstoni Pocock, 1908. Proc. Zool. Soc. Lond. 1907: 1041 [1908].

'in a district from 15–20 miles west of the Putu Mountains, which lie west of the Duobe and Cavally Rivers', Liberia.

Johnston's Genet *Genetta johnstoni*.

Taxonomy Monotypic. Named by Pocock in honour of Sir Harry Johnston, the artist, explorer and collector who did much work in Liberia. Original description from a headless skin purchased from local Liberian hunters. Though originally described as a new species, both Pocock (1908) and Allen & Coolidge (1930) suggested it only represented a subspecies of the Pardine Genet *G. pardina*. The subgenus *Paragenetta* was erected by Kuhn (1960), and an early phylogenetic analysis by Gaubert *et al.* (2002b) suggested exclusion of this species from the *Genetta* clade. More recent molecular evidence (mitochondrial and nuclear DNA) supports the inclusion of this species with the other genets (Gaubert & Veron 2003, Gaubert *et al.* 2004b, c). The species is estimated to have diverged from other basal rainforest genets during the middle Pliocene (Gaubert & Begg 2007). Synonyms: *lehmanni* (described on the basis of a skull without skin). Chromosome number: $2n = 50$ (Gaubert *et al.* 2004a).

Description A slender genet with a thick, soft coat and elongated face. Sexes similar in colour and size. Face characteristic of the genus, with a dark mask from muzzle to lips, contrasted by a pair of supra- and subocular white spots. Muzzle and forehead generally darker than other genets. Upper labial spots reduced. Large eyes contrasting with thin muzzle. Pupil vertical. Relatively elongated ears. Ground colouration from ochre-yellow to yellowish-grey. Chest and ventral pelage varies from yellowish-grey to buff. Nuchal stripes often fused. Full dark continuous mid-dorsal line strongly contrasting with the surrounding blackish to rufous-brown spots. Dorsal crest with longer hairs sometimes apparent. Large dorsal spots generally aligned in three rows. The first two rows of spots often coalesce into complete or partial lines, especially at the rump. Spots of the flank, thigh and shoulder smaller and dark. Hairs of the scapula with a very large cortex and a globular medulla containing many air spaces. Hindlimbs and forelimbs dark-brownish. Tail densely furred, and

Palatal and dorsal views of skull of Johnston's Genet *Genetta johnstoni*.

annulated with 8–9 pale rings to the tip. Dark rings broaden from the proximal part of the tail. In subadults coat densely spotted and pattern very irregular, but mid-dorsal line clearly marked. Perineal glands developed in both sexes (length: 30–40 mm; width: 15–20 mm), with tripartite structure like other genets. One pair of nipples.

Skull elongated and narrow, with flattening of the mandible and dentition weak.

Geographic Variation None recorded.

Similar Species

Genetta pardina. Sympatric. Larger and more heavily built; broader muzzle; first rows of spots not coalesced; tip of the tail with a large dark ring.

G. poensis. Sympatric. Dorsal spots greatly fused in various parts of body; nuchal stripes not clearly delimited.

G. bournoni. Sympatric. Dorsal spots partly coalesced at the rump; nuchal stripes clearly delimited.

Poiana leightoni. Sympatric. Smaller; ears large and rounded; spots smaller and dark, no mid-dorsal line.

Distribution Endemic to Africa. The range of this species is poorly known due to cryptic and nocturnal habits and a paucity of field studies (23 specimens in collection), but it is largely restricted to the forests of the Upper Guinea rainforest block in West Africa, having been sighted and collected in Liberia (Harbel, Putu Mts, Cavally R., Kpeaple, Bo, Tappita, forest south of Freemantown, Sapo N. P.), Guinea (Kolenté Plates, Macenta, Ziama Forest, Mt Nimba), Côte d'Ivoire (Yalé, Mt Nimba, Tai N. P.) and Ghana (Tarkwa) (see Gaubert *et al.* 2002a). There are no confirmed records from Sierra Leone, but they probably do occur.

Habitat Inhabits dense rainforest. In Tai N. P., frequently observed in wetland areas including swamp forest (poor drainage areas dominated by prop-root trees and raffia palms) and riverine habitat (A. E. Dunham pers. obs.). A specimen collected in a region of moist woodlands and

Genetta johnstoni

savanna (Kolenté Plates, Guinea) makes its restriction to rainforest questionable (Gaubert *et al.* 2002a), and indeed an ecological niche modelling study by Papes & Gaubert (2007) found that Johnston's Genet has a larger potential geographical range than other rainforest genets from West Africa.

Abundance Little is known about the abundance of this species. However, frequent sightings in Taï N. P. near the Centre de Recherche en Ecologie Tropicale (CRET) Station suggest it may be locally abundant, at least in protected areas of suitable habitat (also suggested by museum collections for Ziamia F. R. and Mount Nimba Biosphere Reserve; P. Gaubert pers. obs.).

Adaptations The densely spotted and dark general colouration (especially on the limbs) is characteristic of forest genets, providing camouflage against the uneven patterning of light in a forest environment. The constriction of the zygomatic arch, flattening of the mandible, reduction of the jugal teeth and inflection of the angles of upper and lower incisors suggest adaptation to an insectivorous diet (Kuhn 1960; and see Rosevear 1974, Crawford-Cabral 1981, and Lamotte & Tranier 1983).

Foraging and Food No information, but probably insectivorous as suggested by dentition.

Social and Reproductive Behaviour Radio-tracking data of two individuals and frequent nocturnal sightings in Taï N. P. suggest that this species is mainly solitary and nocturnal. Pairs are occasionally sighted. During the day, it sleeps in tree holes or on large branches in the canopy. Over a period of one month, a radio-collared ♀ returned before dawn each day to sleep in the canopy of a single tree (approximately 20 m high). A radio-collared ♂ was observed sleeping in different trees each night over a period of several weeks (A. E. Dunham pers. obs.). Males are possibly non-

territorial or have larger ranges. Additional information concerning the social or reproductive behaviour of Johnston's Genet is lacking.

Reproduction and Population Structure An adult ♀ caught in late Jul from Taï N. P. showed signs of having recently finished lactating (healing bite marks and hair loss around teats but no milk produced). Assuming a typical lactation period of six months, her young may have been born in Jan or Feb, corresponding with the end of the dry season. Juvenile genets have been observed in Taï N. P. in early Jun; however, species identity was equivocal. Although it is unknown if breeding is seasonal in this species, the timing of reproduction in similar species (Common Genet *G. genetta* and Cape Genet *G. tigrina*) coincides with the wet season, presumably linked with a peak in insect abundance (Taylor 1969). The number of young has not been recorded, although the presence of only two teats suggests that a litter-size greater than two is unlikely.

Predators, Parasites and Diseases Crowned Eagles *Stephanoaetus coronatus* have been reported to prey upon Johnston's Genet in Taï N. P. (Shultz 2002) and may be an important predator throughout their range. Johnston's Genets sleep in the canopy during the day, which may make them particularly vulnerable to other large aerial predators. Remains of viverrids have also been found in scats of Leopards *Panthera pardus* within the range of this species (Jenny 1996).

Adult ticks (*Haemaphysalis moreli*), common parasites on civets and genets in tropical rainforests, were found on specimens from Taï N. P., together with a less specialized species, *Ixodes cumulatimpunctatus* (J.-L. Camicas pers. comm.). Diseases afflicting Johnston's Genet have not been recorded.

Conservation IUCN Category: Vulnerable A2cd. CITES: Not listed.

Johnston's Genet is considered a rare species with a restricted area of occurrence. Because of the lack of field surveys and the cryptic nature of this animal, it is unclear whether this species is common within its limited range or habitat. Intensive deforestation resulting from agriculture, logging and mining pressures has reduced the once continuous forest stretch of the Upper Guinean forest zone to a few remaining blocks of intact forest. Severe hunting pressures may also be affecting populations of Johnston's Genet. Animals are taken by commercial and local hunters for the sale of both meat and skins. In Man, Côte d'Ivoire, skins are used for making purses (P. Gaubert & C. Crémère pers. obs.). Skins of Johnston's Genet (together with Pardine Genet) can also be used for traditional ceremonies (associated with masked dancers at funeral celebrations in Gouléako Dioula, Côte d'Ivoire; A. E. Dunham pers. obs.). Hunting of genets is intense even within protected areas, including Mt Nimba (Lamotte 1998), Ziamia Forest (Wilson 1992) and Taï N. P. (Hoppe-Dominik 1990, 1997). Ecological data and field surveys are needed to determine which habitats are occupied by this species and whether secondary growth and moist woodland areas provide suitable habitat.

Genetta maculata LARGE-SPOTTED GENET (BLOTCHED GENET)

Fr. Genette commune à grandes taches (Genette à taches rousses); Ger. Gemeine Grossfleckgenette (Rostfleckgenette)

Genetta maculata (Gray, 1830). Spicil. Zool. 2: 9. 'in Africa Boreali' [changed to '6 km from Hirna (Harrar Road, 2180 m), Ethiopia' by Gaubert *et al.* 2003a] (see Taxonomy for type locality).

Large-spotted Genet *Genetta maculata*.

Taxonomy First described from a living specimen kept at the Tower of London Menagerie, the type specimen seems absent from any current collection. Schwarz (1930) modified the type locality to 'interior of Senegal', but without argument or justification (Rosevear 1974, Schlawe 1981). Another name used to designate the species over the past 20 years has been *rubiginosa*, but Schlawe (1981) and Crawford-Cabral & Pacheco (1992) have shown that this name is invalid. In order to maintain consistency and introduce stability in the use of species names, Gaubert *et al.* (2003a, b) erected a neotype for *G. maculata*, thus fixing its type locality to a non-ambiguous location. This suggestion is in accordance with Article 75.5 (Replacement of unidentifiable name-bearing type by a neotype) of the International Code of Zoological Nomenclature (1999). The proposed neotype is a female specimen (skull and tanned skin), collected 6 km from Hirna (Harrar road, 2180 m), Ethiopia, on 20 March 1971, during the third 'Mission en Ethiopie' conducted by J. Dorst. It is deposited and catalogued at the Muséum National d'Histoire Naturelle of Paris (MNHN – CG 1972-395). Nevertheless, a recent statement of ICZN (2007) ruled that the specific name *maculata* Gray, 1830 should not be conserved.

There has been considerable debate about the taxonomic delimitations within the large-spotted genet complex (see Gaubert 2003a, Gaubert *et al.* 2003a, b, 2004a, b, 2005b, c, Fernandes & Crawford-Cabral 2004, Grubb 2004b, and Wozencraft 2005 for discussion). Suffice it to say that analyses of discrete morphological characters and skull morphometrics have provided strong evidence for establishing species-level boundaries between *G. maculata* and the Cape and Pardine Genets, *G. tigrina* and *G. pardina*, of South and West Africa respectively (Crawford-Cabral 1980–81, Schlawe 1981, Crawford-Cabral & Pacheco 1992, Gaubert *et al.* 2001). Even so, *G. maculata* appears to constitute a super-species comprising several valid species (Crawford-Cabral 1980–81, Crawford-Cabral & Pacheco 1992, Crawford-Cabral & Fernandes 1999, 2001), including the form *letabae* from south-east Africa (see Gaubert *et al.* 2004a, 2005c), but further studies are required to clarify the structure of *G. maculata* populations before taxonomic conclusions can be drawn. The lineage leading to the clade grouping *G. maculata* and *G. tigrina* is estimated to have diverged in the middle Pleistocene (Gaubert & Begg 2007).

Proposed synonyms: *aequatorialis*, *albiventris*, *deorum*, *erlangeri*, *fieldiana*, *gleimi*, *insularis*, *letabae*, *matschiei*, *mossambica*, *pumila*,

Lateral view of skull of Large-spotted Genet *Genetta maculata*.

schraderi, *soror*, *stuhmanni*, *suahelica*, *zambesiana*, *zuluensis*. Chromosome number: $2n = 52$ ($FN = 96$) (specimen from Ethiopia; Gaubert *et al.* 2004a).

Description A slender genet. Sexes similar in colour and size. Facial mask well marked, with a thin dark vertical line on the muzzle. Sub- and supra-ocular white spots contrasting with the dark muzzle. Pelage relatively short and soft. Ground colouration extremely variable: sandy-grey, pale yellow, rufous-grey and grey-yellow. Throat, chest and ventral pelage whitish-grey to pale yellowish. Nuchal stripes well defined. Mid-dorsal line same colour as spots, and begins after the shoulder. No erectile dorsal crest (hair short). Spots or blotches black to rufous-brown and very variable in shape and size, some specimens having two colourations (mid-dorsal spots rufous-brown and spots of the flanks black). Spots of the first two dorsal rows rounded to squared, and sometimes coalesced at the rump. Hair of the scapula with air spaces interspersed within the globular medulla. Hindlimbs and forelimbs of similar ground colouration and well spotted. Posterior region of hindlimbs densely covered in dark hairs, this colouration extending to the under part of the hindfeet and bordering the toes but much less markedly than in the Common Genet *G. genetta*. Upper parts of forefeet and hindfeet lightly spotted. Under parts of forefeet same as ground colouration. Tail relatively short (ca. 80–90% of HB) with short hair, and distinctly annulated with seven to nine pale rings. Elongated dark tip caused by a suffusion of one or two of the last pale rings with dark hairs. In juveniles, coat densely spotted and general pattern very irregular. Two pairs of nipples.

The skull is of medium size, with a thin sagittal crest and a narrow interorbital constriction. The caudal entotympanic bone is not ventrally inflated. The lingual cusp on P^3 tends to be reduced, but is more marked than in the Cape Genet.

Geographic Variation The extreme variability of size, coat patterns and colouration, within specimens from the same region and sometimes, possibly, from the same litter (e.g. Kingdon 1977), confuses attempts to determine valid subspecies on the basis of morphological considerations. However, the craniometrical work of Crawford-Cabral & Fernandes (2001) proposes at least three distinct taxa in southern Africa:

G. m. letabae: NE Namibia, SW Zambia, South Africa. Differs from *zambesiana* by its larger size and larger dorsal spots (J. Crawford-Cabral pers. comm.). This form was considered a distinct species

following the morphometric and DNA study of Gaubert *et al.* (2005b).

G. m. zambesiana: Mozambique, Malawi, Zimbabwe and Angola. Matschie (1902) described *zambesiana* as being characterized by nine small and narrow spots in the first dorsal row.

G. m. 'mossambica': misuse of subspecies name (see *G. angolensis* profile). Mozambique (Boror). Narrow spots, dark tonalities. Probably relatable to *zambesiana*.

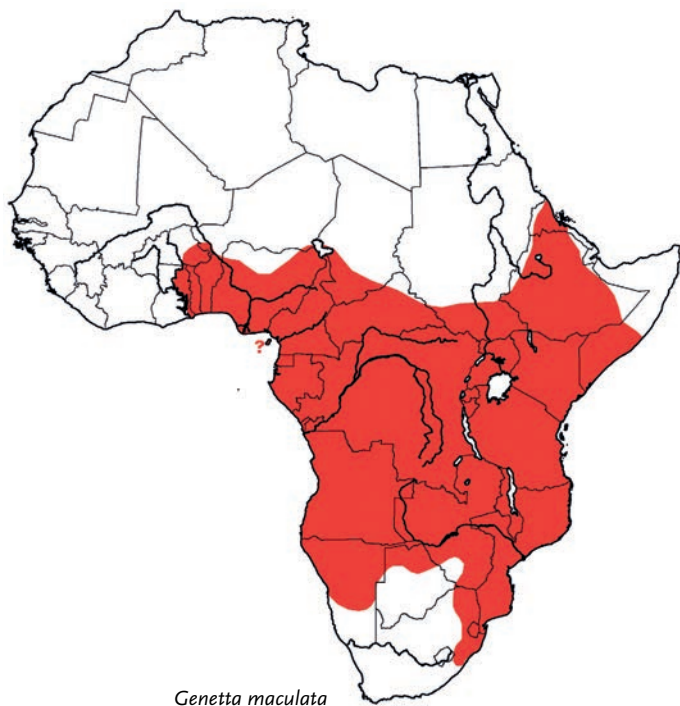

Distinctions amongst East African forms (e.g. *stuhmanni*, *schraderi*, *aequatorialis*, *matschiei*, *pumila*, *deorum*) rely on the colouration of the hindlegs, the number of spots in the first and second rows and the relative breadth of the second caudal ring (J. Crawford-Cabral pers. comm.), thus making the discrimination of clear morphological entities very subjective. Melanistic specimens regularly occur in central and East Africa (e.g. DR Congo, Kenya, Burundi, Tanzania).

Similar Species

- Genetta thierryi*. Sympatric. Smaller; dark rings of the tail rufous-brown, mid-dorsal line split longitudinally by a line of pale hairs.
- G. abyssinica*. Sympatric. Smaller; mid-dorsal line split longitudinally by a line of pale hairs, first rows of mid-dorsal spots fused in stripes.
- G. servalina* and *G. cristata*. Sympatric. Back and flank densely spotted, regular annulation with bright rings to the tip.
- G. victoriae*. Sympatric. Larger; mid-dorsal line only suggested by a median row of spots, back and flank densely spotted.
- G. genetta*. Sympatric. Pelage longer, mid-dorsal line with long erectile hairs; dorsal spots narrow and mainly coalesced; tip of the tail whitish.
- G. pardina*. Occurs west of Volta R., but eastern range limit unknown. Larger. Dorsal spots large and not coalesced.
- G. poensis*. Sympatric. Dorsal spots greatly fused in various parts of body; nuchal stripes not clearly delimited.
- G. angolensis*. Sympatric. Pelage longer, mid-dorsal line with long erectile hairs; feet very dark.
- G. tigrina*. Narrow hybrid zone in KwaZulu–Natal in South Africa (Gaubert *et al.* 2005b). Mid-dorsal line with longer hairs and always dark; mid-dorsal spots large and not coalesced.

Distribution Endemic to Africa. Ranges from north and east of the Volta R. east to the wet regions of Eritrea and Somalia (presence uncertain in Djibouti). The exact northern limits of their range are poorly known, but they reach the Sudanian–Sahelian savannas (Zakouma N. P., Chad; R. Cornette pers. comm.) and L. Chad. Ranges southwards to C Namibia and KwaZulu–Natal (see Gaubert *et al.* 2005c). Possibly present on Bioko I.

Habitat A ubiquitous genet, which can be found in miscellaneous habitats such as rainforest (but usually in open corridors and secondary growth), swamp zones, riverine vegetation, open and closed woodlands, moist forests, savanna–forest mosaics, thickets and even grassy savanna (Smithers 1971, Kingdon 1977, Yalden *et al.* 1996). The Large-spotted Genet avoids extremely dry savanna and truly arid regions, preferring habitats close to water, whereas the Common Genet inhabits drier habitats (Rautenbach & Nel 1978). Opportunistic and commonly occurs in cultivated areas, farmlands and suburban areas (Kingdon 1997, Angelici *et al.* 1999a,

b). Sightings of this species in undisturbed dense rainforest could be due to misidentifications of other genet species, although specimens clearly attributable to this species have been trapped both in primary and secondary rainforests in Nigeria (Angelici *et al.* 1999a, b). According to Nigerian hunters, the best places to capture this species are mixed and mosaic habitats, i.e. the ecotone between rainforest and open fields or between rainforest and cultivated lands (F. M. Angelici pers. comm.). A recent ecological study found that the presence of this species in Nigeria is positively correlated with 'derived savanna', 'oil palm plantations' and other altered habitats, whereas it is negatively correlated with various types of forests (Angelici & Luiselli 2005). The species can often be seen foraging in open habitats, but always near a forested place. Can live at relatively high altitudinal ranges, for example, to 3400 m in the Simien Mts, Ethiopia (Yalden *et al.* 1996), Kilimanjaro, Tanzania (Grimshaw *et al.* 1995), and Mt Kenya (more than 3300 m – BMNH specimen; Young & Evans 1993).

Abundance Relatively common. In Swaziland, this is the most common nocturnal carnivore and occurs at higher densities in protected areas (4.5/km²) than on private ranches (0.3/km²) (Monadjem 1998). May evade observation partly because of its nocturnal and elusive habits. Census techniques greatly influence the frequency of sightings as does habitat and the time of night or year in which observations are attempted. In Bayelsa State, SE Nigeria, where this species is present, sightings are not common (only three contacts for 67 nights of transect survey using spotlights) (F. M. Angelici & L. Luiselli pers. obs.). However, it is rather common in bushmeat markets and frequently trapped by local hunters (Angelici *et al.* 1999b, c).

Adaptations This species is both terrestrial and arboreal. Duckworth (1995) reported that 36 of 41 animals seen in Nechisar N. P. in Ethiopia were on the ground, but they are accomplished

climbers and may regularly be seen climbing amongst clumps of foliage to hide or taking shelter in the forks of branches (Smithers 1971, Kingdon 1977).

This species is predominantly nocturnal, resting up during the day in trees, hollow logs, under tree roots, in disused burrows of Aardvark *Orycteropus afer* or springhares *Pedetes* spp., under piles of boulders, rock overhangs, caves, as well as man-made shelters (e.g. roofs of houses, stacked hay bales). Resting sites are re-used by both sexes. In the Rift Valley, Kenya, and Omo N. P., Ethiopia, genets were recorded to be more active between sunset and midnight than during the day (Ikeda *et al.* 1982, Fuller *et al.* 1990).

A low basal metabolic rate and a high thermal conductance may allow the reduction of heat storage when resting in burrows during the day (Henneman & Konecny 1980). This species shows an unusual occurrence in the urine, namely the presence of sulphocysteine, a sulphur amino-acid derived from the conversion of excessive amounts of sulphite (which is an important intermediary compound in the metabolic pathway from sulphur amino acids to inorganic sulphate), but the adaptive value of this peculiarity is unknown (Crawhall & Segal 1965). Anal sacs contain two complexes of sebaceous glands involved in a steroidogenic function (Kayanja & Schliemann 1981). As with the Pardine Genet, distinctively coloured forest forms might be morphotypes adapted to rainforest.

Foraging and Food The Large-spotted Genet is an active and versatile predator, foraging both in trees and on the ground; they are solitary, foraging mainly by night and occasionally during bright moonlight (Waser 1980). Prey are caught by careful stalking followed by a final pounce and are bitten several times, and sometimes shaken, before being killed (Happold 1987, Skinner & Chimimba 2005). It is mainly carnivorous although vegetable matter is often present in the diet. In some parts of its range, fruits, seeds and berries can be an important source of food. The animal prey spectrum includes terrestrial and aquatic gastropods, bivalves, centipedes and millipedes, spiders, scorpions, insects, crustaceans, fish, amphibians, reptiles (including lizards and snakes), small birds and eggs, and mammals up to the size of a hare. Extrapolating from its low basal

Large-spotted Genet *Genetta maculata*.

metabolic rate, Henneman & Konecny (1980) proposed that it could be less carnivorous than previously suggested.

It seems that the Large-spotted Genet, like the widespread Common Genet, is able to adapt its diet to prey availability, rodents generally constituting the main source of energy. For example, in a sample of 136 stomachs from Zimbabwe, from all seasons, murids had a 68% occurrence (with multimammate mice *Mastomys* spp. the primary prey), followed by insects (40%), birds (15%), arachnids (9%), reptiles (8%), wild fruits (8%), shrews (3%), centipedes (3%), amphibians (2%), lagomorphs (1%) and fish (1%) (Smithers & Wilson 1979). On the other hand, in Botswana, insects predominated (90% occurrence), followed by murids (47%, with the Pouched Mouse *Saccostomus campestris* the most frequent prey), arachnids (27%), wild fruits (17%), centipedes (10%), birds (7%) and reptiles, amphibians and other arthropods (1% each) (Smithers 1971). In both samples, insects were represented mainly by Coleoptera, Orthoptera and Isoptera; Lepidoptera and Hymenoptera (Formicidae) were present in few numbers in Zimbabwe. The prevalence of insects in the Botswana sample could indicate a bias against murids, as a high proportion of the sample was taken at the end of a four-year drought, when murid numbers were low (Skinner & Chimimba 2005).

According to studies in the Shimba Hills in coastal Kenya, the Large-spotted Genet can be rather frugivorous and plays a considerable role in seed dispersal (Engel 1998b, 2000). In 515 defaecations collected from two genet latrines over a period of 31 months, seeds and other fruit remains had a relative occurrence of 74% versus 82% for arthropods and 44% for other food remains (i.e. small mammals, reptiles, birds, snails, leaves). In this area the genets fed on fruits of more than 40 species, many of which were common and shared with the African Civet *Civettictis civetta* and other frugivores; comparative diet analyses indicated niche overlap as well as specific niche separation (Engel 2000).

Males have been reported to kill poultry with greater frequency than ♀♀ and have been supposed to become addicted to this kind of foraging (Carpenter 1970). In Zimbabwe, five of 11 identified birds from stomach contents were domestic fowls (pheasants, young peafowl, pigeons and chickens) (Smithers & Wilson 1979). There is little to suggest that they take carrion, although Rautenbach (1982) recorded the presence of carrion and maggots in stomachs from South Africa. Carpenter (1970) reported two cases in KwaZulu–Natal where genets captured bats (genera *Eptesicus*, *Scotophilus* and *Rhinolophus*) at a fairly high frequency (about six individuals per night). These observations confirmed data of Azzaroli & Simonetta (1966), who found two bats (genus *Tadarida*) in the stomach of a specimen from Somalia, and Rautenbach (1982), who recorded the Cape Pipistrelle *Pipistrellus capensis* in one stomach. Lack (1977) reported a case of unidentified genets feeding on tree nectar in Ghana.

Recently, Angelici & Luiselli (2005) examined 56 stomachs from SE Nigeria. Among small mammals, the following species were recorded: Tullberg's Soft-furred Mouse *Praomys tullbergi*, *Cricetomys* sp. (juv.), West African Pygmy Mouse *Mus musculoides*, Spotted Grass-mouse *Lemniscomys striatus*, Peters's Striped Forest Mouse *Hybomys univittatus*, *Dendromus* sp., Nigerian Shrew *Crocidura nigeriae*, Fraser's Musk Shrew *Crocidura poensis* and *Crocidura* sp. Among insects, Orthoptera were recorded from 11 stomachs and Coleoptera from eight, while other food items included birds and bird eggs, reptiles, fruits and seeds, other insects, centipedes and spiders. Analysis of

biomass contributions indicated that the young giant rats (*Cricetomys* sp.) were the most important prey type, and Tullberg's Soft-furred Mouse was the second most important prey type. In other forest habitats in Nigeria, genets were supposed to be mainly carnivorous, feeding on small vertebrates, and possibly also on eggs, invertebrates and fruits (Happold 1987).

Angelici (2000) calculated food niche overlap values between different species in Nigeria and these indicated that the diet of the Large-spotted Genet was most similar to that of the African Civet, with approximately 70% of the diet in common. A multivariate statistical model on diet composition suggested that the highest potential for inter-specific competition should have concerned this species and the Egyptian Mongoose *Herpestes ichneumon*. Yet, despite obvious niche separation, figures showed that the Large-spotted Genet and the Marsh Mongoose *Atilax paludinosus* had about 61% of their diet in common in Nigerian rainforests. Angelici & Luiselli (2005) indicate that Large-spotted Genets and Crested Genets *Genetta cristata* are grossly similar in terms of dietary preferences, and simulation analyses suggest that competition for food should be relatively high, because about three-quarters of the quantitative diets of the two species were identical. However, the similarity between species is proportionally less evident when biomass is considered. Moreover, it is noteworthy that both species are differently influenced by various environmental factors. This result seems clearly to suggest that, whereas the Large-spotted Genet prefers altered or secondary habitats, the Crested Genet inhabits preferentially primary dry forests, bush-mango plantations and other forest types.

In KwaZulu–Natal this species also has strong spatial niche overlap with both the Marsh Mongoose and Slender Mongoose *Herpestes sanguineus* (Maddock & Perrin 1993). None the less, its nocturnal way of life and use of the vertical dimension probably enables this genet to avoid competition with mongooses.

Social and Reproductive Behaviour It is not clear whether this species is territorial (see Rosevear 1974, Estes 1991), but it seems that ♂♂ defend ranges that overlap those of several ♀♀ (Estes 1991). Carpenter (1970) reported genets using regular latrine sites in KwaZulu–Natal, which was confirmed by Engel (1998a) from Kenya. Furthermore, some ground latrines are shared between genets, civets and some mongoose species (Engel 2000). Females released 35 km away from capture sites returned home within a few days (Carpenter 1970). These data indicate probable territoriality, at least in ♀♀, as in the Common Genet. Males may wander within ranges as large as 500 ha (Carpenter 1970), whereas ♀♀ seem more territorial, with ranges nearing 25 ha. In a radio-tracking study carried out in the Rift Valley, Kenya, five genets were reported to range over areas from 100 to 1000 ha (mean values: ♂♂ 590 ha; ♀♀ 280 ha). Home-ranges overlapped between sexes (Fuller *et al.* 1990). Territories are marked with secretions from the perineal glands, urine and faeces (which include secretions from the anal glands). Tree scratching possibly also plays a role in marking.

Although primarily solitary, pairs are seen during the breeding season. Males, after having sniffed the vulva of the ♀, urinate and/or deposit musk, and exhibit a facial grimace. This facial attitude is provoked by the sensitivity of the vomeronasal organ of the ♂ to the pheromones produced by the ♀. A courting ♂ follows the ♀ closely, and produces grumbling and couching calls. At the beginning, the ♀

keeps turning away from the ♂, tail and hindquarters low, and flees. However, she may eventually answer the male's calls and allow him to come into close contact. Once in contact, both partners sniff their faces and genitalia, and rub their cheeks. The ♀ holds the tail up, and, as a mating signal, crouches with raised hindquarters and tail deflected sideways. The ♂ clasps the ♀ on the groin area with chest and belly resting on her lower back, and intromission occurs with pelvic thrusting as the ♀ curves her spine. The ♂ may sometimes bite the neck of the ♀ during the final seconds of the copulation, which usually lasts five minutes. Coupling pairs often meow. At the end of the copulation, the ♀ may anal-drag and roll on her back, and both partners lick their genitals (Dücker 1965). Births take place in hollow trees, nests of leaves and even under roofs in urbanized habitats (Estes 1991, Skinner & Chimimba 2005).

Reproduction and Population Structure Two breeding peaks have been reported from Kenya, the main peak between Oct and Dec, and a second peak between Mar and May (Taylor 1969). In coastal Kenya, Engel (1998b) trapped a genet and witnessed the birth of one kitten before late Dec at the beginning of the dry season. In South Africa, Pienaar (1964) reported a litter of three young in Feb from Kruger N. P., Rautenbach (1982) recorded two gravid ♀♀ in Nov, both with three fetuses (2L : 1R), and Rowe-Rowe (1971) estimated births to occur between Aug and Mar in KwaZulu-Natal. Elsewhere in southern Africa, there are records of three kittens (two weeks old) found in a hollow tree in N Namibia in Oct (Shortridge 1934), births from Aug to Feb in Zimbabwe and a single ♀ lactating during Feb in Botswana (Smithers 1971); juveniles estimated to be four weeks old were taken in Oct and Nov in Zambia (Ansell 1960a). These data suggest that the breeding season extends from Aug to Mar in southern Africa (Skinner & Chimimba 2005); pregnant ♀♀ from the northern part of the southern African sub-region were caught carrying 2–5 fetuses (average 2.9; n = 10) (Skinner & Chimimba 2005).

The time of gestation is recorded to last 70–77 days (Taylor 1969, Happold 1987, Estes 1991). Neonates are blind but already covered with hair so the coat pattern is readily discernible (Happold 1987). Eyes open at ten days and canines erupt at four weeks. They are shed after the permanent canines have erupted just prior to attainment of asymptotic mass at 11 months (Rowe-Rowe 1971). The mother licks her kittens anogenitally, and consumes their excrements (Estes 1991). Young genets begin to take solid food at about six weeks. Rowe-Rowe (1971) reported that a captive individual started killing prey and eating live vertebrates at about 28 weeks. Longevity is up to ten years (Mitchell 1911, Flower 1931, Anonymous 1960, Depierre & Vivien 1992).

Predators, Parasites and Diseases Predators are likely to include both terrestrial (e.g. large cats, large canids, Spotted Hyenas *Crocuta crocuta*) and aerial (eagles, eagle-owls) species. Miscellaneous parasites may affect the species, including: *Dirofilaria genettæ* (in connective tissue), *Ascaris* sp., *Linguatulidae* sp., *Ctenophalides conversus* and *C. craterus* (external parts of the body) and *Dipylidium gervaisi* (intestines) (Stiles & Baker 1935).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although it is possible that genets may be undergoing some localized declines in a few areas, they have a wide distribution range,

occur in a variety of habitats and are present in many protected areas on the continent. They are hunted and trapped for bushmeat; in a large study area comprising four regions of SE Nigeria, 22 specimens were found in markets or in the possession of local hunters during a period of 213 days (Angelici 2000). Since genets do have a bad reputation as poultry thieves, farmers sometimes poison or trap this species (e.g. in southern Africa; see Stuart 1990) and they are also occasionally killed by domestic cats and dogs.

Genetta pardina PARDINE GENET (WEST AFRICAN LARGE-SPOTTED GENET)

Fr. Genette pardine (Genette à grandes taches d'Afrique de l'Ouest); Ger. Westafrikanische (Grossfleckgenette)

Genetta pardina I. Geoffroy Saint-Hilaire, 1832. Mag. de Zool. I. Mammifères 1832–1838: Cl. I, pl. 8. 'intérieur du Sénégal'.Pardine Genet *Genetta pardina*.

Taxonomy Described from a living female specimen at the Ménagerie du Jardin des Plantes, Paris. The species has long been considered synonymous with other large-spotted genets (*G. maculata*, *G. tigrina*) and continues to be so regarded by a number of authors. However, following comprehensive morphological and molecular studies, this species is here recognized as a distinct species (Crawford-Cabral 1980–81, Gaubert 2003a, Gaubert *et al.* 2004a, b). The forest 'forms' *poensis*, *schoutedeni* and the recently described *bourloni* constitute a distinct clade not directly related to *pardina* (see Gaubert 2003a, Gaubert *et al.* 2004b, 2005c, Wozencraft 2005). The form '*schoutedeni*' (provisional name) was considered a distinct species by Gaubert (2003a) and Gaubert *et al.* (2004b) and is characterized by dorsal spots not fused, feet bright, tail distinctly annulated, and skull with caudal entotympanic bone extremely inflated. The taxonomic and geographic status of this form is still in need of further investigation, and is not treated here. The Pardine Genet lineage is estimated to have diverged during the Early to Middle Pleistocene (Gaubert & Begg 2007). The specific epithet is the diminutive of the Latin *pardus* (leopard). Synonyms: *amer*, *dubia*, *pantherina*. The series of specimens representing *genettoides* Temminck, 1853, may represent hybrids between *G. pardina* and Large-spotted Genet *G. maculata* (Gaubert 2003a) and the name is probably best considered *incertae sedis*. Chromosome number: $2n = 52$ (Couturier & Dutrillaux 1986). Specimen karyotyped under the name *G. maculata*, but proved to belong to *G. pardina* after DNA analysis (see Gaubert *et al.* 2004a, b).

Description A heavily built genet. Sexes similar in colour and size. Facial mask well marked, with a thin dark vertical line on the muzzle. Sub- and supra-ocular white spots contrasting with the dark

muzzle. Ear broad-based and slightly rounded. Pelage relatively short and rough. Ground colouration from yellowish-grey (Guinea) to pale or sandy-grey (Senegal, Côte d'Ivoire). Throat, chest and ventral pelage whitish-yellow to grey. Nuchal stripes well defined. Mid-dorsal line wide and dark without long crest hairs, beginning after the shoulder. Dorsal spots elongated and squared, either dark brown or brown-rufous, not coalesced and bordered by a dark ring. First two rows form a line of separated spots. Width of spots equal to the mid-dorsal line. Hindlimbs and forelimbs same colour as the ground colouration and well spotted. Upper parts of the forefeet spotted; upper parts of the hindfeet unspotted. Underparts of feet dark-brown. Tail shorter than the other genets (ca. 70–80% of HB), thickly furred but hair relatively short, and annulated with 6–7 pale rings. Tip of tail with an elongated dark ring caused by the reduction of the last pale ring (7th or 8th). Hairs of the scapula with a globular medulla containing no air spaces. In juveniles of six months, pattern of spots similar to adult but spots of the flank, thigh and shoulder smaller and darker. Two pairs of nipples. The skull is large, with thin sagittal crest and caudal entotympanic bone ventrally inflated.

Geographic Variation None recorded.

Similar Species

- Genetta johnstoni*. Sympatric. Smaller; dorsal spots rufous-red and coalesced; tail annulated with pale rings to the tip.
- G. thierryi*. Sympatric. Smaller and paler; dorsal spots and dark rings of the tail rufous-brown, mid-dorsal line split longitudinally by a line of pale hairs.
- G. genetta*. Sympatric. Longer hair especially on the dorsal crest and tail; dorsal spots thinner and partially merged into lines; tuft of the tail whitish.
- G. poensis*. Sympatric. Dorsal spots greatly fused in various parts of body; tail half part dark; nuchal stripes not clearly delimited.
- G. bourloni*. Sympatric. Dorsal spots partly coalesced at the rump; almost half of the tail completely dark.
- Poiana leightoni*. Sympatric. Smaller; ears large and rounded; spots smaller and dark, no mid-dorsal line.

Distribution Endemic to Africa, with a continuous range in the West African Sudanian and Guinean zones from Senegal to Ghana. The eastern boundary is uncertain. Crawford-Cabral (1980–81) suggested the Volta R. as a possible barrier to the species; however, further studies are needed in the Dahomey Gap region in order to define its eastern range limits and to determine possibilities of overlap or hybridization with the Large-spotted Genet.

Habitat Occurring in a wide range of habitats, but generally restricted to moist, closed habitats such as primary and secondary rainforests, gallery forests and moist woodlands. Also occurs in forest plantations, bush-lands and suburban areas (Coe 1975, Hoppe-

Dominik 1990, Sillero-Zubiri & Marino 1997). Rosevear (1974) suggested that the species could be present in drier open woodlands.

Abundance Thought to be common within its range, but status unknown (Hoppe-Dominik 1990, Grubb *et al.* 1998). Night-time field surveys carried out from a vehicle in Niokolo-Koba N. P. (Senegal) led to an estimated frequency of occurrence of 0.70/100 km (Sillero-Zubiri & Marino 1997). However, the nocturnal and discrete habits of this species might result in artificially low count estimates.

Adaptations Ground colouration seems to depend on habitat (yellow-rufous in forest and moist woodland, and greyer and paler in open woodland and savanna), possibly resulting in crypsis in different environments.

Foraging and Food Diet thought to be similar to that of the Common Genet *G. genetta*, but includes more invertebrate prey and fruit (Sillero-Zubiri & Marino 1997, Grubb *et al.* 1998). Rodents are suspected to be the main staple. A specimen collected in Adopodioumé, Côte d'Ivoire, had its stomach filled with remains of *Lophuromys* sp. (Brush Furred Mice), insects, palm fruits and grass (Rahm 1961). Several individuals were seen regularly lapping the nectar of a savanna tree *Maranthes polyandra* in Mole N. P., Ghana, possibly transferring pollen (Lack 1977) (however, species identity is uncertain because records are from a possible contact zone with the similar Large-spotted Genet; see Gaubert 2003a).

Social and Reproductive Behaviour The Pardine Genet is solitary and nocturnal. As a forest and woodland species, presumed to live mostly in trees (Jones 1966). However, no field

observations or morphological investigations have yet supported this supposition. Rosevear (1974) supposed that it more frequently makes use of rock crevices for shelter and breeding than do the high-forest genets like Johnston's Genet *G. johnstoni* or Servaline Genet *G. servalina*. Additional information is lacking.

Reproduction and Population Structure Poorly known. Two one-month-old juveniles were found in the Lamto region, Côte d'Ivoire, in Apr and one subadult ♂ in Jun (Bourlière *et al.* 1974). Another subadult specimen deposited at the Muséum National d'Histoire Naturelle of Paris (CG 1911-838), originated from Côte d'Ivoire and was collected in Jul (its age was estimated at 5–6 months). Thus, a birth period or peak ranging from about Jan to Mar is possible. Maximum longevity recorded in captivity nears 10 years (Mitchell 1911, Flower 1931, Anonymous 1960).

Predators, Parasites and Diseases Probably susceptible to predation from aerial raptors and larger carnivores. Sambon (1922) recorded *Armillifer armillatus* (Linguatulidae) as a parasite of the species. Ixodid ticks (*Haemaphysalis rugosa*) specializing on Viverridae were found on specimens from moist woodlands of Senegal (Camicas 1978). Adult ticks (*Haemaphysalis moreli*), chiefly hosted by civets and genets, were found in W Côte d'Ivoire and E Senegal (Camicas *et al.* 1972).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Assumed to be common within its limited range, and at least present in several protected areas. Bourlière *et al.* (1974) noted that skins were often seen in the surrounding villages of the Lamto region, Côte d'Ivoire. This statement can be broadened to all the West African bushmeat markets. Coe (1975) reported great pressure on the species by local hunters (Mano tribe, Liberia).

Genetta piscivora AQUATIC GENET

Fr. Genette aquatique; Ger. Wasserschleichkatze

Genetta piscivora (J. A. Allen, 1919). J. Mammal. 1: 25. 'Niapu, Belgian Congo' [DR Congo, Niapu, 2° 25' N, 26° 28' E)].Aquatic Genet *Genetta piscivora*.

Taxonomy Monotypic species. First named (in the genus *Osbornictis*) for H. F. Osborn, president of the American Museum of Natural History; *piscivora* contains the Latin words *piscis* for fish and *vorare* for 'to devour'. Long included in *Osbornictis* (e.g. Van Rompaey 1988, Wozencraft 1993); Hunt (2001) even included it in a subfamily separate from *Genetta*. Gaubert *et al.* (2004c) suggested that *Osbornictis* and *Genetta* are congeneric, in agreement with Verheyen (1962) and Stains (1983), and this classification was adopted by Wozencraft (2005). Estimated to have diverged in the middle Pliocene from a series of basal, rainforest genets (Gaubert & Begg 2007). Synonyms: none. Chromosome number: not known.

Description Dark rufous, unspotted genet with black, bushy tail. Head pale brown with reddish tinge; two yellowish to white spots on the forehead; front and sides of the muzzle and cheeks white. Eyes large. Rhinarium small, without a median sulcus. Vibrissae white, long, downwardly pointing. Ears exteriorly blackish, naked interiorly. Pelage long and dense. General colour uniform dark chestnut brown; underparts slightly lighter. Greyish underfur dense. Fore- and hindlimbs dull brown; upper surface of feet brownish-black. Feet small; sole of forefoot naked, and sole of hindfoot with distinct metatarsal pads (Gaubert *et al.* 2001, 2002b). Tail black and bushy with long (45–50 mm) black hairs and brownish-grey underfur (25–30 mm). The young are slightly darker.

Compared with the sympatric Giant Genet *Genetta victoriae* the dentition is generally frailer, there is a greater diastema between the premolars (which have high trenchant central cusps) and the molars are more reduced. Also shorter extension of the premaxillae in front of the canines, palatal breadth 10% narrower and abbreviated rostrum. The lingual cusp in the upper third premolar is absent.

Geographic Variation None recorded.

Similar Species

Atilax paludinosus. Larger, overall dark brown to blackish. The Aquatic

*Genetta piscivora*

Genet's typical colour and facial marking distinguish it clearly from sympatric *Genetta* species (including *G. maculata*, *G. servalina*, *G. victoriae*), which are characterized by having a spotted coat and ringed tail.

Distribution Endemic to DR Congo, from the right bank of the Congo R. eastward to the Rift Valley. Kingdon (1977) speculated that it might occur in W Uganda, and Verschuren (1978) cites an unlikely observation from Burundi (near Kigwena), but thus far no specimens have been collected outside DR Congo.

Habitat Occurs in shallow headwaters of streams, preferably clear and flowing over red clay and sand, as well as small brooks; seasonally limited to pools in rainforests between 460 and 1500 m. The species is discontinuously distributed within its range and most specimens were collected in forests dominated by Limbali (*Gilbertiodendron*) trees (Colyn & Gevaerts 1986). Nearly all specimens were obtained from local hunters who caught them with snares usually put out on trails near small rivers (Van Rompaey 1988).

Abundance Considered among the rarest of African carnivores, and known only from around 30 museum specimens. Both the Bambuti pygmies and neighbouring Bantu agriculturists consider the species to be very rare; in 53 hunts in the Ituri Forest only two individuals (or 1.8% of all carnivores) were captured (Hart & Timm 1978). According to hunters near Katshungu village it is not rare in the region north of Lugulu R. (Verheyen 1962) and also not rare between the Tshopo and Congo Rivers (Colyn & Gevaerts 1986).

Lateral, palatal and dorsal views of skull of Aquatic Genet *Genetta piscivora*.

Adaptations Crepuscular and nocturnal. Sharp narrow carnassial teeth are clearly adapted to deal with slippery vertebrate prey such as fish. Among viverrids olfactory bulbs range in volume from about 3 to 6% of total brain volume with a mean of 4.7%; they form only 3.5% for the Aquatic Genet. Relatively small olfactory bulbs seem to point to a relatively poor sense of smell, expected in a piscivorous species (Radinsky 1975a). Rests in fallen hollow trunks and riverside debris. Can climb sloping trunks up to a couple of metres but without a genet's climbing ability (A. Root pers. comm.). Small, naked feet and bushy tail do not seem adapted for actually swimming in the water but more for prowling around at the margins (W. Duckworth pers. comm.). As such, while able to swim, they do not do so readily and would not be required to do so in the shallow streams they favour (A. Root pers. comm.). The long vibrissae serve to attract insect-eating fish when touching the surface of the water.

Foraging and Food Piscivorous. Small pools or slowly flowing brooks are approached with an extremely slow, gliding stalk. The Aquatic Genet moves slowly along the edge alternately patting the surface (the wrist is bent back almost to the vertical and the surface struck with a downward pivoting action), and testing it with its vibrissae. Possibly the movement of the fish is detected this way, and/or the whiskers and patting action serve to attract the fish. Insect-eating fish such as barbels (*Barbus* spp.), up to 300 mm, catfish (*Clarias* spp.), talking catfish (*Synodontis* spp.) and cyprinids of the genus *Labeo* are caught with a rapid, open-mouthed strike and carried away (A. Root pers. comm.).

According to local hunters the Aquatic Genet also eats cultivated cassava tubercles (*Manihot* sp.) left to soak in small streams (Hart & Timm 1978), and crustaceans (see Schouteden 1950), which is

highly unlikely considering the sectorial teeth. Two adult captives never ate frogs, tadpoles or crabs but a bottle-raised youngster that had never seen the feeding behaviour of an adult tried to eat all three. None of them showed any interest in moths or beetles that flopped into the pools in their enclosure (A. Root pers. comm.).

Social and Reproductive Behaviour The Aquatic Genet seems generally to be solitary in its habits. Two specimens, a pregnant ♀ and an adult ♂, were captured only two-and-a-half weeks apart from the same local area of forest (Hart & Timm 1978). Faeces are deposited in genet-like middens, and urine on several marking spots. Appears to be able to co-exist with the Marsh Mongoose *Atilax paludinosus* (A. Root pers. comm.).

A captive ♂ and ♀ showed no signs of stress at living together in a 8 m × 8 m cage but occasionally would make very aggressive tom-cat-like miaows when the ♂ was pursuing the ♀ and trying to mate. They also had a chuffing call used to each other and their keeper (A. Root pers. comm.).

Reproduction and Population Structure Nothing is known about the reproduction of the Aquatic Genet except that a ♀ collected on 31 Dec contained one embryo 15 cm in length (Hart & Timm 1978).

Predators, Parasites and Diseases There is no information on predation on the Aquatic Genet. Out of 11 skulls examined, one showed frontal sinus damage probably due to a trematode, *Achillurbandia* sp. (Colyn & Van Rompaey 1989).

Conservation IUCN Category: Data Deficient. CITES: Not listed.

Legally fully protected in DR Congo (Ordinance No. 79-244 of 16 Oct 1979). Hunted as bushmeat by the Bambuti pygmies; the meat is taboo to all, except male elders (Hart & Timm 1978, Colyn *et al.* 1987). Present in Okapi N. P. and presumably in several other protected areas in its range. This species is a priority for further survey work to further investigate the limits of its distribution, its population status and precise habitat requirements, and other aspects of its ecology.

Genetta poensis KING GENET

Fr. Genette royale; Ger. Königs-Ginsterkatze

Genetta poensis Waterhouse, 1838. Proc. Zool. Soc. Lond. 1838: 59. 'Fernando Po' [Bioko I., Equatorial Guinea].King Genet *Genetta poensis*.

Taxonomy Described from a skin supposed to come from Bioko I., Equatorial Guinea, but De Pousargues (1896) and Pocock (1908) doubted its geographical origin. The species belongs to the grouping commonly called the large-spotted genet 'forest forms' of West Africa (together with *bourloni*, *pardina* and *schoutedeni*; see Pocock 1908, Rosevear 1974, Crawford-Cabral 1980–81, Schlawe 1981, Gaubert 2003a). *Genetta poensis* has been the focus of much taxonomic debate, being either considered synonymous with, or related to, the Pardine Genet *G. pardina* (see Matschie 1902, Crawford-Cabral 1980–81, Schlawe 1981, Wozencraft 1993, Grubb *et al.* 1998) or listed as a valid species (Rosevear 1974). Its name was erroneously used for designating the Crested Genet *G. cristata* (Jeannin 1936, Happold 1987). Gaubert (2003a) recognized the species on the basis of coat pattern and hair ultrastructure characters, later confirmed by molecular phylogenetic investigation (Gaubert *et al.* 2004b) and accepted by Wozencraft (2005). Estimated to have diverged very recently, during the middle Pleistocene (Gaubert & Begg 2007). Synonyms: none. Chromosome number: not known.

Description Heavily built genet. Similar to Pardine Genet, but spots completely dark and coalesced in various parts of the body, and almost half of the tail is dark. Sexes similar in colour and size. Facial mask well marked, with a thin dark vertical line on the muzzle. Sub- and supra-ocular white spots contrasting with the dark muzzle. Ear broad-based and slightly rounded. Pelage relatively short and rough. Ground colouration from pale yellowish-grey to yellow. Throat, chest and ventral pelage whitish-yellow to grey. Nuchal stripes not clearly delimited. Mid-dorsal line dark without long crest hairs, beginning after the shoulder. Dorsal spots elongated and 'squared', completely dark and greatly coalesced in various parts of the body. Hindlimbs and forelimbs dark and well spotted. Upper parts of the fore- and hindfeet spotted. Underparts of feet dark. Tail thickly furred but hair relatively short, and its proximal part annulated with four to six pale rings; distal half of tail almost completely dark. Skull large, similar to Pardine Genet; temporalis muscles attached to narrow, elevated occipital crest.

*Genetta poensis*

Geographic Variation None recorded.

Similar Species

- Genetta pardina*. Sympatric. Dorsal spots not coalesced; tail annulated almost to the tip, which is covered by a large dark ring.
- G. johnstoni*. Sympatric. Dorsal spots rufous-red and coalesced; tail annulated with pale rings to the tip.
- G. bourloni*. Sympatric. Dorsal spots partly coalesced at the rump; nuchal stripes clearly delimited.
- G. servalina*. Sympatric. Dorsal spots not coalesced; tail annulated with pale rings to the tip; tip bright.
- Poiana leightoni*. Sympatric. Smaller; ears large and rounded; spots smaller and dark, no mid-dorsal line.

Distribution Endemic to Africa, inhabiting rainforest blocks, in Liberia, Côte d'Ivoire, Ghana, Equatorial Guinea (Bioko I.) and Republic of Congo (Gaubert 2003a).

Habitat Collection localities suggest restriction to rainforest (Gaubert 2003a).

Abundance Unknown, but scarcity of records suggests this is a rare and localized species.

Adaptations Coalesced spotted coat patterns suggest long-term adaptation to more humid and closed habitats.

Remarks There is a paucity of information available on the ecology of this species. They are solitary, and probably both carnivorous and frugivorous.

Conservation IUCN Category: Data Deficient. CITES: Not listed.

Hunting pressure is probable, as most of the museum skins were collected from local hunters or bushmeat markets. The species, represented by ten known specimens in collections, has not been collected since 1946 (Gaubert 2003b), and is a priority species for further survey work to establish its status in the wild.

Genetta servalina SERVALINE GENET

Fr. Genette servaline; Ger. Servalgenette (Waldgenette)

Genetta servalina Pucheran 1855. Rev. Mag. Zool. 7 (2): 154. Gabon.

Taxonomy Original description is based on a skin sent to France from Gabon by Audry Leconte. The name presumably refers to the resemblance with the Serval *Leptailurus serval*. Considered to be a 'primitive' genet by Crawford-Cabral (1981), later confirmed by its basal position within the *Genetta* clade (Gaubert *et al.* 2002b, 2004b), with the species diverging in the Late Pliocene (Gaubert & Begg 2007). The Crested Genet *G. cristata*, considered by some authors

to be conspecific (e.g. Coetzee 1977, Wozencraft 1993), is now generally considered to represent a distinct species (Rosevear 1974, Crawford-Cabral 1980–1981, Gaubert *et al.* 2004b, Wozencraft 2005).

Five subspecies are currently recognized (Van Rompaey & Colyn 1998). Of supposed synonyms, the form *aubryana* Pucheran, 1855 is considered to be a lighter colour phase of *G. s. servalina*, while the

Servaline Genet *Genetta servalina*.

form *intensa* Lönnberg, 1917 is recognized by Coetzee (1977) as a subspecies, but considered a colour phase by Crawford-Cabral (1970) and later (1980–81) as a possible ‘subrace’ of *G. s. bettoni*. Synonyms: *archeri*, *aubryana*, *bettoni*, *intense*, *lowei*, *schwarzi*. Chromosome number: not known.

Description Slender, relatively long-legged and long-faced genet. Pelage short, soft and more velvety than other *Genetta*. Ground colour greyish to ochraceous-yellow. Nuchal line poorly developed. Spots may tend to fuse near the spine, suggesting a dark mid-dorsal line. Numerous closely grouped brownish-black spots on the back and flanks, rarely forming longitudinal lines, weaker and more scattered on the ventral side, which is greyish to black. Forelegs may have small spots down to the feet; hindlegs down to the ankle. Feet light to brownish-black. Metatarsal and metacarpal pads not connected to interdigital pads. Tail long, cylindrical with 9–12 dark rings with yellowish-white rings between. Tip of tail white, yellowish, or black. Hairs show a clear banding pattern and a visible, globular medullary configuration with many air spaces. One pair nipples. In the skull, the caudal entotympanic bone is ventrally inflated. In adult animals, the maxillo-palatine suture is aligned with the P³ main cusp (Gaubert *et al.* 2001).

Geographic Variation

G. s. servalina: forests of central Africa west and north of the Congo R. up to the Sanaga R. (although see Gaubert *et al.* 2006 who give records from north of the Sanaga R.). Upperside tawny to greyish. Spots brownish-black. Hindlegs dark brown; feet brownish-black. Populations between the Ubangi and Congo Rivers have lighter tones half-way between the nominate *servalina* and the eastern *bettoni*; both Allen (1924) and Crawford-Cabral (1970) suggested that they might represent distinct subspecies.

G. s. bettoni: montane forests in the Kivu area, E DR Congo, southward to Baraka (on L. Tanganyika, DR Congo), eastward in Uganda to Kenya (Mt Kenya). Similar to *G. s. servalina* but general appearance lighter and size on average one-seventh smaller with corresponding reduction in the size of the teeth. Those from Upper Uele R., Kibali-Ituri, towards Semliki Valley, E DR Congo, are darker, due to the larger and more closely placed black spots and may represent a different subspecies (*G. servalina intensa*) or a dark colour phase of *G. s. bettoni*.

G. s. schwarzi: Congo basin, south of the Congo and Lualaba Rivers. Larger than *G. s. servalina*. Tendency for spots to form rows on the flanks and stripes on the shoulders. Later thought not to merit subspecific rank by Crawford-Cabral (1980–81).

G. s. lowei: geographically isolated in several Eastern Arc Mts blocks, being recorded from the Udzungwa Mts, South Nguru Mts and the Uluguru and Rubeho Mts. Yellow-orange base colour. White facial spots suffused with orange. Legs and feet light coloured.

G. s. archeri: geographically isolated in Jozani Forest, Zanzibar, Tanzania. Upperside ochraceous with rather short velvety pelage and numerous irregular black spots. Throat and ventral part of insides of fore- and hindlegs clear, smoky grey; lower outside parts light-coloured with small spots. Tail of holotype relatively short haired and soft-furred with ten light-coloured rings, these being narrower than the nine darker rings. Dorsally, light-coloured rings have some light-brown hairs mixed intermedially on the dorsal side. Both skull and teeth measurements are considerably larger than in *G. s. bettoni*.

Similar Species

Genetta cristata. South-easternmost limits of distribution not clearly established; possibly sympatric in Gabon and Congo (Gaubert *et al.* 2006). Nuchal or mid-dorsal crest.

G. maculata. Sympatric. Fewer and larger body spots; shorter legs; tapering tail with fewer rings and black tip.

G. victoriae. Sympatric. Much larger; darker coloured, longer legs; prominent suborbital spot, and two black neck stripes starting from behind the ears.

G. poensis. Sympatric. Dorsal spots greatly fused in various parts of body; nuchal stripes not clearly delimited.

Nandinia binotata. Sympatric. Heavier; more brownish coloured; two light-coloured shoulder spots; soles of fore- and hindfeet naked to wrist or ankle; tail not distinctly ringed.

Poiana richardsonii. Sympatric. Smaller, and more slender; spots smaller; lighter coloured.

Distribution Endemic to Africa. Ranges from S Cameroon, south of the Sanaga R., and Central African Republic and southwards in Equatorial Guinea, Gabon, Congo to S Sudan (Imatong Mts and Didinga Mts; Dieterlen & Nikolaus 1985), Uganda (Muhavura Mt; Gyldenstolpe 1928), Rwanda (Parc National des Volcans and Ruggege Forest; Elbl *et al.* 1966), Kenya (Taylor 1970b, Kingdon 1977), and possibly also in Burundi (Kibira Forest; Wilson 1990). There are discontinuous populations in Tanzania, including from the Udzungwa Mts and Nyumbanitu Mts (Kingdon 1977, De Luca & Mpunga 2002, Brink *et al.* 2002), South Nguru Mts and Uluguru Mts (Rovero *et al.* 2006) and Rubeho Mts (Rovero *et al.* 2008). Gaubert *et al.* (2006) also give museum records from north of the Sanaga R., from several additional localities in Tanzania (Mikindani, Uimba Ebene, Kondoia, and Mandera, the latter a locality lying on the East African coast), as well as from Kitobwe and Lumumbashi in SE DR Congo (but these are not mapped here). Also present on Zanzibar (Van Rompaey & Colyn 1998, Goldman & Winther-Hansen 2003).

Genetta servalina

Lateral view of skull of Servaline Genet *Genetta servalina*.

Habitat Primary and secondary lowland, sub-montane and montane forests and gallery forests. Recorded up to 2900 m on Mt Muhavura (Gyldenstolpe 1928) and 3500 m on Mt Elgon, Kenya (Kingdon 1977). Traces of the presence of the Servaline Genet have been found in the sub-alpine and alpine zones up to 4425 m on Mt Wusuwameso, DR Congo (Verschuren 1972). Habitats from which they have been recorded include: wet forests with a rainfall of over 1625 mm a year in Kenya (Taylor 1970b); acacia country on the plains at the south end of the Rwenzori Mts in DR Congo (Thomas & Wroughton 1910); high-altitude bamboo forest in the Udzungwa Mts (De Luca & Mpunga 2002); valley bottom with discontinuous canopy cover but dense understorey (Rovero *et al.* 2006); ground-water forest and coral rag thicket on Zanzibar (Goldman & Winther-Hansen 2003); and open deciduous shrubland in Congo (Gaubert *et al.* 2006).

Abundance Charles-Dominique (1978), walking and canoeing 268 km and checking an area of 6.4 km² primary and secondary forest in Gabon, observed seven individuals and estimated the average density at 1/km². In Equatorial Guinea, density was 0.8/km² (Fa *et al.* 1995). Very common in the Irangi region, DR Congo (Rahm 1966). Kingdon (1977) noted that the species appeared to be particularly common at an altitude between 2100 and 3000 m on Mt Elgon, and it is also common in moist forests of the Udzungwa Mts at altitudes of 300–1800 m (De Luca & Mpunga 2002, F. Rovero pers. comm.).

Adaptations Arboreal and nocturnal. Palmigrade forefoot and semi-digitigrade hindfoot. A high-set scapula allows a great abduction of the forelimb so that walking along a branch the legs are kept in a flexed position and can be swung out in a lateral arc, allowing a faster correcting movement should it slip (Taylor 1970a). Rahm (1966) found it more arboreal than the Large-spotted Genet *G. maculata*; however, they have been both observed and photo-trapped on the ground (Charles-Dominique 1977, Kingdon 1977, Goldman & Winther-Hansen 2003).

Foraging and Food Omnivorous. In Dzanga-Sangha Special Reserve, Central African Republic, 77% of 35 scats contained mammalian prey (mostly shrews and rodents, but also bats, pangolin, monkey, and Blue Duiker *Philantomba monticola* – although the last three prey items were probably scavenged), 71% arthropods (mostly termites, beetles and orthopterans), 14% herpetofauna (snakes, lizards and anurans), 6% birds and 3% fruit (Ray 1996, Hutterer & Ray 1997, Ray & Sunquist 2001). Diet similar to that of the Large-spotted Genet from the same region (Rahm & Christiaensen 1963). A Servaline Genet was observed scavenging a duiker (*Cephalophus* spp.) killed five days before by a Leopard *Panthera pardus* at an altitude of 3400 m (Verschuren 1972). Hunts on the ground and at low level in bushes (Charles-Dominique 1977).

Servaline Genet *Genetta servalina*.

Social and Reproductive Behaviour Either solitary or in pairs (Rahm 1966). Faeces are often deposited under overhanging rocks without forming latrines (Verschuren 1972).

Reproduction and Population Structure Births have been recorded in Uganda from Feb to Aug (Kingdon 1977). Recorded to live more than 14 years in captivity (Weigl 2005).

Predators, Parasites and Diseases A nematode worm *Toxocara vincenti* was recovered from a specimen in Congo (Grabner 1981). Ticks (*Haemaphysalis leachi*) have been recovered from Ugandan animals (Allen & Lawrence 1937). Four of eight fresh heads of Servaline Genets from NE DR Congo contained trematodes, *Achillurbania* sp. in the frontal sinuses and eight out of 36 examined skulls showed frontal sinus damage, probably due to this parasite. *Mammamonogamus* spp., parasitic worms of the respiratory system, were present in the nasal cavities of one specimen and Metastrongylidae in two other specimens from DR Congo (Colyn & Van Rompaey 1989). Trypanosomes responsible for sleeping sickness (*Trypanosoma brucei* non *gambiense* group 1, *T. b. gambiense* group 1, *T. congolense* 'savanna type' and *T. vivax*) have been found in specimens from S Cameroon (Herder *et al.* 2002).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Genets make up nearly 20% of the carnivore bushmeat in NE DR Congo (Colyn *et al.* 1987) and 32/year were sold at a bushmeat market in Equatorial Guinea (Fa *et al.* 1995). Skins used for wrist-bracelets and dancing hats (Carpaneto & Germe 1989) and are a favourite skin for loin-cloths among both Mbuti and Ba'aka pygmies. In Congo, they are hunted for bushmeat and traditional medicine (Wilson & Wilson 1991). Since the recent rediscovery of Lowe's Servaline Genet in the Udzungwa Mountains N. P. (Brink *et al.* 2002, De Luca & Mpunga 2002), after a gap of nearly 70 years, and subsequent records in Uluguru North F. R. and Kanga F. R. (Rovero *et al.* 2006) and Rubeho Mts (Rovero *et al.* 2008), further research is needed to determine whether this species might be more widely distributed in other Eastern Arc Mountain blocks, particularly the Ukaguru Mts that lie between the Udzungwa and South Nguru Mts (Rovero *et al.* 2006).

Genetta thierryi HAUSA GENET

Fr. Genette de Villiers; Ger. Haussa-Genette.

Genetta thierryi Matschie, 1902. Verh. V Internat. Zool. Congr. 1901: 1142. 'Hinterland von Togo von 9° N. Br. ab', restricted to 'Borogu = Borgou, (10° 78' N, 0° 65' E)?' by Schlawe (1981).

Hausa Genet *Genetta thierryi*.

Taxonomy Monotypic. Named in honour of a Oberleutnant Thierry, supposed by Rosevear (1974) to have been stationed in Togo. Described from a series of skins. Has been included in subgenus *Pseudogenetta* (see Kuhn 1960 and Crawford-Cabral 1980–81) with the Ethiopian Genet *G. abyssinica*. There has been inconsistent use of nomenclature since Schlawe (1981) discovered that the type specimen of *G. rubiginosa* Pucheran, 1855, in fact belonged to the species *G. thierryi*. Following prevailing usage (Articles 23.9.1 and

.2; International Code of Zoological Nomenclature, 1999), *thierryi* should become the *nomen protectum* used for designating the Hausa Genet, and *rubiginosa* should be considered a *nomen oblitum* (Gaubert *et al.* 2003a, b). The species represents the earliest offshoot of the genus *Genetta* (Gaubert *et al.* 2004b), appearing ca. 8 mya (Gaubert & Begg 2007). Synonyms: *villiersi*, *rubiginosa*. Chromosome number: not known.

Description One of the two smallest genet species (second to the Ethiopian Genet). Sexes similar in colour and size. Facial mask lightly marked. Muzzle and forehead pale grey, with a thin dark vertical line on the muzzle. Subocular white spots well marked, but supraocular spots absent. Ears rounded. Hairs short and straight. Pelage pale, blotched with brown-rufous spots following linear patterns down the back. Ground colouration varying from yellow-brown (Mali) and pale grey (Casamance, Senegal) to pale beige (N Senegal). However, variations also exist within the same locality. Throat, chest and ventral pelage greyish-white. Nuchal stripes either irregular or marked by two thin parallel lines. Mid-dorsal line rufous brown, non-contrasting with the rest of the dorsal markings; starts after the shoulder and usually split longitudinally by a line of pale hairs (at least for the upper part). Dorsal spots elongated and aligned in two rows. The row flanking the mid-dorsal line partially coalesces just before the rump. Spots of the flank, thigh and shoulder smaller and darker. Hindlimbs and forelimbs unspotted, same colour as the background colouration. Line bordering the outer side of the forefoot pads and inner side of the hindfoot pads brown. Central depression of the forefoot hairless. Tail narrow but thicker at its base with longer hairs, usually annulated with eight pale rings. Annulation

Palatal and dorsal views of skull of Hausa Genet *Genetta thierrii*.

not distinct because of the brownish to rufous extensions of the dark rings. Tip with a long dark ring caused by the reduction of the last pale ring (9th). In juveniles, general colouration darker, pattern of spots irregular, but mid-dorsal line present and annulation of the tail identical to the adult. Hairs of the scapula with a globular medulla containing no air spaces. Perineal glands present on both ♂ and ♀. Two pairs of nipples. The skull is reduced in size, with an elongated postorbital process. The caudal entotympanic bone is rounded and very inflated in comparison to the ectotympanic bone (bullae).

Geographic Variation None recorded.

Similar Species

Genetta genetta. Sympatric. Taller; black dorsal crest; tuft of tail whitish.

G. pardina. Sympatric. Taller and darker; mid-dorsal line large and dark, spots not fused.

G. johnstoni. Not sympatric, inhabiting only dense rainforest in West Africa. Taller and darker; mid-dorsal line large and dark; tail annulated with pale rings to the tip; tuft of tail whitish.

G. maculata. Sympatric east of the Volta R. Taller; mid-dorsal line large and brownish-dark.

Poiana leightoni. West Africa only, in rainforest habitats. Similar in size, but mid-dorsal line absent, spots small, rounded, and not coalesced, and tail annulated with pale rings present to the tip.

Distribution Endemic to Africa. Sparsely distributed in the West African savanna zone from Gambia and Guinea-Bissau to Cameroon; the easterly limit of distribution requires clarification.

Habitat Usually moist and dry savannas with open woodlands. However, the species seems to adapt to different habitats since specimens have been collected and sighted in moist woodlands (Casamance, Guinea-Bissau), rainforest (Sierra Leone, Ghana, Côte d'Ivoire) and even dry wooded steppes (Senegal).

Abundance Considered rare. Possibly common in some restricted areas like E Senegal and Casamance (from collections of the I.R.D. (former O.R.S.T.O.M.) of Dakar, partially deposited at the Muséum National d'Histoire Naturelle of Paris). Hoppe-Dominik (1990) stated that the species was widespread throughout its range, but provided no evidence.

Genetta thierrii

Adaptations Colouration and length of hair is related to habitat, as with the similar widespread Common Genet *G. genetta*: hair is short and paler in savanna habitat, but longer and yellower in forest habitat. The cross-section shape of the dorsal guard hairs at the base of the spatula is round or slightly ovoid (Gaubert *et al.* 2002b), which is exceptional among the members of the genus (but similar in Ethiopian Genet). This conformation probably makes the hair less flexible, but nothing is known about its actual adaptive value.

Foraging and Food No specific information available, but likely to resemble other genets.

Social and Reproductive Behaviour Little known. It is thought to bear young in holes dug in the ground or amongst rocks (Rosevear 1974). A juvenile specimen was found asleep in a dead tree near the Lamto Station, Côte d'Ivoire (Bourlière *et al.* 1974).

Reproduction and Population Structure Unknown. However, two subadults (estimated age: 8–10 months) from Mali were collected early Nov (L. Granjon pers. comm.), thus suggesting births around Jan to Mar, corresponding with the dry season.

Predators, Parasites and Diseases Probably similar predators as other genets. Ixodid ticks (*Haemaphysalis rugosa* and *H. moreli*) specializing on Viverridae were found on specimens from moist woodlands of Senegal (Camicas *et al.* 1972, Camicas 1978). The mites *Laelaps lavieri* and *L. liberiensis* were also recorded in Côte d'Ivoire (Herrin & Tipton 1976).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Dekeyser (1956) reported that the species is locally hunted and its tail is used for ceremonial and ornamental purposes in Casamance, Senegal (Diola and Bassari tribes). Reported from bushmeat markets throughout its range. In the past, there has also been regional and

international traffic for their skins or as pets, although there was no record of this species (or any other genet for that matter) in commercial trade reported to CITES for the period 1995–2005. During 2001, five kittens were found by customs in transit from Lagos, Nigeria, to Manila, the Philippines (H. Van Rompaey pers. comm.).

Genetta tigrina CAPE GENET

Fr. Genette à grandes taches d'Afrique du Sud; Ger. Suedliche Grossfleckgenette

Genetta tigrina (Schreber, 1776). Die Säügethiere 3 (17): pl. 115 [1776]; text, 3 (25): 425 [1777].
'von dem Vorgebirge der guten Hofnug', Cape of Good Hope, South Africa.

Cape Genet *Genetta tigrina*.

Taxonomy The specific epithet '*tigrina*' means tiger-like, although coat pattern is in no way reminiscent of tiger stripes. Described from a specimen that died at the Menagerie of Prince William V of Orange-Nassau, near The Hague (iconotype; see Tuijn & Van der Feen 1969). Until recently some authors considered the Cape Genet *G. tigrina* and Large-spotted Genet *G. maculata* conspecific (Coetzee 1977, Meester *et al.* 1986). Others have disagreed with this on the basis of pelage pattern, as well as skull and teeth characteristics (Roberts 1951, Cabral 1966). Both craniometrics (Crawford-Cabral 1980–81, Crawford-Cabral & Pacheco 1992) and discrete morphological characters (Schlawe 1981, Gaubert 2003a) argue for recognition of *G. tigrina* as a valid species. Speciation might be a recent phenomenon or still in progress given the relative uniformity of mtDNA haplotypes distributed between *maculata* and *tigrina* (Gaubert *et al.* 2005b). Hybridization zones with Large-spotted Genet (specifically the form *letabae*) occur in KwaZulu-Natal (Pringle 1977), but are likely to be very localized (Gaubert *et al.* 2005b). The lineage leading to the clade grouping *G. maculata* and *G. tigrina* is estimated

to have diverged in the middle Pleistocene (Gaubert & Begg 2007). There are currently two recognized subspecies. Synonyms: *methi*. Chromosome number: not known.

Description Similar to Large-spotted Genet, but hair slightly longer and dark spots very large and not coalesced. Sexes similar in colour and size. Facial mask well marked, with a thin dark vertical line on the muzzle. Subocular white spots contrasting with the dark muzzle. Supraocular spots less contrasting. Ground colouration whitish-yellow or grey. Throat, chest and ventral pelage grey to whitish-grey. Nuchal stripes well defined. Large mid-dorsal line with crest, intermediate in length between that of the Large-spotted Genet and the Common Genet *G. genetta*, begins behind the shoulder. Hair on the scapula region without air spaces within the globular medulla. Hindlimbs very dark, with a thin row of bright hairs on the anterior surface. Forelimbs with posterior part dark. Upper parts of forefeet and hindfeet lightly spotted. Thigh and shoulder with large spots. Tail relatively short (ca. 81–85% of HB) with hair length intermediate between the Large-spotted Genet and the Common Genet *G. genetta*, and clearly annulated with 7–8 bright rings. The first dark rings are larger than in the Large-spotted Genet, and the last bright ring is more apparent, even though it is covered by a dark dorsal line; tip of the tail is dark. Two pairs of nipples.

The skull is characterized by a thin sagittal crest, caudal entotympanic bone very flattened in comparison with the ectotympanic bone, and lingual cusp of P³ very reduced.

Geographic Variation

G. t. tigrina: southern coastal South Africa from the Western Cape to Eastern Cape. Coat and skull characteristics as in 'Description'.

G. t. methi: known only from the south of Umsigaba R., Pondoland, but may occur slightly further north (Roberts 1951). Colouration and pelage pattern similar to *tigrina*; size considerably larger, especially teeth (P⁴ and M¹), with greatest diameter of P⁴ 11.5 mm (cf. 9.0–9.8 mm in *tigrina*); hair shorter.

Similar Species

Genetta genetta. Sympatric (*felina*; see *G. genetta*). Hair longer, mid-dorsal line with longer erectile hair; dorsal spots narrow and partially coalesced; tip of the tail bright.

G. maculata. Sympatric in S KwaZulu-Natal (*letabae*; see *G. maculata*). Pelage pattern very similar, but mid-dorsal line with short hair; limb and foot brighter; first dark rings of the tail narrower; skull with a more marked postorbital constriction.

Distribution Endemic to South Africa. Well represented in higher rainfall areas from Western Cape through Eastern Cape to S KwaZulu-Natal, south of 32° S, and to the neighbouring S Lesotho border. Sympatric with the Common Genet (*G. g. felina*) throughout its range (see Gaubert *et al.* 2005b). There is a narrow hybrid zone with Large-spotted Genet (*letabae*) in S KwaZulu-Natal (Gaubert *et al.* 2005b).

Habitat Occurs in wooded or dense habitats such as Lowland and Mountain Fynbos (heathland) and forests in the Western and Eastern Cape (Stuart 1981). Mostly present in permanent-watered zones such as riverine associations. Sometimes found in exotic scrub (Western Cape) as well as open grasslands during foraging activities (Stuart 1981).

Abundance There is no information on their abundance, but they are not uncommon. Haagner (1920) reported the species to be common in what was then the Cape Province.

Adaptations Unknown, but clearly bound to the unique climate and vegetation of the Cape.

Foraging and Food Roberts *et al.* (2007) provided the first comprehensive report on the diet of *G. tigrina* as determined from scat analysis ($n = 372$), and found the species to have an opportunistic,

generalist diet. These authors studied seasonal variations in diet in the coastal dune forest of the Dwesa N. R., Eastern Cape Province, South Africa. The food items with the highest relative percentage occurrence were Coleoptera, Orthoptera and Mammalia. However, by volume they ate mostly grass (perhaps to aid digestion, to dislodge hair in the intestines, to induce vomiting, among other purposes), followed by Coleoptera and Orthoptera. Main prey items originated from the litter layer or low-lying bushes, such as arachnids, insects, myriapods and most mammals. The latter included ten rodent species (especially *Dendromus* sp., *Otomys* sp., *Graphiurus* sp. and *Mastomys* sp.), and two golden-mole and two shrew species, from 10 to 100 g mass. Birds appeared under-represented in the diet for a semi-arboreal carnivore, but remains of birds in the diet did peak during winter and spring probably as a result of the main nesting period in spring. Roberts *et al.* (2007) also recorded myrmecophagy (reported as absent in genetids' diet by Wemmer 1977), although this could result from contamination of scats at the latrine sites. The remains of scorpions in scats suggest that *G. tigrina* may have disarmed them by attacking and consuming the pedipalps and stinger un-masticated before consuming the remainder. There was some variation in diet between habitats and seasons.

Elsewhere, rodents (Namaqua Rock Rat *Aethomys namaquensis* and Southern African Vlei Rat *Otomys irroratus*), birds (Egyptian Goose *Alopochen aegyptiaca* and birds of the family Columbidae), insects (Coleoptera and Orthoptera), spiders and pill millipedes, freshwater crabs, earthworms, plants (seeds, leaves and green grass) and even chewed bark and wood have been recorded in the diet (Stuart 1981). They have been seen feeding in rubbish dumps in Cape Point, Goukamma and De Hoop Nature Reserves (Western Cape) (Stuart 1981), and Roberts *et al.* (2007) suspected that fish found in the diet of animals in their study were probably scavenged from the beach or elsewhere.

Social and Reproductive Behaviour Solitary, but pairs occasionally seen during the breeding season. One individual was observed resting during the day in a hollow oak tree, 3 m above the ground, in Jonkershoek Valley, Western Cape (Stuart 1981).

Reproduction and Population Structure A lactating ♀ caught in Jan had recently given birth and a juvenile ♂ of about six weeks was collected in Mar (Stuart 1981). Given these data, it is possible that a birth season extends from Jan to Feb. Longevity reported up to 15 years in captivity (Anonymous 1960).

Predators, Parasites and Diseases Probably same predators as the Common Genet. Two species of ectoparasites (Acaria) were reported in the Cape: *Haemaphysalis leachi* (group) and *Ixodes* sp. (near *oldi*) (Stuart 1981).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Though not particularly subject to hunting pressure, they are sometimes killed by farmers in retaliation for their preying on small domestic stock and poultry. Trapping, poisoning and shooting could have an effect on numbers of the species in certain areas (Stuart 1990). Present in several protected areas throughout its range, such as West Coast N. P. (Avery *et al.* 1990) and Kammanassie Mountain State F. R. (Nel *et al.* 1980).

Genetta victoriae GIANT GENET

Fr. Genette géante; Ger. Riesengenette

Genetta victoriae Thomas, 1901. Proc. Zool. Soc. Lond. 1901: 87. Entebbe, Uganda. Corrected to 'Near Lupanzula's, 10 miles west of Beni, Ituri Forest, Congo (Kinshasa)' by Moreau *et al.* (1946).

Giant Genet *Genetta victoriae*.

Taxonomy Monotypic. Has been included with the true servaline genets, Crested Genet *G. cristata* and Servaline Genet *G. servalina*, owing to its densely spotted coat and the absence of a continuous mid-dorsal line (e.g. Crawford-Cabral 1981a, Gaubert *et al.* 2002b); however, the species shows marked morphological differences, particularly in the skull and morphological and molecular studies do not support a monophyletic grouping with servaline genets (Gaubert *et al.* 2004b, Gaubert & Begg 2007). Rather, the species places as a single, second offshoot of the genus *Genetta* (following the lineage leading to *G. thierryi*), diverging in the late Miocene. The name *victoriae* refers to the mistaken locality of the holotype, Entebbe, on L. Victoria. Synonyms: none. Chromosome number: not known.

Description Large, dark-coloured, long-legged genet. Pelage short, close and thick. Top of muzzle and forehead whitish with a black median line starting in front of the eyes. Sides of muzzle and orbital ring black. Prominent suborbital white spot. Nose below nostrils 14 mm wide (cf. 10 mm in other *Genetta* spp.). Vibrissae long; ears rounded. Two black bands on neck, starting behind ear. Dorsal pelage yellowish to ochraceous-white; guard hairs ca. 25 mm long. Ventral pelage paler and also spotted. Conspicuous discontinuous black

mid-dorsal line (with hair relatively long) formed by fusing of spots. Numerous, well-defined, small black spots on body, thighs, shoulder and upper foreleg give the animal its general dark appearance. Legs and feet brown to black; feet relatively small for its size, and soles hairy. Tail relatively short, cylindrical and bushy, tapering near the tip; guard hairs 25–30 mm long. Ca. six white rings between dark rings that are twice as wide; tip of tail dark. One pair of abdominal nipples. In the skull, the caudal entotympanic bone is ventrally inflated.

Geographic Variation None recorded.

Similar Species

Genetta servalina. Sympatric. Smaller; less darkly coloured; larger dorsal spots; shorter legs.

G. maculata. Sympatric. Smaller; less darkly coloured; larger, squared dorsal spots; short legs.

Civettictis civetta. Sympatric. Much heavier; hindlegs longer than frontlegs; relatively shorter, thicker tail.

Distribution Endemic to Africa. Largely confined to an area between the Congo, Lualaba and Oubangui Rivers in DR Congo (approximately 18°E–30°E and 4°N–4°S). Thomas (1901) described the species based on a skin sent to London from Entebbe, but Johnston (1902) stated that he collected the skin from a very dense part of the forest on the Semliki R. in NE DR Congo, and hence not at Entebbe. Moreau *et al.* (1946) restricted the locality to Lupanzula's village and stated that 'although there are no authentic records of this genet from Uganda, we believe it to occur'. Indeed, skins of genet kittens from the Bwamba Forest, Toro District, Uganda, an eastern extension of the Semliki Forest, seemed to be certainly this species, and Bere (1962) mentions its presence from the Semliki Forest in Uganda. Kingdon (1977) observed a specimen along a forest road in W Uganda. Recently, a large genet photographed in Nyungwe N.P. in Rwanda has been positively identified as this species (Dinets 2011).

Depierre & Vivien (1992) mention two specimens from the Sangmelina forest area in Cameroon (ca. 750 km west from its most western expected distribution), possibly mistaken identification for

the Crested Genet. Gaubert *et al.* (2006) provide museum records that expand the range 500 km south, including localities from deciduous forest on the left bank of the Congo R. in S DR Congo (but these are not mapped).

Habitat Occurs in lowland and medium-altitude rainforests up to 1800 m. Two specimens identified as Giant Genets by Gaubert *et al.* (2006) from Kakanga and Mukulu, in S DR Congo, apparently were collected in deciduous forest.

Abundance The Giant Genet is patchily distributed, being quite abundant in some areas and nearly absent in intervening, apparently suitable habitat; for example, they are very rare in the area between the Uma and Enano Rivers, east of Kisangani, and fairly common between Kisangani and Buta, and between the Aruwimi and Lindi Rivers (Schreiber *et al.* 1989).

Adaptations Semi-arboreal; the long legs may be an adaptation to a more terrestrial way of life than shown by other genets. The dark colouration and numerous spots are typical for a forest species.

Foraging and Food Omnivorous, taking carrion, termites, pambaa fruits, bananas (*Musa* sp.) and oil palm fruits (*Elaeis guineensis*). Raids poultry coops (Carpaneto & Germe 1989). In captivity, rice, bananas, milk and rodents are eaten (Rahm 1966).

Social and Reproductive Behaviour Solitary, active either by day and by night or only by night, according to different authors; a

Lateral view of skull of Giant Genet *Genetta victoriae*.

single animal was observed trotting along a forest road at about 22:30h (Kingdon 1977). Sleeps in hollow trunks of dead trees or among vines (Carpaneto & Germe 1989).

Reproduction and Population Structure According to the Mbuti pygmies of NE DR Congo, the Giant Genet has only one young per litter (Carpaneto & Germe 1989).

Predators, Parasites and Diseases Predators probably include aerial raptors and larger forest carnivores. A louse *Felicola* (*Parafelicola*) *lenicornis* was listed by Hopkins (1949). Out of 33 skulls examined, two showed frontal sinus damage probably due to a trematode *Achillurbandia* sp. (Colyn & Van Rompaey 1989).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Hunted as bushmeat (Colyn *et al.* 1987) and for food by Mbuti pygmies; only eaten by elders. Skin used to make hats and other ceremonial objects (Carpaneto & Germe 1989). There are records from the Ituri Forest and Okapi Faunal Reserve in DR Congo and from Nyungwe N. P. in Rwanda, and it probably occurs in several other protected areas in its range, such as Maiko N. P.

GENUS *Poiana* Linsangs (Oyans)

Poiana Gray, 1864. Proc. Zool. Soc. Lond. 1864: 520.

The genus holds two species, the Central African Linsang *Poiana richardsonii* and West African Linsang *P. leightoni*, although the latter has been considered a subspecies by several authors (Wozencraft 1993). The African linsangs, or oyans, are small, slender, genet-like carnivores characterized by a small head, pointed muzzle, long body and short legs. General colour yellowish-brown with numerous small, brownish-black spots and sometimes a narrow mid-dorsal line. Underparts whitish to creamy. Pelage very short, soft and dense with fine underfur. Legs spotted; feet with five toes; sharp, retractable claws. Plantigrade forefeet and digitigrade hindfeet (Taylor 1988), as in *Genetta*. Interdigital depression naked. Metatarsal pads developed as in *Genetta*, forming a naked line nearly up to the heel of the hindfoot. Long, cylindrical tail with 9–14 dark rings. Dental formula: $I^{3/3}, C^{1/1}, P^{4/4}, M^{1/2} = 38$. Dentition differs from *Genetta* in the usual absence of M^2 , which, if present, is very small.

Poiana has often been compared with the Asian Linsang (genus *Prionodon*, formerly genus *Linsang*), both being forest dwellers and having similar morphotypes as well as diet. Pocock (1915)

provisionally classified the African linsangs with the Asian linsangs. However, in addition to skull differences (Gregory & Hellman 1939), *Prionodon* has no scent glands, no metatarsal pads, but an intervening hairy space between the plantar and metacarpal pads. The great distance or 'scattered distribution' between the two species of *Poiana* is generally held to indicate ancient stock (Booth 1954). Crawford-Cabral (1993b) considers *Poiana* a genet that acquired a *Prionodon*-like dental formula and questions the reasons for maintaining *Poiana* as a valid genus distinct from *Genetta*. Molecular phylogenetic analysis has shown that the African and Asian linsangs were distinct lineages having acquired morphological similarity by convergence, with *Poiana* grouping as sister-taxon to *Genetta* whereas *Prionodon* branched as the sister-group of Felidae (Gaubert & Veron 2003). Divergence time between the African linsang lineage and genets was estimated to be middle to late Pliocene (Gaubert & Cordeiro-Estrela 2006).

Harry Van Rompaey & Marc Colyn

Poiana leightoni WEST AFRICAN LINSANG (WEST AFRICAN OYAN)

Fr. Poiane d'Afrique occidentale; Ger. West Afrika Linsang

Poiana leightoni Pocock, 1907. Proc. Zool. Soc. Lond. 1907: 1043 [1908]. 'fifteen to twenty miles [24 to 32 km] west of the Putu Mountains, which lie west of the Duobe and Cavally Rivers. The Cavally R. is the eastern boundary line between Liberia and the Côte d'Ivoire, and the Duobe is one of its tributaries joining the Cavally about seventy miles [113 km], as the crow flies, from its mouth, after running for over one hundred miles [161 km] nearly parallel to the main stream' [Liberia].

West African Linsang *Poiana leightoni*.

valid species (Rosevear 1974) on the basis of pattern differences that are likely to be very ancient (Kingdon 1997) (see also Gaubert *et al.* 2002b, Wozencraft 2005). Synonyms: *liberiensis*. Chromosome number: not known.

Description Small, slender, genet-like carnivore. Ground colour yellowish-fawn but not always different from yellowish to reddish-brown of Central African Linsang. Large, longer than wide, irregular spots on back and flanks; much smaller spots on fore- and hindlimbs and on flanks near belly. Spots are more or less arranged into four to five longitudinal rows and they form longitudinal stripes on neck. Throat, chest and belly white. Underfur of back and flanks greyish-white, of belly white. Dorsal pelage soft and very short. Underfur abundant (hairs ca. 10 mm), guard hairs few (ca. 10 mm). Thin, sometimes interrupted, mid-dorsal stripe from between the shoulders to the root of the tail. Ten to twelve chevron-shaped dark tail-rings, narrower laterally and ventrally; no intermediate dark tail-rings.

Geographic Variation None recorded.

Similar Species

Poiana richardsonii. Allopatric, occurring in central Africa only. Dark tail rings not chevron shaped; spots smaller.
Genetta spp. Various sympatric forms, but all larger in size.

Taxonomy Originally described as *liberiensis*, but a printed amendment slip in *Proceedings of the Zoological Society of London* reads 'Erratum: p. 1043: for Subsp. *liberiensis*, nov. read Subsp. *leightoni*, nov.' Species named after the collector of the type specimen, Leonard Leighton. Although long considered as a subspecies of Central African Linsang *P. richardsonii* (e.g. Wozencraft 1993), it is now treated as a

*Poiana leightoni*

Distribution Endemic to the Upper Guinea forests of West Africa. Present in SW Côte d'Ivoire, where known from two confirmed records: Gagnoa (Beaufort 1965), where a specimen was taken from a bushmeat market, and Nzi-Alakro (Awakro) (Bourlière *et al.* 1974). There is a record from Sangbé N. P. (see Hoppe-Dominik 1990), but this requires confirmation. In E Liberia, there are records from Biple, Bongle, Deaple, Duotown, Igua, Siamonrovia, Tappita, and on the road between Bia and Zwedru (Kuhn 1965) and Mali and Bao Town (Taylor 1989a). The presence of this species in the Kounounkan Massif in SW Guinea (Barnett *et al.* 1996) requires confirmation. Davies (1990) mentioned that the species may occur in the Gola Forest in Sierra Leone, but there is no confirmed record of the species from the country.

Habitat An inhabitant of the rainforest canopy.

Abundance There is no information available on the population status of this species; the most recent confirmed records are from Liberia in the late 1980s. According to Rosevear (1974), the species is rare and very localized.

Adaptations According to H.-J. Kuhn (in Nowak 1999) the West African Linsang builds a round nest of green material at least two metres from the ground, but usually higher, in which several individuals sleep for a few days, and then moves on and builds a new nest. Previously, it was reported that they sleep in abandoned squirrel nests but native hunters claim that squirrels sleep in abandoned nests of the West African Linsang. The former seems more likely as Mudappa (2001) observed in India that Jerdon's or Brown Palm Civet *Paradoxurus jerdoni* prefer resting during the day in nests of the Malabar Giant Squirrel *Ratufa indica*.

Remarks There is little information available on the ecology of the species. Insects, birds, plant material and kola nuts are recorded from the diet (H.-J. Kuhn, in Nowak 1999), and they also prey on small rodents and possibly reptiles.

Conservation IUCN Category: Data Deficient. CITES: Not listed.

Along with the Liberian Mongoose *Liberiictis kuhni*, Johnston's Genet *Genetta johnstoni* and Bourlon's Genet *G. bourloni*, the West African Linsang is one of the few carnivores with a very restricted range in parts of the Upper Guinea rainforest, a region that continues to experience relatively high rates of net forest loss, and highlighting the importance of this region as one of the core areas for viverrid and herpestid conservation in Africa (Schreiber *et al.* 1989). The West African Linsang may occur in Sangbé N. P. in Côte d'Ivoire (Hoppe-Dominik 1990) and the type locality is not far away from the northern boundary of Liberia's Sapo N. P. (Schreiber *et al.* 1989); it probably occurs in other protected areas within its range. There is a clear need for further survey work targeting this species using the appropriate survey techniques, particularly to better determine its current range and population status, and to investigate other basic aspects of its biology.

Frontal view of West African Linsang *Poiana leightoni*.

Poiana richardsonii CENTRAL AFRICAN LINSANG (CENTRAL AFRICAN OYAN)

Fr. Poiane d'Afrique centrale; Ger. Zentral Afrikanischer Linsang

Poiana richardsonii (Thomson, 1842). Ann. Mag. Nat. Hist., ser. 1, 10: 204. 'Fernando Po' [Bioko I., Equatorial Guinea].Central African Linsang *Poiana richardsonii*.

Taxonomy Two subspecies. Originally described as *Genetta richardsonii*, the generic name *Poiana* given by Gray in 1864, based on the type locality Fernando Po. Species named after Dr John Richardson, Inspector of the Naval Hospital at Haslar. Synonyms: *ochracea*, *poensis*. Chromosome number: not known.

Description Small, slender, short-legged, genet-like carnivore. Muzzle pointed. Ears wide and rounded. Eyes large and yellowish-brown. Rhinarium grey. Ground colour yellowish to reddish-brown. Small, unequal brownish-black spots of various shapes and sizes all over the back and flanks, coalescing into stripes on neck. Spots do not form longitudinal lines and are very small on thighs and forelimbs. Absent or small, sometimes interrupted mid-dorsal line. Throat and underside greyish-pale and unspotted. Underfur greyish to creamy. Pelage short and soft. Underfur abundant (hairs 10–11 mm), guard hairs few (13–15 mm). Feet greyish-fulvous and unmarked. Soles hairy, except for digital pads and a narrow bare line on the plantar surface. Tail cylindrical, slightly shorter or longer than head and body with 9–14 dark rings with often small, distinct to faint dark intermediate rings in the centre of the light rings. Males may be slightly larger than ♀♀.

Geographical Variation

P. r. richardsonii: S Cameroon, Equatorial Guinea (including Bioko I.), Gabon and Congo.

P. r. ochracea: DR Congo from the Rift Valley to Mayumbe. Ground-colour sometimes more rusty-red but not always different; underside and insides of limbs yellowish and darker; spots in general smaller and more widely spaced; dark tail rings smaller than light rings, and no intermediate dark rings.

Similar Species

Poiana leightoni. Allopatric, occurring in West Africa only. Dark tail rings chevron-shaped; spots larger.

Genetta spp. Larger.

*Poiana richardsonii*

Distribution Endemic to central Africa, ranging from S Cameroon and S Central African Republic, Equatorial Guinea (including Bioko I.), Gabon, Congo and DR Congo up to the Rift Valley.

Habitat The canopy of lowland and montane forests. On Bioko I., at about 17:10h, an individual was observed walking in a dry, rocky stream bed with little vegetation, before it fled to the forest (Harrington *et al.* 2002).

Abundance Not rare on Bioko I. (Eisentraut 1973), and reported as quite common in NE DR Congo (Rahm & Christiaensen 1963). Charles-Dominique (1978) recorded a density of 1/km² in primary forest in Gabon.

Adaptations Probably similar to West African Linsang *P. leightoni*. Nocturnal and arboreal, sleeping on thick tangled vines (Bates 1905) and rarely venturing to the ground. In Gabon trapped with traps set 2 m high on a branch connecting two vegetation blocks. Able to jump by bending the body before jumping (P. Charles-Dominique pers. comm.).

Foraging and Food Both carnivorous and frugivorous according to hunters of NE DR Congo (Rahm & Christiaensen 1963, Nowak 1999), taking rodents, birds, insects and vegetable material. Said to kill chickens (Carpaneto & Germi 1989). P. Charles-Dominique (pers. comm.) did not find the remains of fruit in digestive tracts of two trapped specimens; a captive refused all sorts of fruit.

Palatal and dorsal views of skull of Central African Linsang *Poiana richardsonii*.

Social and Reproductive Behaviour Nothing known.

Reproduction and Population Structure A ♀ had milk in two teats in Oct and there are usually two young (Bates 1905). There may be two litters per year (Nowak 1999). Very few *Poiana* have been kept in captivity, but a captive specimen was still alive after five years and four months (Jones 1982); longevity in the wild is probably much longer.

Predators, Parasites and Diseases Ten out of 11 skulls examined showed frontal sinus damage, probably due to a trematode, *Achillurbandia* sp. This high percentage (91%) of cranial damage could indicate that the animals were caught as a result of abnormal behaviour. The species lives high in the canopy, rarely coming down to the ground; at least eight of the 11 studied specimens were trapped on the ground, possibly as a result of a parasitic infection (Colyn & Van Rompaey 1989).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although common in its wide range in a region of relatively intact habitat, they are probably experiencing localized declines as a result of forest loss and forest fragmentation due to logging, mining and slash-and-burn farming, as well as due to bushmeat hunting. *Poiana* make up nearly 1% of the carnivore bushmeat in NE DR Congo (Colyn *et al.* 1987). Five *Poiana* were identified out of more than 37,900 animals sold as bushmeat in Malabo market, Bioko I. (Harrington *et al.* 2002). Objects such as tobacco- and medicine-pouches, and ceremonial objects, are made from the skin (Thomas & Wroughton 1910).

Measurements

Poiana richardsonii

HB (♂ ♂): 370 (321–400) mm, n = 9

HB (♀ ♀): 360 (346–395) mm, n = 5

Subfamily VIVERRINAE – African Civet

Viverrinae Gray, 1821. London Med. Repos. 15: 301.

The subfamily Viverrinae, as traditionally defined, consists of three African (*Civettictis*, *Genetta*, *Poiana*; see earlier for the taxonomic validity of the genus name *Osbornictis*) and two Asiatic genera (*Viverra*, *Viverricula*), with a total of 22 species in these five genera listed by Wozencraft (2005). More recently, Gaubert & Cordeiro-Estrela (2006), on the basis of both morphological grounds and molecular phylogenetics, proposed differentiating the Viverrinae *sensu stricto* (terrestrial civets) from the Genettinae (genets and oyans), which is the approach followed here. Diagnostic characters of the Viverrinae are: feet digitigrade; thenar and hypothenar pads absent or residual; ratio between head-body and tail > 1.5; black- and white-striped 'collar' on the neck; perineal glands with a deep interglandular poach for musk storage in ♀ ♀; caudal entotympanic bone ventrally inflated, showing a pyramidal shape; paraoccipital process strong, exhibiting a ventral prolongation; and thick dentition, with a well-developed talonid on M1.

The subfamily includes the genera *Viverra* and *Viverricula* (both from Asia), and *Civettictis* (from Africa), which contains a single

species, the African Civet *C. civetta*. African Civets adapt to almost all terrestrial habitats throughout their range, with the exception of extremely arid regions and high-altitude mountain habitats. Size and body mass are the greatest among African viverrids. The genus *Civettictis* has long metapodials and extremely reduced metatarsal pads (Taylor 1988). Limbs are short compared with body length. Digitigrade feet distinguish them from the plantigrade Asiatic subfamilies (Paradoxurinae and Hemigalinae) and the semi-digitigrade Genettinae. The coat is spotted and the tail is clearly annulated with alternating bright and dark rings. The tail is not more than half as long as the body, and there is a characteristic black and white 'collar' on the throat. A well-marked and dark mid-dorsal line is usually present, often extending on the tail. There are no sub-orbital bright spots. The perineal glands are well developed. The caudal entotympanic bone is very inflated, and the paroccipital process is strongly developed and has a triangular shape. Teeth are heavily built, with a large talonid in M₁ and the lingual cusp of P₃ almost unapparent.

General biology and adaptations are as in Viverridae (see Family Viverridae profile). The African Civet has a rather omnivorous diet, and foraging occurs mainly on the ground. Periods of birth may be spread over a wide range, with sometimes poorly marked seasonality; females can have two to three litters a year (Ray 1995b).

Civet-like fossils appear in Eurasia from 20–13 mya, mainly as dental remains. The first records of African taxa occur at the beginning of this period (e.g. *Orangictis*). Plio-Pleistocene records

are rich and show the high diversification of the group into a complex of Eurasian and African taxa, currently still referred to *Viverra*, *Megaviverra*, *Vishnuictis*, *Civettictis* and *Pseudocivetta*. The extant African genus (*Civettictis*) appears in the early Pliocene of Ethiopia (L. Werdelin pers. comm.).

Philippe Gaubert

GENUS *Civettictis*

African Civet

Civettictis Pocock, 1915. Proc. Zool. Soc. Lond. 1915: 134.

The genus contains a single species, the African Civet *Civettictis civetta*, which is distributed throughout much of sub-Saharan Africa wherever there is adequate vegetation cover. African Civets are easily recognized as being the largest members of the Family Viverridae residing in Africa. External characters that separate them from other small carnivores include their disproportionately large hindquarters, low-headed posture, erectile dorsal crest and elongated and robust skull.

Formerly regarded as congeneric with the Asian civets (genus *Viverra*). The species was first included in the genus *Civettictis* by Pocock (1915), and with the exception of Ellerman *et al.* (1953) and Coetzee (1977), who continued to include it in *Viverra*, has been retained in *Civettictis* by most authors (e.g. Gregory & Hellman 1939, Petter 1969, Ewer 1973, Rosevear 1974, Kingdon 1977, 1997, Meester *et al.* 1986, Wozencraft

1993, 2005, Ray 1995b), based on the following differences: auditory bullae of *Viverra* smaller and more rounded than those of *Civettictis*; paroccipital process more rounded in *Civettictis*; molars broader and flatter in *Civettictis*, but sharper and narrower in *Viverra*; the hindfoot in *Viverra* lacks a metatarsal pad (present in *Civettictis*); the soles of *Viverra* are hairy, those in *Civettictis* naked anterior to the central pads; the claws of *Viverra* are short, semi-retractile and protected by skin lobes, whereas those in *Civettictis* are long and non-retractile; and the inner faces of each of the two lobes of the perineal gland of *Civettictis* possess an orifice, which connects with the sac that stores the gland's secretion (absent in *Viverra*).

Justina C. Ray

Civettictis civetta AFRICAN CIVET

Fr. Civette d'Afrique; Ger. Afrika Zibetkatze

Civettictis civetta (Schreber, 1776). Die Säugethiere 3 (16): pl. 111 [1776]; Text: 3 (24): 418, 3:index, p. 587[1777]. 'Guinea, Kongo, das Vorgebirge der guten Hoffnung und Aethiopien,' restricted to 'Guinea' (= former French Guinea) by Allen (1924: 117).

Taxonomy As many as six subspecies have been described, but there is so much individual variation in marking patterns and colouration that taxonomic validity of subspecies designations must be viewed with suspicion (Gregory & Hellman 1939, Rosevear 1974, Coetzee 1977, Meester *et al.* 1986, Kock *et al.* 2000). Synonyms: *australis*, *congica*, *matschiei*, *megaspila*, *orientalis*, *pauli*, *poortmanni*, *schwarzi*, *volkmanni*. Chromosome number: 2n = 38; the X chromosome is a large metacentric or submetacentric and the Y is a medium acrocentric or subacrocentric (Todd 1967).

Description Short-legged, blotched and striped, dog-like carnivore with disproportionately large hindquarters, dark facial mask and white neck stripes. Head broad, eyes relatively small. Ears small and rounded, but protrude from head, black on back, and white fronts and rims. Forehead whitish or grey, with black band across face above eyes. Bands of white from behind ears to front of shoulders. Dorsal pelage coarse and wiry in texture. Ground colour varies from whitish to reddish-buff, and underlying spotting pattern distinct. Arrangement of markings is highly variable, with no two individuals having the same pattern; patterning is irregular, with deep brown to black spots arranged in irregular rows. Guard hairs

Lateral view of skull of African Civet *Civettictis civetta*.

longer and thicker than underfur. Erectile crest formed by line of shaggy black hairs (up to 120 mm in length) along the spine from neck to tail. Whitish stripe along contour of back visible when spinal crest erected. Tail (ca. 55% of HB) coarse-haired with long bristles giving bushy appearance, laterally flattened and tip pointed. Dorsal surface of tail black, with five partial white rings. Paws and lower limbs black. Each foot with five digits; first toes set back from others and not visible in tracks. Soles naked anterior and lateral to the central pads. Claws long, curved and essentially non-retractile. Metacarpal pads bi-lobed and connected to palmar pad by one or more thin strips of skin; metatarsal pads on hindfeet present. Two pairs abdominal nipples. Females ca. 10% larger and heavier than

African Civet *Civettictis civetta*.

♂♂, although with broad overlap (Smithers & Wilson 1979, Ray 1995b, F. M. Angelici pers. comm.).

Skull long, narrow, and heavily built, with a long ovoid braincase and flat profile. Well-developed sagittal crest, strong zygomatic arch, prominent bullae and broad but blunt supraorbital processes. Dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$. Molar tooththrow is well developed, particularly the first upper molars that are broader and larger than in other viverrids. The canines are short and heavy.

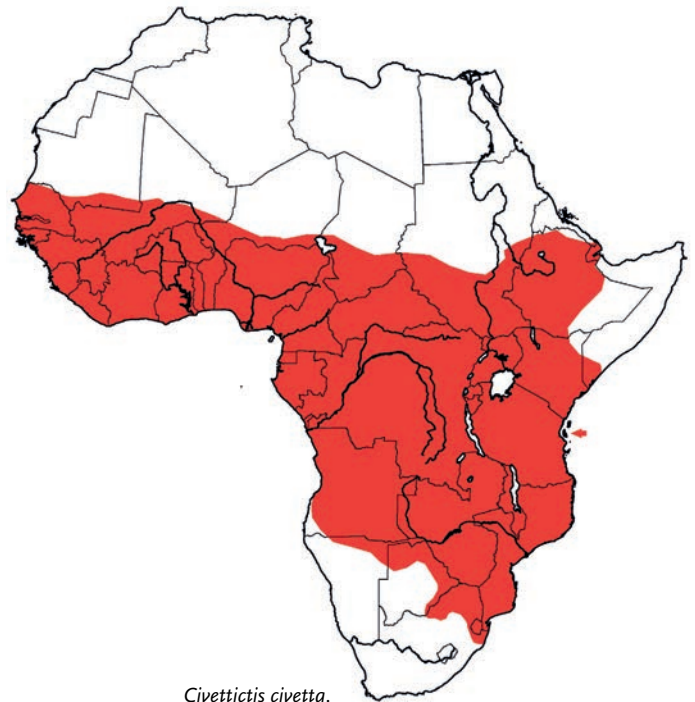

Geographic Variation Although animals taken in Nigeria seem to be slightly heavier than those recorded from southern Africa, there does not appear to be any significant geographic variation in size based on body measurements of specimens from across the range (see Ray 1995b and Measurements). However, there is extensive variation in patterning and colouration across the range. One-third of specimens collected in the north-east of the Congo basin were melanistic (Allen 1924); melanism is less common in West Africa (Rosevear 1974, F. M. Angelici pers. comm.), and not recorded at all in southern Africa (Skinner & Chimimba 2005).

Similar Species

Genetta spp. Smaller body size; dark markings arranged in regular longitudinal lines; longer, less bushy tails (the only genet to approach the African Civet in size is Giant Genet *G. victoriae*).

Proteles cristatus. Disjunct distribution range in southern and East and north-east Africa. Taller, with long ears, and shoulder higher than hindquarters; paler in colour, with thin, widely spaced vertical stripes.

Distribution Endemic to Africa. Distribution has been recorded as extending from 15°N to around 29°S latitude, from Senegal through all West African countries to Cameroon, Central African

Civettictis civetta.

Republic, S Sudan, Ethiopia, the Red Sea coast of Djibouti, and S Somalia (Funaioli & Simonetta 1966, Rosevear 1974, Ray 1995b, Kock *et al.* 2000). Two specimens collected from the dry Sahel savanna of S Mauritania in 2002 extend the range further north than has previously been recorded (Padial & Ibáñez 2005). Southwards they occur widely in all countries, but in southern Africa restricted to extreme NE Namibia (although Berry [1988] recorded a specimen from the Outjo District suggesting that they might be more common than is thought), N and E Botswana, and the north-eastern parts of South Africa south through Swaziland to the coastal region of NE

KwaZulu–Natal (Rowe-Rowe 1992a, Monadjem 1998, Skinner & Chimimba 2005). Present on Zanzibar I. (Pakenham 1984), but absent from Pemba and Tumbatu, and other offshore islands such as Bioko I.

Habitat African Civets are widespread, occupying secondary forest, woodland and bush habitats, as well as aquatic environments. Generally absent from the most arid portions of the continent, with the exception of riverine systems therein (Rosevear 1974, Rautenbach & Nel 1978). African Civets are uncommon in mature interior forest habitats (Sanderson 1940, Grubb *et al.* 1998), but will infiltrate deep forest via logging roads (Ray & Sunquist 2001). In the forest zone of West and central Africa, they thrive under conditions of deforestation and degradation (Grubb *et al.* 1998), and are regularly encountered near villages (Rahm & Christiaensen 1963, Hoppe-Dominik 1990, Angelici *et al.* 1999a). They have been recorded at altitudes as high as 5000 m on Mt Kilimanjaro (Moreau 1944), although they are probably not resident at this altitude (Grimshaw *et al.* 1995).

African Civets sleep in dense vegetation during the day (such as stands of long grass or thickets), in holes made by other animals, under logs, or among tangled roots (Verheyen 1951, Rosevear 1974, Kingdon 1977). One radio-collared male's diurnal resting location was found in the same area of dense juniper 9 of 11 times (Admasu *et al.* 2004c). In Mayombe, DR Congo, terrestrial hollows at the base of uprooted trees used both to hoard whole mature fruits and undigested seeds as well as latrines; such areas were selected according to proximity to fruiting trees and were abandoned once fruiting was over (Pendje 1994). They do not appear to be dependent on the availability of drinking water, but are more common in these areas.

Abundance Generally among the numerically dominant carnivores when present, and common in museum collections. Based on track counts recorded along transects in a lowland forest in SW Gabon, density estimated at 1/km² (Prins & Reitsma 1989). In NE DR Congo, significantly more abundant in post-cultivation regrowth vs. mature forest (Wilkie & Finn 1990). In both study areas, tracks of African Civets were the most commonly encountered of carnivores.

Adaptations Terrestrial, but adept swimmers (Shortridge 1934, Rosevear 1974). Their feet are unsuitable for climbing or digging, the footpad having relatively little overall surface area (Ewer & Wemmer 1974). African Civets climb only rarely (although they are known to clamber along low branches), probably when in pursuit (Rahm & Christiaensen 1963). Both fore- and hindlimbs adapted for sustained trotting, the most common form of locomotion (Taylor 1974, 1976). Heavy lower jaw and accompanying musculature gives the African Civet a powerful bite (Rosevear 1974). The outer upper incisors are enlarged to assist the canines in holding prey. The cheek-teeth are broad and blunt and adapted for grinding and crushing.

The spinal crest is erected when threatened, allowing individuals to assume a large and intimidating posture by increasing lateral body dimensions up to 30% and the size of the light dorsal stripe by as much as six times (Wemmer & Wilson 1983). Scent is not emitted in alarm (Ewer & Wemmer 1974, Kingdon 1977).

Foraging and Food African Civets are omnivorous and opportunistic, with principal food items including fruit, arthropods

and mammals (Bothma 1965, Rosevear 1974, Guy 1977, Randall 1977, Smithers & Wilson 1979, Pendje 1994, Ray 1996, Angelici 2000). Relative importance of these dietary components is variable among localities and seasons. Scats (n = 97) collected from Sengwa valley area, Zimbabwe, were dominated by mammals (84%; mostly rodent and hare), fruits (81%) and arthropods (76%), with birds (22%) and reptiles (10%) also present (Guy 1977). Elsewhere in Zimbabwe, 27 stomachs yielded the highest occurrence for insects (59%), followed by fruit (at least seven species; 52%), murids (41%), reptiles (22%), birds (15%), amphibians (11%) and millipedes (11%) (Smithers & Wilson 1979). Of 30 scats collected from Dzanga-Sangha Special Reserve, Central African Republic, 97% contained arthropods (millipedes, beetles, orthopterans), 73% fruit (at least nine species, dominated by *Staudtia stipitata*) and 30% mammal (rodents and pangolin) (Ray 1996, Ray & Sunquist 2001). In Mayombe district, DR Congo, the fruits of nine species of forest trees are regularly consumed, with *Staudtia stipitata* also favoured (Pendje 1994). In SE Nigeria, 27 stomachs contained mostly rodents, arthropods (millipedes, orthopterans and beetles) and reptiles (snakes and lizards), followed by fruit, birds and shrews (Angelici 2000).

Grass is commonly found in scats, at 60% frequency of occurrence in Dzanga-Sangha Special Reserve, Central African Republic (Ray 1996), and 22% in southern Africa (Smithers & Wilson 1979), but may be consumed more for its mechanical action than nutritional properties. Oil palm nuts are a favoured food source throughout the range, particularly during dry seasons (Pendje 1994, Grubb *et al.* 1998). Aquatic organisms, such as crabs, snails and mudskippers, are also commonly consumed (Rosevear 1974, Kingdon 1977, Grubb *et al.* 1998), and Ewer & Wemmer (1974) noted that captive civets would submerge their faces in water to catch small fish. Domestic poultry houses and gardens are often raided at night (Rosevear 1974, Kingdon 1977). As their teeth are not specially adapted for killing large prey, they have difficulty taking prey as large as Scrub Hare *Lepus saxatilis* and springhares *Pedetes* spp.; however, carrion can be a major food item (Bothma 1965, Guy 1977, Randall 1977). They were recorded preying on prosimian primates in Gabon (Charles-Dominique 1977).

Evidence points towards resource tracking according to availability, with African Civets taking advantage of any food source that happens to be abundant. In Zimbabwe, fruits were increasingly important during the months when fruit was most abundant, with insects taking precedence at other times of the year (Guy 1977). In drier climates, insects generally occur most frequently in African Civet diets during warm and wet summer months when most available (Skinner & Chimimba 2005). In moist forest habitats, where fruits are most abundant, they are often eaten to the exclusion of other foods for long periods of time (Kingdon 1977, Pendje 1994). In tropical forest environments, it is not uncommon for scats to be filled with only one species of fruit for the period of time when it is at its peak (Pendje 1994, J. C. Ray pers. obs.). The highest diversity of fruits is eaten during wet seasons (Pendje 1994). One radio-collared ♂ in the highlands of S Ethiopia utilized a core area that was less than 5% of its home-range, probably in response to enhanced food resources provided by rubbish dumps (Admasu *et al.* 2004c).

Prey is detected predominantly by olfactory and auditory senses, rather than visual (Ewer & Wemmer 1974). Live prey is generally

seized by mouth and secured by teeth. Paws are not used except to hold down the food item while pulling off pieces with incisors (Ewer & Wemmer 1974, Kingdon 1977, Schliemann 1990, Skinner & Chimimba 2005). Able to eat poisonous or distasteful fruits, insects and snakes, and most studies reveal that millipedes are commonly found in their diet (Guy 1977, Randall 1977, Ray 1996, Angelici 2000); they exhibit some degree of tolerance of noxious chemicals, as in the defence secretions of termite soldiers (Richardson & Levitan 1994). Stomach of one specimen killed in Dar es Salaam, Tanzania contained 12 Gutteral Toads *Bufo gutturalis*, the skin of which contains noxious poisons (K. Howell pers. comm.). Prey attack methods detailed in Ewer & Wemmer (1974). African Civets are likely to play an important role in dispersing seeds of forest trees; in Mayombe the average minimum dispersal distance was ca. 40 m from the parent tree (Pendje 1994).

African Civets are predominantly nocturnal, with peak activity beginning just before sunset until midnight (Rosevear 1974, Randall 1977). During a recent camera-trapping survey (55 trap-nights) undertaken in Zanzibar, all photographs of African Civets ($n = 8$) were taken during night hours, between 20:00h and 04:00h (Goldman & Winther-Hansen 2003). Seems to travel and forage habitually along the same routes (Rahm & Christiaensen 1963).

Social and Reproductive Behaviour Solitary, except when breeding (Rahm & Christiaensen 1963, Rosevear 1974, Kingdon 1977, Admasu *et al.* 2004c, Skinner & Chimimba 2005), and probably territorial (Rahm 1966, Randall 1977, Bearder & Randall 1978). One radio-collared subadult ♂ in S Ethiopia ranged over 11.1 km² during a 17-month period (Admasu *et al.* 2004c).

African Civets utilize latrines, depositing faeces in fixed places generally situated alongside roads or trails. Some latrines are used frequently, and then abandoned for several months (Randall 1977). Faeces are never buried, but rather piled on top of one another in shallow hollows (Gaillard 1969, Randall 1977, Bearder & Randall 1978, J.C. Ray pers. obs.). In one study in southern Africa savanna, latrines were communal, composed of scats of multiple individuals, and individuals visited more than one latrine (Randall 1977). However, exclusive use of latrines has been reported in a study in DR Congo (Pendje 1994), and in captive animals (Ewer & Wemmer 1974).

Scent-marking plays a role in communication and marking; both sexes have perineal and anal scent glands for this purpose (Pocock 1915, Ewer & Wemmer 1974, Jacob & Schliemann 1983). Secretions from anal glands added to faeces for long-lasting odour, probably serving a territorial marking purpose (Bearder & Randall 1978). Indeed, Rahm & Christiaensen (1963) followed the tracks of one individual that marked path intersections with anal secretions. Perineal gland secretions are used in marking objects along established routes, the function of which may be to provide olfactory information, such as sexual status, as scents are often overlaid by multiple individuals (Kingdon 1977, Randall 1977). Perineal secretions harden with age, but can retain strong odour for more than three months, even when covered by rain or insects (Randall 1977). Unfamiliar areas marked most extensively (Ewer & Wemmer 1974, Randall 1977, Schliemann 1990).

Adults are generally silent, except for ♀♀ in oestrus. In captive animals, the most frequent vocalization is a contact call, most often heard when cubs communicate with littermates, or when mothers

African Civet *Civettictis civetta*.

summon young (Ewer & Wemmer 1974). Known to hiss or growl in alarm or warning (Rosevear 1974).

All published mating and parturition records are from captive animals. Mating often preceded by courtship chases, which are initiated by the ♀, the dominant member of the pair (Kingdon 1977). Two matings in captive animals lasted 40 and 70 sec (Ewer & Wemmer 1974). Pair bonds not likely to be maintained in the wild following mating; captive ♀♀ are hostile to ♂♂ once cubs are born (Ewer & Wemmer 1974).

Reproduction and Population Structure In southern Africa, breeding occurs during warm, wet summer months with juveniles and gravid ♀♀ have been recorded from Aug to Jan (Skinner & Chimimba 2005). Rosevear (1974) reports no obvious breeding season in West Africa. The majority of births (19/22) at the Jersey Zoo in the Channel Islands occurred during the warmest period of the year (May–Oct) (Mallinson 1969, 1973). Gestation period ranges from 60 to 81 days (Ewer & Wemmer 1974, Kingdon 1977). Litter-size of captive animals 1–4 ($n = 27$; Mallinson 1969, 1973, Ewer & Wemmer 1974), but may be as many as five (Skinner & Chimimba 2005).

Females are polyoestrous, and may have two or three litters in one year. Maximum recorded duration of receptivity during oestrus is six nights; will go into heat 14 days following the loss of a litter (Mallinson 1973, Ewer & Wemmer 1974). Young are born fully furred, weigh about 300 g, with eyes open and in an advanced state relative to most carnivores (Ewer & Wemmer 1974). The coat pattern is poorly defined at birth, becoming clear during early stages of development (Skinner & Chimimba 2005). Weaning takes place from 14 to 16 weeks, with solid food provided by the mother in the second month (Ewer & Wemmer 1974). Captive ♀♀ attain sexual maturity at one year old, and give birth to first litters at 14 months (Ewer & Wemmer 1974). One captive animal lived to 28 years (Jones 1982, Weigl 2005).

Predators, Parasites and Diseases Large carnivores, such as Lions *Panthera leo* and Leopards *P. pardus*, probably prey on African

Civets opportunistically (Kingdon 1977). They were recorded in two of 117 Spotted Hyaena *Crocuta crocuta* scats in Niokolo-Koba N. P. in Senegal (Di Silvestre *et al.* 2000).

The following ticks have been recovered from animals in Kruger N. P., South Africa: *Amblyomma hebraeum*, *A. marmoreum*, *Boophilus decoloratus*, *Haemaphysalis leachi*, *H. zumpti*, *Ixodes* sp., *Rhipicephalus appendiculatus*, *R. evertsi*, *R. kochi* (which has a restricted distribution in NE South Africa, and was recovered from an animal taken near Pafuri), *R. simus*, *R. zambeziensis* and *R. zumpti* (Horak *et al.* 1987, 2000). In Ghana, African Civets appeared to be the major host for *Haemaphysalis leachi* and *Ixodes oldi* (Ntiemoa-Baidu *et al.* 2005). Horak *et al.* (2004) recovered the flea *Ctenocephalides damarensis* from animals in South Africa.

Pozio *et al.* (2005) recorded *Trichinella britovi* from a single animal taken in NW Guinea; trichinellosis is a human disease caused by eating raw or undercooked meat of animals infected with the larvae of *Trichinella* worms, but is typically considered a rare human disease in Africa, because of the practice of eating only well-cooked meats and religious laws that forbid the consumption of pork.

African Civets are also reported to be vectors of rabies (Enurah *et al.* 1988, Bingham *et al.* 1994), and are also susceptible to yellow fever (Dick 1952).

Conservation IUCN Category: Least Concern. CITES: Appendix III (Botswana).

African Civets remain relatively common within their wide distribution range, occur in a variety of habitats and are present in numerous protected areas. However, they may be undergoing some localized declines due to hunting. They are one of the most abundant mammals found in bushmeat markets within SE Nigeria, where they are utilized for both food and skin (Angelici *et al.* 1999c). They are frequently trapped for meat in Sierra Leone (Grubb *et al.* 1998), E DR Congo (Carpaneto & Germi 1989) and the savannas of N Central African Republic (R. Ruggiero pers. comm.). On Zanzibar I., African Civets appear regularly in the summaries of animals taken by National Hunters (subsidized by the Ministry of Agriculture), in spite of their protected status (Goldman & Winther-Hansen 2003). In N Congo, African Civet meat is so highly prized that it is rarely sold, with hunters opting instead to consume it themselves (R. Ruggiero pers. comm.). During one study following 96 hunters over a 1.5-year period in villages surrounding Banyang-Mbo Wildlife Sanctuary, Cameroon, African Civets represented 1% of the total offtake and biomass, and 7% of the carnivore offtake and 18% of the carnivore biomass (Nzouango & Willcox 2000). In Kisangani region, DR Congo, they represented only 2.3% of small carnivores trapped as bushmeat (Colyn *et al.* 1987), although this may have reflected its relative rarity in this forest region. The degree to which this species is killed in retribution for predation on domestic animals (e.g. Weladji & Tchamba 2003) is somewhat confounded by its being hunted for meat in many parts of its range (Ray *et al.* 2005).

African Civets are economically important due to their perineal secretion, a waxy substance which can be refined into the compound civetone, and which was exploited for many centuries as a fixing agent for perfumes (Dannenfeldt 1985). The African Civet musk trade has a long history, with present-day husbandry practices little changed over centuries. Males are preferentially harvested due to their larger perineal glands that are thought to produce a higher quality secretion. Even though there have been synthetic alternatives for this substance since the 1940s, civetone remains an important export commodity for Ethiopia, but also, to a lesser extent, for Niger and Senegal (Ray 1995b, Abebe 2000, Ray *et al.* 2005). Anal secretions (composed of a mixture of lipids, including cholesterol esters, monoester waxes, cholesterol and fatty acids), on the other hand, have no characteristic odour or commercial value (Bearder & Randall 1978, Jacob & Schliemann 1983, Saldern *et al.* 1987).

Measurements

Civettictis civetta

TL (♂ ♂): 1296 (1225–1374) mm, n = 8
 TL (♀ ♀): 1296 (1250–1370) mm, n = 11

Family HYAENIDAE
HYAENAS, AARDWOLF

Hyaenidae Gray, 1821. London Med. Repos. 15: 302.

| | | |
|-----------------------------|--------------------------|--------|
| <i>Hyaena</i> (2 species) | Striped and Brown Hyaeas | p. 262 |
| <i>Crocuta</i> (1 species) | Spotted Hyaeana | p. 272 |
| <i>Proteles</i> (1 species) | Aardwolf | p. 282 |

The hyaena family, Hyaenidae, today is the small remnant of a once extensive Eurasian radiation of more or less dog-like, hunting and scavenging carnivores of medium to very large size (Werdelin & Solounias 1991). At the present time, the family includes only four species: Spotted Hyaeana *Crocuta crocuta*, Striped Hyaeana *Hyaena (Hyaena) hyaena*, Brown Hyaeana *Hyaena (Parahyaena) brunnea* and the Aardwolf *Proteles cristatus*. Since the first three species are carnivorous/omnivorous meat-eaters and scavengers (though both species of *Hyaena* include a considerable amount of non-animal protein in their diet; Mills 1990), and the latter is a specialized feeder on social insects, the family retains considerable ecological diversity, despite its limited species richness. However, given that the diets of all four species require adaptations to ingesting food items that would not be healthy or digestible for a majority of carnivores, it is conceivable that the feeding diversity seen in hyaenas today stems from the evolution of such dietary tolerance in a common ancestor of all modern hyaena species living in the Miocene.

There has been controversy regarding the phylogeny and taxonomy of modern hyaenas, but the traditional view, going back to the nineteenth-century discovery of the Brown Hyaeana (Thunberg 1820), was that the Aardwolf was basal to the other three species, with Brown and Striped Hyaeanas closely related, and the Spotted Hyaeana as their closest relative. However, some prominent studies incorporating fossil taxa (Galiano & Frailey 1977, Werdelin & Solounias 1991) concluded on the basis of morphological data that the genus *Hyaena* as traditionally conceived is paraphyletic and that the Brown Hyaeana is the closest relative of the Spotted Hyaeana (though Werdelin & Solounias [1991] acknowledged that the supporting data were meagre). This required raising the subgenus *Parahyaena* Hendey, 1974 to the generic level. The first molecular phylogenetic study of extant hyaenas was that of Jenks & Werdelin (1998). These authors used sequence data from the cytochrome *b* gene of mtDNA to conclude that the traditional view was broadly correct, and that Brown and Striped Hyaeanas were each other's closest relatives. This view has been confirmed by Koepfli *et al.* (2006), who used an extensive data set of seven nuclear gene segments as well as the complete mtDNA cytochrome *b* gene to conclusively show that the Aardwolf is cladistically basal, Brown and Striped Hyaeanas are sister taxa, and Spotted Hyaeanas are a sister to this group. With this study the issue of the phylogeny of extant hyaenas has been laid to rest.

However, that agreement has been reached on hyaena phylogeny does not settle the issue of taxonomy. Brown and Striped Hyaeanas need not be placed in the same genus just because they are each other's closest relatives. This is especially true of a group such as the hyaenas, where the living species form a small, relictual subset of the diversity recorded in the fossil record. Since this is a matter of ranking, there

Spotted Hyaeana *Crocuta crocuta* skeleton.

Aardwolf *Proteles cristatus* skeleton.

Tentative phylogenetic tree for extant Hyaenidae (after Koepfli *et al.* 2006).

is a strong element of subjectivity, but the rank of different taxa can also be important to public perception, conservation issues and so on, so attempts should be made to find criteria that afford some measure of objectivity and comparability between taxa. One criterion that seems have stood the test of time is that of Hennig (1966), who suggested that the age of a group could be an arbiter of its rank. For Carnivora, a useful cut-off point for the generic level could be the Miocene–Pliocene boundary. In most carnivoran families with a good fossil record and where cladistic precepts of taxonomy have been followed, Miocene taxa tend to have been accorded separate generic status from living taxa, whereas many Plio–Pleistocene taxa have been considered congeners with living ones. There may be exceptions and changes might be due to an end-Miocene turnover in carnivores and carnivore-like mammals (Werdelin & Turner 1996a), but at least this concept can be used as a rule of thumb: if a split between taxa predates the Miocene–Pliocene boundary they should be considered separate genera, if it is younger they should, perhaps, be considered at most subgenera (note that this timetable might not be valid for mammal orders other than carnivores).

When this rule of thumb is applied to hyaenas and combining dates from the fossil record with those from molecular studies (Jenks & Werdelin 1998, Koepfli *et al.* 2006), it is clear that *Proteles* and *Crocuta* derive from lineages that split from the other two taxa in the Miocene. Data for Striped Hyaena and Brown Hyaena are more equivocal. The molecular data of Koepfli *et al.* (2006) suggest a date of 4.2 (6.4–2.6) mya for this split so, if the modal date is accepted, subgeneric status for these taxa is indicated. However, some fossils named *Ikelohyaena abronia*, retrieved from several Miocene and Pliocene sites in Africa, may belong to the Striped Hyaena lineage to the exclusion of Brown Hyaenas. If so, the *Hyaena hyaena* lineage dates back to the Miocene, and *Hyaena* and *Parahyaena* should be raised to the generic level. The data are at present inconclusive and either path is acceptable, both that of Werdelin & Solounias (1991) and Koepfli *et al.* (2006), who use *Parahyaena* as a full genus, and that of Jenks & Werdelin (1998), Wozencraft (2005) and this volume, in which it is treated as a subgenus of *Hyaena*.

Hyaenidae originated in Eurasia in the early Miocene, ca. 20 mya (Werdelin & Solounias 1991), with small forms reminiscent in morphology and presumably ecology of modern-day civets. They went through a major radiation of dog-like forms in the middle and late Miocene, centred on Eurasia, but with extensions into Africa and North America (one genus). The earliest African record of Hyaenidae is from the middle Miocene of Morocco and it is not until the late

Chewing musculature in (above) Spotted Hyaena *Crocuta crocuta* and (below) Aardwolf *Proteles cristatus*.

Miocene (<11 mya) that the family is firmly established in sub-Saharan Africa. Thus, hyaenas came late to Africa and then in the form of well-known Eurasian genera such as *Protictitherium*, *Ictitherium* and *Hyaenictitherium* (Nakaya *et al.* 1984, Werdelin 2003a). Curiously, the only specialist bone-cracking hyaena of the Miocene, *Adcrocuta eximia* (Werdelin & Solounias 1990), although present at some North African sites, never reached sub-Saharan Africa, leaving an apparent ecological vacuum in the carnivore guild there (Werdelin & Turner 1996b). Some endemic African species of Hyaenidae evolved during the Miocene, and towards the end of the Miocene, the first endemic hyaena genera, *Ikelohyaena* and *Werdelinus*, appear (Hendey 1974b, Werdelin & Solounias 1991, De Bonis *et al.* 2010). The former, from the latest Miocene and early Pliocene of South and East Africa, is very similar to, though more primitive than, the modern Striped Hyaena, and could, in fact, be congeneric with it. Shortly after the appearance of this taxon, the first Brown Hyaena evolved, also as an African endemic (Werdelin 2003b), and by 3.5 mya the Spotted Hyaena had also evolved in Africa (Werdelin & Lewis 2008).

The four taxa of Hyaenidae share a number of features of their biology, some of which must have been inherited from the common ancestor, while some have evolved *de novo* in the modern lineages in response to parallel environmental challenges. The hyaenid head is triangular in overall shape, with strongly developed masticatory musculature, a prominent feature in most of the living animals. Unique, caudally elongated frontal sinuses are present in all living hyaenids (as well as several fossil species), except the Aardwolf; the sinuses completely overlie the brain cavity, a condition apparently unique in the history of the Carnivora (Joeckel 1998). The dental formula in living hyaenas is $I^{3/3}, C^{1/1}, P^{4/3}, M^{1/1} = 34$, except for the Aardwolf, which has lost its anterior-most premolars. It is curious that the Aardwolf, in which the cheekteeth have been reduced to pegs, still retains a nearly full complement of teeth, and Koepfli *et al.* (2006) view this as an argument in favour of a relatively late date for the evolution of the Aardwolf.

The pelage is spotted (*Crocuta*) or transversely striped (remaining taxa). In the Brown Hyaena a long mane of dark brown guard hairs covers the forequarters, upper limbs and part of the torso. These

guard hairs, and the hairs of the mane of the Aardwolf, are among the longest of any member of the Carnivora. A 'primitive' coat pattern, at least in the group to which living hyaenas belong, would seem to be transverse stripes to the body and legs. Similarities in the patterns of the Aardwolf and its larger relative, the Striped Hyaena are, therefore, likely due to retention from a common ancestor.

All species are digitigrade and highly cursorially adapted (e.g. Andersson 2004). The differing life-styles of the various taxa suggest that the cursorial features of the skeleton of Hyaenidae (elongated limbs, locked elbow joint, etc.) are more likely to be due to adaptations to long-distance, energy-efficient foraging in open environments than to adaptations to rapid pursuit hunting (Janis & Wilhelm 1993). The sloping-back posture and somewhat rocking-horse running gait of Striped, Brown and Spotted Hyaenas are due to elongation of the forelimb relative to the hindlimb (Kingdon 1977, Spoor 1985, 1986). This is seen to a much lesser degree in the Aardwolf, though in this case it is exaggerated by the erectile mane and robust digging forequarters of the animal.

Hyaenas occur in a wide variety of habitats, from semi-desert, savanna and open woodland to dense dry woodland. The Spotted Hyaena also occupies montane habitats of the Ethiopian and East African domes. Hyaenids differ greatly in social behaviour, though these differences are sometimes exaggerated due to the extreme adaptations of the Spotted Hyaena. Spotted and Brown Hyaenas live in fission–fusion clans of variable size, while Striped Hyaenas often rest in pairs or groups. However, the two species of *Hyaena* forage singly though they may congregate at a food source if it is rich enough, while Spotted Hyaenas often forage in groups of differing sizes. The Aardwolf is monogamous and occupies a perennial territory that is aggressively defended. Greeting ceremonies involving genital sniffing

and anal pouch eversion are similar in the larger species, but more extreme in the Spotted Hyaena.

The fossil record of the Hyaenidae shows living hyaenas to be but a remnant of a once extensive radiation across Africa and Eurasia and into North America. In spite of this, the fossil record for the Aardwolf is currently almost non-existent. Where the fossil record of the extant hyaenas and their lineages has been studied, the trend towards relictual distributions is also evident. The Striped Hyaena spread into western Eurasia and the Indian sub-continent relatively recently, with no fossil record to show for it (Rohland *et al.* 2005). Within Africa, however, its range has contracted in the Pleistocene–Holocene, as it is no longer present in areas of southern Africa where it once occurred, as shown in the fossil record. The Brown Hyaena has apparently always had its distribution centred in southern Africa, but is known to have at least occasionally extended its range into East Africa (Werdelin & Barthelme 1997). A migration corridor for such expansion is hard to perceive in contemporary habitats. The Spotted Hyaena today has a wide distribution in Africa, yet this distribution is only a small remnant of its distribution in the Pleistocene. At the height of its expansion, the Spotted Hyaena (either the modern species or one or more fossil species – the taxonomy is controversial) ranged throughout Eurasia from the Pacific coast of Siberia to the British Isles and throughout those parts of Africa for which a fossil record is known. The Eurasian forms became abruptly extinct towards the end of the Pleistocene and the range of the modern African species appears to have been contracting ever since. Thus, while there is no immediate cause for alarm, it is worth noting that the Spotted Hyaena today occupies only a fraction of its former range, with unknown consequences for its viability as a species.

Lars Werdelin

GENUS *Hyaena*

Striped and Brown Hyaenas

Hyaena Brisson, 1762. Regnum Animale, 2nd ed., p. 168.

A genus of carnivorous/omnivorous Hyaenidae, here subdivided into two subgenera, *Hyaena* (*Hyaena*), Striped Hyaena and *Hyaena* (*Parahyaena*), Brown Hyaena (see discussion in family profile). Both species are solitary foragers but tend to rest in pairs or groups, the Brown Hyaena more so than the Striped. The two species are allopatric today, but were at least potentially sympatric at times in the past, as both species have been recorded from sites in South Africa. However, a more likely scenario may be that their respective geographic ranges have fluctuated somewhat depending on changes in climate and environment during the Plio–Pleistocene and that they have thus replaced each other in the fossil record without being truly sympatric. The *Hyaena* (*Parahyaena*) lineage cannot be followed fully in the fossil record, but given its absence from East Africa after the early Pliocene (although there was a short incursion in the middle Pleistocene; Werdelin & Barthelme 1997), it must be concluded that it has for the most part been a southern African endemic. Fossils from there are known from the early Pleistocene onwards and all appear to represent the modern species (Werdelin & Turner 1996b). The *Hyaena* (*Hyaena*) lineage is more fully documented through the presence of a Pliocene form, *Hyaena makapani*, known from South and East Africa (Toerien 1952, Werdelin & Lewis 2005), which is

Striped Hyaena *Hyaena hyaena*.

smaller and more gracile than the living species (which replaces it in the latest Pliocene–earliest Pleistocene).

Lars Werdelin

***Hyaena brunnea* BROWN HYAENA (STRANDWOLF)**

Fr. Hyène brune; Ger. Braune Hyäne (Schabrackenhyäne)

Hyaena brunnea Thunberg, 1820. K. Svenska Vet.-Acad. Handl. Stockholm, p. 59.
 'Goda Hopps Udden; Södra Afrika' [South Africa, Western Cape Prov., Cape of Good Hope].

Brown Hyaena *Hyaena brunnea*.*Hyaena brunnea*

Taxonomy The taxonomy of the Brown Hyaena is still a matter of some conjecture. Jenks & Werdelin (1998) recommended that in the absence of clear-cut data regarding generic rank among hyaenas, and because genetic data unite Striped Hyaenas *Hyaena hyaena* and Brown Hyaenas as sister taxa relative to *Crocota* and *Proteles*, the former two should be lumped together in the genus *Hyaena*. At the same time, they noted evidence for the timing of the split between the Striped and Brown Hyaena at approximately 6 mya, i.e. in the Miocene. They acknowledged this relatively old date by placing the two in different subgenera, *Hyaena* (for Striped) and *Parahyaena* (for Brown), respectively. Wozencraft (1993), following Werdelin & Solounias (1991), raised *Parahyaena* to genus level (and see Bronner *et al.* 2003), but later Wozencraft (2005), on the basis of the evidence presented by Jenks & Werdelin (1998), returned the species to *Hyaena*.

Substantial individual variation led to early erection of several subspecific names (see synonyms). Pocock (1934a) recognized two subspecies, with *melampus* representing a different form, but most subsequent authors (Ellerman *et al.* 1953, Coetzee 1977, Meester *et al.* 1986) have not adopted this approach, and morphological evidence suggests that they should both be rejected (Jenks & Werdelin 1998). Synonyms: *fusca*, *makapani*, *melampus*, *striata*, *villosa*. Chromosome number: $2n = 40$; there are 70 autosomal arms; the X chromosome is submetacentric and the Y chromosome is acrocentric (Wurster-Hill 1973).

Description Medium-sized, dog-like animal with typical hyaena build, being higher at shoulders than at rump, giving appearance of a sloping back. Head, neck and shoulders massive, hindlegs, in comparison, appear almost wasted. Muzzle black, forehead lighter. Whiskers long and black. Ears long, about 140 mm, and pointed. Pelage shaggy, dark brown to black, except around neck and shoulders, which are off-white to tawny-white, as are underparts and insides of limbs. The long hair along the mid-dorsal line can be raised in a conspicuous display. Close up, body colour is uneven, with darker bands caused by broad black tips of guard hairs lying in juxtaposition. On upper parts of limbs are a series of white bands.

Tail is relatively short, dark and bushy. Forefeet much larger than hindfeet, a feature clearly marked in the spoor and making it possible to distinguish spoor of a Brown Hyaena from a Spotted Hyaena *Crocota crocuta*, where differences in size between forefoot and hindfoot are less marked. There is a clear difference between male and female reproductive organs, with the testes showing clearly just below the anus, unlike with the Spotted Hyaena. Females have two pairs abdominal nipples.

A characteristic feature of the skull is the shape of the braincase, which is narrower than in the Spotted Hyaena and not pear-shaped (Skinner 1976). Skull is highest at about level of intertemporal constriction, sloping off very gradually backwards and abruptly forwards to the nasals. Sagittal crest is well developed, but little evidence of a supra-occipital crest. Zygomatic arches broad (though less robust than in the Spotted Hyaena). Postorbital bars are incomplete (Skinner & Chimimba 2005). Dentition typically hyaenid.

Geographic Variation See Taxonomy.

Similar Species

Hyaena hyaena. Not sympatric, occurring only as far south as N and C Tanzania. Slightly smaller, with a pale grey to beige pelage and darker vertical stripes on the body and legs.

Crocota crocuta. Sympatric. Larger, and with spots on body, with round, not pointed ears and a short coat. Young adults tend to have darker spots and are light around the neck, and in poor light and at a distance may be mistaken for Brown Hyaena.

Distribution Endemic to southern Africa except for a marginal extension into the arid parts of SW Angola. The range of the Brown Hyaena has shrunk significantly since the end of the eighteenth century when it was last recorded from Table Bay in the extreme south-west of the continent. At the end of the nineteenth century it was still regularly found as far south as Malmesbury and Beaufort West in the then Cape Province, South Africa.

Current Distribution Still widespread in southern Africa. In Angola, only recorded from the south-west of the country (Crawford-Cabral & Simoes 1990). In Namibia sporadically encountered over most of the country, mainly along the coast, in Etosha N. P., and in Bushmanland in the north-east (Hofer & Mills 1998a), as well as from the Caprivi strip (Purchase *et al.* 2007). Widespread in Botswana, excluding the extreme north (Smithers 1971). In Zimbabwe mainly in the western parts of the country and also the extreme south (Smithers & Wilson 1979). In Mozambique reported from the Banhine Flats, an arid area in the south-west of the country (Smithers & Lobão Tello 1976). Records from Malawi are erroneous (see discussion in Ansell & Dowsett 1988) and there are no records from Zambia. In South Africa, recorded in recent years from the extreme south in the Western Cape (Gansbaai and Bredasdorp), where it was believed to be extirpated, so may be recolonizing some of these areas (Hofer & Mills 1998a). Occurs sporadically in the northern regions of the Eastern and Western Cape, and in the Northern Cape, particularly north of the Orange R. in the Kgalagadi Transfrontier Park and in the Richtersveld. Historically, they occurred over the entire Free State, but today are very sparsely dispersed over all except the western parts. Still occurs in most of North West Province, and the western parts of Mpumalanga and Limpopo Province; even occurs sporadically in Gauteng near densely populated areas. Found in many of the smaller game reserves, but absent as a breeding species over the eastern lowveld areas encompassing the Kruger N. P. and surrounding private reserves. Never common in KwaZulu-Natal, but recorded irregularly in the drier regions in the north-west; recently introduced into Hluhluwe-iMfolozi Park, the Eastern Shores of the Greater St Lucia Wetland Park, and Itala G. R., although their historical occurrence there is uncertain (Rowe-Rowe 1992a). Occurs only in the west of Lesotho (Lynch 1994). Presence in Swaziland is not confirmed, but they are likely to occur in the north-east and extreme west and north-west of Swaziland (Monadjem 1998).

Habitat Found in desert areas (e.g. the Namib) with annual rainfall less than 100 mm, particularly along the coast, as well as semi-desert, open scrub, and open woodland savanna with a maximum rainfall up to about 650 mm (Mills 1998a). It is independent of drinking water, but needs some type of cover in which to lie up during the day. Mills (1990) found that during the hot summer months in the SW Kalahari in Botswana they favoured the deep shade provided by Shepherd's Bush *Boscia albitrunca* or would use holes in the ground. They also have an ability to survive close to urban areas (see Skinner 1976).

Abundance Studies in Kgalagadi Transfrontier Park concluded that there are about 400 Brown Hyaenas in the park. Because of its secretive nature and nocturnal habits it is easily overlooked; therefore, numbers and distribution records may underestimate population size. Given this proviso, the total population size on the continent has been estimated at a minimum of 5000–8000 individuals, with

Lateral, palatal and dorsal views of skull of Brown Hyaena *Hyaena brunnea*.

Botswana having the largest population (an estimated 3900 animals) (Hofer & Mills 1998b).

Adaptations The powerful teeth and jaws, and associated well-developed head and neck muscles, enable Brown Hyaenas to crack open larger bones than other carnivores, except other hyaenas, and thereby extract highly nutritious marrow locked up in leg bones. The zygomatic arches swing out broadly at the back, providing ample room for the well-developed masseter and temporalis muscles. The teeth, in particular, are large and specialized for crushing bones, especially the premolars where the anterior and posterior cusps are reduced and the central cusp is enlarged, giving the tooth a conical hammer-like structure. The upper outer incisors are larger than the other incisors and canine-like and help the stout lower canines in holding and pulling. The lower canines are more curved than the upper ones and have a cutting ridge on the inside. The first two upper premolars are small, but the third and fourth are larger and more robust, with the fourth also having a shearing function (carnassial). The second lower premolars are small, but the third and fourth premolars are robust and strong and together with the third and fourth upper premolars are the most important bone crushers. The upper molars are elongated, set at right-angles to the toothrow, and occlude against the posterior shelves of the lower molars, performing a grinding function. The first lower molars are mainly for slicing and shearing and form the lower carnassial.

The massive forequarters of the Brown Hyaena enable them to carry large carcasses long distances to their cubs; in one instance an

individual carried 7.5 kg of a domestic cow calf back to a den from a distance of 15 km (Mills 1990). Their senses of hearing and sight appear to be particularly well developed, as is their sense of smell; carrion is mainly detected by smell, and even old and dry carcasses can be detected from 2 km downwind (Mills 1978b, 1990).

An evertable anal pouch is situated between the rectum and the base of the tail. It consists of a central region of enlarged sebaceous glands, a peripheral region of apocrine tissue and a groove running down the middle. The pouch secretes two distinct substances, a white paste rich in lipid (secreted from the sebaceous glands) and a black paste rich in lipo-fuchin (secreted from the apocrine glands). These substances are pasted onto plant stalks in an elaborate scent-marking behaviour, unique to the hyaenas, known as pasting (the black secretion is pasted higher than the white) (Mills *et al.* 1980).

Foraging and Food Brown Hyaenas are primarily scavengers of a wide range of vertebrate remains, supplementing their diet with wild fruits, insects, birds' eggs and the occasional small animal that is killed (Skinner 1976, Mills 1978a, 1982a, 1990, Mills & Mills 1978, Owens & Owens 1978, Skinner & Van Aarde 1981, Siegfried 1984, Stuart & Shaughnessy 1984, Maddock 1993b, Burgener & Gusset 2003, Maude & Mills 2005, Kuhn *et al.* 2008). Hunting is unspecialized and opportunistic, directed at small animals only (including seal pups) and largely unsuccessful. Of 128 hunts observed in the S Kalahari, only six (4.7%) were successful (including kills of Southern African Springhare *Pedetes capensis*, Springbok *Antidorcas marsupialis* lambs and a Bat-eared Fox *Otocyon megalotis*). Their success rate hunting Springbok *Antidorcas marsupialis* lambs was only 6% (far lower than Spotted Hyaenas) (Mills 1990). Carrion forms the primary component of the diet, particularly from ungulate carcasses.

Brown Hyaena exhibit a predilection for Ostrich *Struthio camelus* eggs that are easily carried and opened, something that the larger Spotted Hyaena seems to have greater difficulty in accomplishing. Average daily consumption rate was calculated as 2.8 kg per day (Mills 1990). In the S Kalahari (Kgalagadi Transfrontier Park) the Tsama Melon *Citrullus lanatus* and Gembok Cucumber *Acanthosicyos naudinianus* are important in its diet, providing also much of the animals' moisture requirements.

Along the Namib Desert coast, Brown Hyaenas feed predominantly on Cape Fur Seal *Arctocephalus pusillus* pups, only 2.9% of which were killed by the hyaenas (Goss 1986), and also scavenge other marine organisms washed up on the shore. In faecal analysis studies of hyaenas in the Namib Desert, Cape Fur Seal remains were the predominant prey item present in scats (Skinner & Van Aarde 1981, Siegfried 1984, Stuart & Shaughnessy 1984, Kuhn *et al.* 2008). Skinner *et al.* (1995) observed six occasions of hyaenas actually killing seal pups, when the hyaena would walk among the pups, bite one on or behind the head and carry it out of the seal colony.

Brown Hyaenas are mainly nocturnal with some crepuscular and diurnal activity. In the S Kalahari, they were particularly active from about 18:00 to 08:30h during the summer months and from about 16:30 to 06:00h during the winter months (Mills 1990). They are strictly solitary foragers, covering large distances in search for food. In the S Kalahari it spends on average 80% of the hours of darkness active and covers an average of 31.1 km per night, with the maximum recorded being 54.4 km (Mills 1990). Food items are often taken back to the den to provision the young, and bone assemblages have

been shown to reflect faunal composition of the area at that time (Skinner & Van Aarde 1981, Skinner *et al.* 1998, Skinner 2006, Kuhn *et al.* 2008).

Excess food is often stored. On one occasion a Brown Hyaena came across an Ostrich nest containing 26 eggs. It ate seven eggs in two nights and scatter-hoarded the remainder under bushes or in grass clumps at distances of up to 2 km from the nest. On ten occasions where hyaenas cached food, items were retrieved within 72 hours (Mills 1990).

The impact of the Brown Hyaena on domestic animals is usually small (Mills 1998a), although sheep and goats in particular, but also calves, poultry, domestic dogs and cats have very infrequently been recorded as kills. In agricultural areas of Mpumalanga and Limpopo Province, Skinner (1976) reported two cases of stock killing over several months that ceased once the individual predator was removed, even though there were other Brown Hyaenas in the area; for the most part, carrion and medium-sized and small indigenous animals were commonly eaten.

Social and Reproductive Behaviour Brown Hyaenas live in clans ranging in size from a solitary ♀ and her cubs to groups containing several ♀♀ and their offspring of different ages. Adult ♂♂ either remain with their natal clan, become nomadic, or immigrate into a new clan (Owens & Owens 1979b, Mills 1990). Although members of a clan forage singly, several may come together at a large food source (although when they do they usually feed one at a time) and members of a clan defend a common, fixed territory. In the S Kalahari clan territories were found to vary in size from 235 to 480 km² (n = 6; Mills 1990) and along the Namib Desert coast territory size for eight and 12 animals covered 420 km² and 220 km², respectively (Skinner *et al.* 1995). In agricultural areas of Gauteng, the range of a translocated adult ♂ was only 49 km², suggesting that agricultural development may in some instances be advantageous to the Brown Hyaena (Skinner & Van Aarde 1987). The type of food in the territory determines clan size, while the manner in which the food resources are distributed determines territory size (Mills 1990).

Territorial ownership and probably also information between group members is communicated mainly through pastings as well as by defecating at latrines. Brown Hyaenas distribute pastings throughout the territory, particularly in the core areas; an individual pastes on average 2.6 times per km moved (with no difference between sexes), and increase pasting frequency near territory boundaries. Pastings are placed on grass stalks, bushes or rocks. Pastings are so well distributed over a Brown Hyaena territory that an individual is hardly ever more than 500 m from an active pasting, which lasts for over 30 days (Mills *et al.* 1980, Mills 1990).

Latrines are scattered throughout the territory but tend to be concentrated around the boundary. Boundary latrines are visited more frequently than those within the territory. Latrines have a saucer-shape, are about 1 m in diameter and 150 mm deep. Latrines are used as marking posts, with a small stool placed in each as the hyaena moves from one to the other. Some latrines are used over a short period only, while other latrines are used over a period of years (Skinner & Van Aarde 1981, Mills 1982a).

Meetings between clan members involve mutual sniffing around the head and face, neck and body, and anal pouch. Muzzle wrestling

between subadults, and between subadults and adults (though rarely between adults) and allogrooming between all age classes, was also evident (Mills 1982a, 1990). No dominance hierarchy was found within the clans in the S Kalahari, although this may be different in other areas. In the Central Kalahari, Owens & Owens (1996) found a separate linear dominance hierarchy within each sex, and that the highest-ranking ♀ shared equal rank with the alpha ♂.

Territorial fights are usually ritualized neck-biting bouts between two animals of the same sex from different clans accompanied by loud yelling and growling by the submissive animal. Meetings between individuals of different sexes and from different groups are often amicable.

Both nomadic and immigrant ♂♂ may mate and all adult ♀♀ in a clan may reproduce, although the matriarch appears to produce more cubs than the others (Mills 1990). Mills (1990) described six mating bouts, with mean mating frequency 0.13 mounts/min, the mean interval between mountings 6.6 min, and the mean duration of mounting 42 min.

Cubs are born and raised in dens. The den is usually a single hole in the ground, often a disused Aardvark *Orycteropus afer* burrow, which the ♀ modifies to her requirements, although in some areas caves are used (Skinner 1976, Goss 1986). Dens have a narrow entrance of about 30 cm high and 50 cm wide, and typically have a single entrance (Mills 1990). At most dens a single litter of cubs is raised, but two or even more ♀♀ may share a den in territories where more than one ♀ breeds (Owens & Owens 1979a, Mills 1990). The breeding ♀♀ are usually a mother and her grown-up daughters and although they give priority to their own they may even suckle each other's cubs.

The denning period lasts 15 months, during which time the cubs use several different dens. In the S Kalahari each den is occupied for an average of 3.6 months. Mothers will carry cubs to new dens, but from about six months cubs may even initiate the move themselves (Mills 1990). For the first three months of their lives the cubs are nursed by their mother, typically at sunset and sunrise, after which the milk diet is supplemented to an ever-increasing degree by meat brought to the den. Consequently, Brown Hyaena dens often become littered with bones and other remains. All members of the clan help to feed the cubs by carrying food in the form of meat, skin and bones to the den (see Foraging and Food), although D. Owens & M. Owens (1984) reported differences between the sexes. After weaning, cubs begin to forage for themselves (Mills 1990).

Vocalizations include a loud growl when frightened, a yell or a short deep growl when confronted by Lions *Panthera leo* or in encounters with Spotted Hyaenas, and submissive animals may scream when neck-biting with dominants, or squeal or whine on greeting them. Cubs and subadults utter a soft growl, accompanied by panting, when muzzle-wrestling. Cubs utter a harsh whine prior to suckling, and a soft whine when being groomed. Adult ♂♂ utter a very soft growl when calling cubs in the den. The adults hoot and pilo-erect when approaching others on a kill. The Brown Hyaena has no long distance call analogous to the Spotted Hyaena's whoop, nor do they giggle (Mills 1990).

Reproduction and Population Structure The Brown Hyaena is a polyoestrous, non-seasonal breeder with anoestrous occurring during lactation. In the wild, oestrus in the ♀ lasts 4–6 nights. The gestation period is approximately 97 days and mean litter size is 2.3 (range 1–5; Skinner 1976). Mean inter-litter interval is

Brown Hyaena *Hyaena brunnea* with crest and tail hairs erected.

20.7 ± 4.9 months, although if a litter dies the ♀ will come into oestrus earlier (Mills 1990). Cubs are born with eyes closed, and ear pinnae folded; eyes start to open on Day 8 and are fully open by Day 14, while ears become erect at Day 28 (Schultz 1966). The cubs are weaned at 12–15 months of age. Birth-weight has been calculated as 693 g and full size is reached at about 30 months (Mills 1990). Cub and young adult mortality rates are low, but subadult and old adult mortality appears to be quite high. In the wild, maximum longevity is about 20 years (M. G. L. Mills pers. obs.); a captive individual survived to nearly 32 years (Weigl 2005).

Predators, Parasites and Diseases Over much of its range the Brown Hyaena lives in association with other carnivores and benefits from many of them by scavenging from their kills. Lion kills provide many scavenging opportunities for Brown Hyaenas (e.g. in the Central Kalahari; Owens & Owens 1978), although they are dominated, even sometimes killed, by Lions; Apps (1982) reported an instance in Kgalagadi Transfrontier Park of a Brown Hyaena seemingly shamming death in an attempt to avoid being killed by Lions. The Brown Hyaena is usually dominant over Leopards *Panthera pardus*, Cheetahs *Acinonyx jubatus*, Caracals *Caracal caracal* and often appropriates the kills of these species (Owens & Owens 1978, Mills 1990). Competition for food between the Brown Hyaena and Black-backed Jackal *Canis mesomelas* can at times be severe and vultures too can deprive it of food. The Spotted Hyaena is dominant to the Brown Hyaena and in certain areas deprives it of a significant amount of food. This may have a detrimental effect on Brown Hyaena numbers and may even affect its distribution as where the Spotted Hyaena is common the Brown Hyaena is usually absent or very rare (Mills 1990); this may, for example, partly explain the species' absence in N Botswana.

Wounds inflicted during both inter- and intra-specific fights and starvation, or starvation due to severe wearing down of the teeth and an inability to consume bones, are the main cause of natural mortality in protected areas. Although rabies has been recorded from Brown Hyaena (Swanepoel *et al.* 1993), no evidence for disease being an important form of mortality has been found.

Not a great deal of information is available on parasites. Mills (1982a) mentions fleas often found on cubs, and that the flea

Echinophaga larina was identified from one individual. Hyaenas in the S Kalahari rarely had ticks, although Horak *et al.* (2000) recorded *Haemaphysalis leachi*, *Rhipiceptor nuttali* and *Rhipicephalus simus* on an animal taken in Gauteng. Internal parasites taken from Brown Hyaenas include a tape-worm *Taenia hyaenae* and a nematode *Spirocerca lupi* (Mills 1982a).

Conservation IUCN Category: Near Threatened. CITES: Removed from Appendix II in 1999.

There are a number of large conservation areas with viable populations of the Brown Hyaena, including: Namib-Naukluft, Skeleton Coast, Sperrgebiet and Etosha National Parks (Namibia), Kgalagadi Transfrontier Park (South Africa, Botswana), Pilanesberg N. P. (South Africa) and the Central Kalahari G. R. (Botswana). Outside protected areas the Brown Hyaena may run into conflict with humans, and they are often shot, poisoned, trapped and hunted with dogs in predator eradication or control programmes, or inadvertently killed in non-selective control programmes. In spite of this, they appear to do quite well in many areas. They are also occasionally run over by vehicles in South Africa, though this is unlikely to represent a major threat (Mills 1998a). Although used in traditional medicine and rituals, it is not nearly as sought after in this regard as the Spotted Hyaena (Hofer & Mills 1998b).

Measurements

Hyaena brunnea

TL (♂ ♂): 1445 (1320–1609) mm, n = 16

TL (♀ ♀): 1331 (1105–1516) mm, n = 17

T (♂ ♂): 205 (177–236) mm, n = 14

T (♀ ♀): 223 (170–300) mm, n = 14

HF c.u. (♂ ♂): 211 (191–234) mm, n = 14

HF c.u. (♀ ♀): 212 (200–225) mm, n = 14

E (♂ ♂): 150 (138–161) mm, n = 13

E (♀ ♀): 146 (135–167) mm, n = 14

WT (♂ ♂): 43.6 (35.0–49.5) kg, n = 20

WT (♀ ♀): 40.4 (28.0–47.5) kg, n = 20

Zimbabwe (Smithers & Wilson 1979), S Kalahari (Mills 1982b) and Gauteng and Limpopo Province, South Africa (Skinner & Ilani 1979). Exceptional body weight measurements include those of a ♀ from the Eastern Cape weighing 67.6 kg (P. Swanepoel, in Mills 1998a) and an animal of unrecorded sex weighing 72.6 kg from Mpumalanga (Roberts 1951).

Gus Mills

Hyaena hyaena STRIPED HYAENA

Fr. Hyène rayée; Ger. Streifenhyäne

Hyaena hyaena (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 40. 'India', restricted by Thomas (1911: 134) to 'Benna Mts, Laristan, S. Persia'.

Striped Hyaena *Hyaena hyaena*.

Taxonomy Pocock (1934a, b) condensed the number of subspecies across the entire species' range from the 28 defined by the beginning of the twentieth century to five, based on cranial measurements and pelage characteristics: *H. h. barbara* from north-west Africa, *H. h. dubbah* from north-east Africa, *H. h. syriaca* from Syria, Asia Minor and the Caucasus, *H. h. hyaena* from India and *H. h. sultana* from Arabia (although see Coetzee [1977] who regarded *vulgaris* as a distinct subspecies). Rieger (1979a) suggested integrating these into a smaller, north-east

African-Arabian group composed of *H. h. dubbah* and *H. h. sultana* and a larger, north-west African-Asian group comprising *H. h. barbara*, *H. h. syriaca* and *H. h. hyaena*. However, Jenks & Werdelin (1998) noted the inadequacy of available morphological data on variability to characterize each subspecies and that any classification was provisional. Synonyms: *antiquorum*, *barbara*, *bergeri*, *bilkiewiczzi*, *bokcharensis*, *dubbah*, *dubia*, *fasciata*, *hienomelas*, *hyaenomelas*, *indica*, *orientalis*, *rendilis*, *satunini*, *schillingsi*, *striata*, *suilla*, *sultana*, *syriaca*, *virgata*, *vulgaris*, *zarudnyi*. Chromosome number: 2n = 40, with 32 metacentric-submetacentric and 6 acrocentric autosomes, a metacentric X and an acrocentric Y (Berube-Genest *et al.* 1987).

Description Medium-sized carnivore with overall appearance reminiscent of a dog. Muzzle pointed and head broad with long, pointed ears. Back slopes downward from head to tail. Coat has black vertical stripes on side, horizontal stripes on legs and a distinctive dark patch (or broad, dark 'stripe') on the throat. Underfur colouration pale grey or beige; however, some individuals may appear more white. Pelage colouration varies by region and may vary seasonally in colder parts of its range (Pocock 1934a, Rosevear 1974, Ilani 1975). Ground colour of pelt typically grey to light brown, but may appear strikingly white even within the same population. Cub ground colour appears very white and the contrast between ground colour and black striation patterns is much more apparent (Rosevear 1974, Rieger 1978, A. P. Wagner pers. obs.). Longest hairs are up to 200 mm long (Rosevear 1974) and fall along the mid-dorsal line. The black dorsal mane may be held erect, significantly increasing apparent size of the animal (Schneider 1926,

Lateral, palatal and dorsal views of skull of Striped Hyena *Hyaena hyaena*.

Pocock 1934a, Kruuk 1976, Rieger 1978). Legs appear thin relative to their length and hindlegs are shorter than forelegs. Feet have four toes with short, non-retractable claws (Pocock 1916c). Tail long with long coarse hairs. Well-developed anal pouch, a slit-like glandular orifice over-arching the anus from either side. Anal pouch may be everted and thus be apparent while pasting or presenting during social encounters (Holzapfel 1939, Fox 1971, Kruuk 1976, Rieger 1977, 1978). In juveniles, there is an unusual convergence in genital appearance between sexes (Wagner *et al.* 2007b). Juvenile ♀♀ have well-defined labia-like folds anterior to the vagina. These ridges are hairless and darker than surrounding tissue. Juvenile ♂♂ have smaller, smooth, hairless pre-scrotal skin folds along the middle septum close to, but anterior to, the scrotum. Unlike Spotted Hyena *Crocuta crocuta*, convergence in genital appearance is not complete enough to confuse the sexing of juveniles and adult genitalia appear normal. There is no apparent sexual dimorphism in body measurements and weight (Mendelssohn & Yom-Tov 1987, A. P. Wagner pers. obs.).

Skull differs from that of *Crocuta* in being slightly smaller in size and less massive in overall build (Rosevear 1974) and having a slightly lower profile of the sagittal crest (A. P. Wagner pers. obs.). Permanent dentition distinctly carnassial and dental formula typically hyaenid. Compared with *Crocuta*, the upper molar is much larger, as much as twice or more the size of the first premolar (Rosevear 1974, Coetzee 1977).

Geographic Variation Existing subspecies descriptions are based on limited data except for *H. h. syriaca* in Israel and *H. h. dubbah*

in Kenya (Mendelssohn & Yom-Tov 1987, Wagner 2006). Differences in pelage across the range appear minimal, although the Lebanese population is reported to have a reddish base-coat colour (Lewis *et al.* 1968) and hyaenas on the Arabian peninsula are described as having a yellow mark below the eyes (Gasparetti *et al.* 1985) and the dorsal crest is mixed grey and black rather than predominantly black (Mendelssohn & Yom-Tov 1987). *Hyaena h. dubbah* lacks the pronounced, thickened fold of skin on the throat (somewhat reminiscent in appearance of a goitre), which is apparent in northern populations (A. P. Wagner pers. obs.). Given the comments of Jenks & Werdelin (1998), no subspecies are listed here.

Similar Species

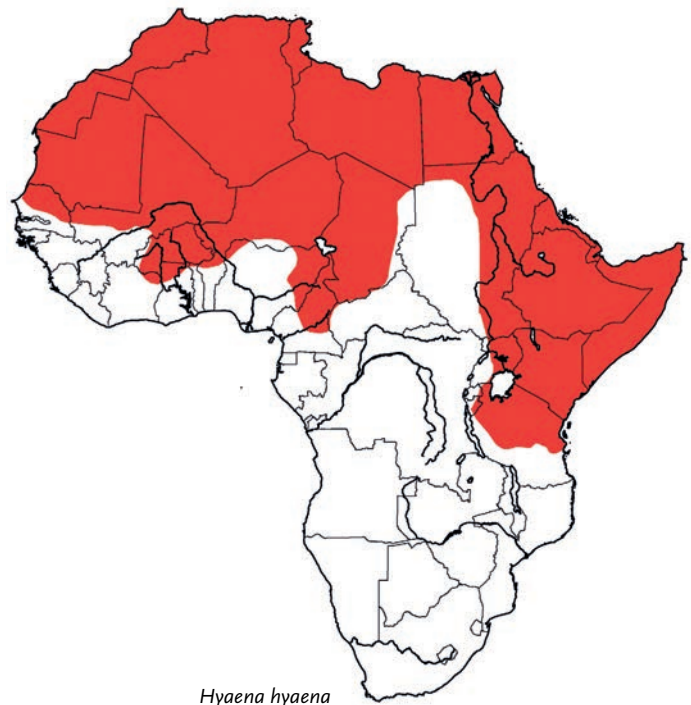

Crocuta crocuta. Sympatric across much of the range. Spotted pelage and back not maned; relatively short tail; short, rounded ears.

Proteles cristatus. Sympatric in East and north-east Africa. Marked difference in body size (about 9 kg) with more gracile build and large pointed ears; finer coat hairs appear glossier than the coarse coat of the Striped Hyena; coat also with black vertical stripes, but more regular; cheekteeth rudimentary.

Hyaena brunnea. Southern Africa only. Stripes on legs only, with characteristic dark, long-haired, shaggy coat, and lacking a distinct mane.

Distribution The Striped Hyena has a very large range extending from Africa, north of and including the Sahel, and including much of East and north-east Africa, through the Middle East and Arabian Peninsula, the Caucasus, Turkey, central Asia, and the Indian sub-continent, though not reaching Bhutan or Burma. Across their wide range, current distribution is patchy and most populations are likely composed of isolated small populations (Hofer & Mills 1998a).

The current distribution of the species was reviewed by Hofer & Mills (1998a). In North Africa, their distribution extends from S Morocco eastward along the extent of the North African coast to

Hyaena hyaena

convergence in male and female external genital appearance from a common ancestral hyaena species (Wagner *et al.* 2007b).

Cubs are raised in dens, which may be holes dug by the mother, holes formed and abandoned by other species (Roberts 1977, A. P. Wagner pers. obs.), deep, natural and sometimes complex, caves (Heptner & Sludskii 1972, Kerbis-Peterhans & Horwitz 1992, Leakey *et al.* 1999), or simple rock depressions less than a metre deep (A. P. Wagner pers. obs.). Where large caves are not available, mothers relocate cubs frequently; starting just a few days after birth, they move cubs to a new (or reuse an old) den every few days or weeks (A. P. Wagner pers. obs.).

Foraging and Food The diet of the Striped Hyaena is still a matter of some debate. However, it has been reported to consume a wide variety of vertebrates, invertebrates, vegetables, fruit and human originated organic wastes (Flower 1932, Harrison 1968, Ilani 1975, Kruuk 1976, Macdonald 1978, Leakey *et al.* 1999, Wagner 2006). It is known to scavenge off Lion *Panthera leo* and Spotted Hyaena kills (Kruuk 1976, Wagner 2006) as well as discarded livestock carcasses (Leakey *et al.* 1999, Wagner 2006). Kruuk (1976), Macdonald (1978), Bouskila (1984), Leakey *et al.* (1999) and Wagner (2006) all found remains of prey items in faecal samples that were likely scavenged. In many areas, Striped Hyaenas have also been described as raiding human graves and carrying away bones (Rosevear 1974, Horwitz & Smith 1988, Leakey *et al.* 1999), and fruit and vegetable crop raiding is considered a serious problem in Israel (Kruuk 1976).

The overall reputation of the species, therefore, is that of an omnivorous scavenger. However, in C Kenya analysis of faecal bone fragments and hairs indicates that hyaenas regularly consume smaller mammals and birds that are unlikely to be scavenged (Wagner 2006). This is in agreement with Kruuk's (1976) observations, but previous interpretations of the limited data available (Rosevear 1974, Skinner & Ilani 1979, Leakey *et al.* 1999) often under-emphasized the evidence for active hunting. In S Kenya, Striped Hyaenas were regularly observed flushing out, chasing and killing juvenile Grant's Gazelle *Nanger granti* (A. P. Wagner pers. obs.). Striped Hyaenas have also been reported chasing hares *Lepus* spp., porcupines *Hystrix* spp., Bat-eared Foxes *Otocyon megalotis*, Cheetah *Acinonyx jubatus* cubs, Dik-dik *Madoqua* spp., and Reedbuck *Redunca* spp. (Kruuk 1976, Skinner & Ilani 1979). Further, there is strong evidence that small livestock (goats and sheep) and dogs are killed (Rosevear 1974, Leakey *et al.* 1999, Kuhn 2005, A. P. Wagner pers. obs.). Thus, the Striped Hyaena foraging strategy includes both active hunting and scavenging.

Several studies have inferred diet by combining data from bone collections with analysis of faecal samples (Kerbis-Peterhans & Horwitz 1992, Leakey *et al.* 1999), while others have inferred diet from den bone collections alone (Skinner & Ilani 1979, Kuhn 2005; and see Skinner 2006). Bone contains organic matter, mostly collagen, at up to 40% in weight (Kruuk 1972). The Spotted Hyaena is able to digest and absorb this organic matter and only the inorganic material is excreted. Striped Hyaenas likely have a similar ability to draw nutrients from digestion of bones. Following a very severe drought in 1962, Kingdon (1977) examined the stomach of one Striped Hyaena that contained nothing but 3 kg of large splintered bones that were so dry that they rattled in the stomach when the hyaena cadaver was shaken! The rest of the digestive tract showed that the animal was subsisting habitually on similar old bones and the digestion was successfully breaking such bones down into congealed white faeces. Bone collections are common at den

sites for the species, but the nutritional role of these bones, the degree to which these collections represent scavenged vs. killed prey and the degree to which bone collections reflect flesh consumed is unclear. In C Kenya, den bone collections represented a much broader range of prey and included far more larger mammals than did scat analysis (Wagner 2006). Significant portions of these bone assemblages were very old bones unlikely to represent scavenging from fresh kills.

Although sometimes found in small groups of up to four individuals while resting, Striped Hyaenas appear to be strictly solitary foragers in Africa (Kruuk 1976, Wagner *et al.* 2008). In Israel, however, groups of hyaenas do converge at feeding sites (Kruuk 1976, Macdonald 1978, Skinner & Ilani 1979, Bouskila 1984), but there is no clear indication of cooperative foraging and relatedness of these observed groups has not been investigated. Foraging activity in Kenya and Tanzania was restricted entirely to night-time except during rain and/or unusually dark and cloudy weather (Kruuk 1976, A. P. Wagner pers. obs.). Under those weather conditions, Striped Hyaenas may return to previously visited kills or carcasses, but do not embark on full foraging forays (A. P. Wagner pers. obs.). Age-specific foraging data are extremely limited, but cubs have been observed accompanying their mothers on foraging forays by 6–12 months of age (Kruuk 1976, A. P. Wagner pers. obs.).

Kruuk (1976) described foraging behaviour in which Striped Hyaenas zig-zagged across the landscape and did not follow set routes, even when returning to the same food source on multiple nights. Striped Hyaenas spent long periods of time sniffing at the base of trees and bushes, but the head was generally held high while travelling. Caching of food under bushes was also observed. Minimum mean distance travelled per night was 19 km at speeds of 2–4 km/h, occasionally trotting at speeds of up to 8 km/h, or running at a maximum of 50 km/h. From observations made at feeding stations in Israel, it was estimated that an adult Striped Hyaena consumes 7–8 kg per night (Skinner & Ilani 1979).

Overall, the evidence indicates Striped Hyaenas in Africa are solitary nocturnal foragers for which fruit and vegetable matter, where available, may play a significant part. Striped Hyaenas also regularly consume insects, invertebrates, small vertebrates and actively hunt small mammals and ground-nesting and/or ground-feeding birds. In addition, they scavenge off carcasses of larger mammals and this activity appears to account for a significant portion of the bones collected at den sites.

Social and Reproductive Behaviour Almost invariably described as solitary in Africa, research in Kenya has shown that Striped Hyaenas routinely rest in pairs and occasionally in groups of up to four individuals (Wagner *et al.* 2008). Adult ♂♂ within a group are typically unrelated or distantly related to other adults in the group (Wagner *et al.* 2007a). However, full-sibling brother–sister and full-sibling brother–brother pairs were observed within groups. Group-living ♂♂ fathered the majority of cubs, but 31% of paternities were extra-group. Multiple paternity was probable in half of the litters examined.

Very little has been recorded regarding direct social interactions outside of captive situations. Kruuk (1976) did note the meeting ceremony between greeting pairs, which involved mutual sniffing of the face, neck and anal regions. The anal pouch was protruded during sniffing and either both hyaenas were standing or one would lie down while exposing the anal region. Observations in captivity (Rieger 1978) match these field observations and Fox (1971) observed anal protrusion displays in cubs at eight weeks of age. The dorsal mane is also erected by Striped Hyaenas in a defensive posture or when threatened and,

Striped Hyaena
Hyaena hyaena.

when aggressive, both the mane and the tail hairs are erected (Schneider 1926, Kruuk 1976, Rieger 1978, A. P. Wagner pers. obs.). Erect or limp dorsal manes have been interpreted as signals that indicate dominant or subordinate status to other hyaenas, respectively (Kingdon 1977).

Home-range sizes in Serengeti N. P. were reported for one ♂ and one ♀ at 44 and 72 km², respectively (Kruuk 1976). In Kenya, mean home-range size for four ♂♂ and six ♀♀ was 68.9 km² (S.E. = 7.8) (Wagner *et al.* 2008), with no significant difference in home-range size between sexes. No two adult ♀♀ were found to have significant home-range overlaps, although groups of up to three ♂♂ and one adult ♀ had almost complete overlap in home-ranges.

Descriptions of mating behaviour come from observations in captivity. Males will follow an oestrous ♀ for several days before being allowed to mate (Bothma & Walker 1999). Mating lasts only one day and consists of up to five mating attempts lasting 15–45 min each, with intervals between mating attempts of about 20 minutes. No pelvic thrusting has been observed (Rieger 1979a).

Cubs are reared in dens (described above) and intense digging behaviour by ♀♀ announces parturition (Rieger 1979a). Mothers carry food back to the den for their cubs (Kruuk 1976, Davidar 1990). When resources are abundant, mothers and their adult daughters may share a range and may use communal dens (A.P. Wagner pers. obs.). Subadult ♀♀ that have not dispersed will frequent their younger siblings' dens and may act as helpers (Wagner *et al.* 2007a). While Bothma & Walker (1999) reported that ♂♂ remain with the ♀ until cubs are raised, given the shared use of space when no cubs are present, it is not clear to what extent ♂♂ participate in cub rearing. In S Kenya, where resident adult ♀♀ (mother-daughter) and a juvenile ♂ routinely provisioned and interacted extensively with cubs at individual and communal dens, visits by the resident adult ♂ were rare, brief and did not include provisioning (A. P. Wagner pers. obs.).

Striped Hyaenas are considerably quieter than Spotted Hyaenas (Rosevear 1974) in terms of both volume and frequency of vocalizations, and are generally silent. However, Kruuk (1976) noted that Striped Hyaenas are more vocal in Israel and their relative silence in East Africa may reflect a behavioural response to avoid dominant carnivores in the region. Vocalizations are similar to those of the Spotted Hyaena and include whining by cubs before suckling, giggling when frightened,

yelling when being chased by conspecifics, howling in a defensive position, growling when play or food-fighting, and a call by the mother to her cub(s) (Kruuk 1976, Rieger 1981, A. P. Wagner pers. obs.).

Reproduction and Population Structure Parturition is aseasonal and gestation lasts 90–91 days (Pocock 1941, Ronnefeldt 1969, Heptner & Sludskii 1972, Skinner & Ilani 1979). Litter-sizes in the wild range from 1–4 cubs and from 1–5 in captivity (Skinner & Ilani 1979, Rieger 1981, Wagner *et al.* 2007a). In captivity, newborn cubs weigh 660–700 g (Skinner & Ilani 1979, Rieger 1981) and reach mean weights of 796 g at one week, 1.5 kg at four weeks, 2.8 kg at eight weeks and 5.6 kg by 28 weeks (Skinner & Ilani 1979). In the wild, cub weights were recorded at 2 kg at 2–3 weeks of age (A. P. Wagner pers. obs.). Cubs are born blind with white to grey fur and clear black stripes. Eyes open at 7–8 days, and teeth erupt at 21 days; cubs start to eat meat after the first month (Rieger 1981). Weaning in captivity takes place after eight weeks, but in the wild cubs have been observed suckling at 4–5 months (Ilani 1975) and 10–12 months (Kruuk 1976). Sexual maturity is reached at 2–3 years (Rieger 1979b), although one ♀ in captivity gave birth at the early age of 18 months (Rieger 1979b). In captivity, postpartum oestrus follows 20–21 days after birth and oestrous cycles last 40–50 days (Rieger 1979a, b).

Little has been reported regarding sex ratios in the wild. However, in Kenya the two complete litters sexed had three ♂♂ in one litter and one male and one female cub in the other (Wagner *et al.* 2007a). The well-sampled adult population had a sex ratio of 0.8 : 1 adult ♀♀ to ♂♂ (Wagner *et al.* 2008). As there are no long-term studies of the species in the wild, longevity has only been reported in captivity at 23–24 years (Rieger 1979a; and see Weigl 2005). From the Laikipia study, non-age-specific probabilities of survival for adult hyaenas (those over two years of age) were estimated for the duration following the time each hyaena was first identified. Survival to six months post-identification was estimated at 0.96 (n = 27), 0.89 for survival to one year post-identification (n = 27), 0.62 for two years (n = 21), and the probability of surviving three years after a hyaena was first identified was 0.47 (n = 17) (Wagner 2006). Of the nine cubs identified before six months of age (three female, four male, two unknown sex), at least four (two female, two male) had survived to at least two years. This is a minimal survival rate as the cubs were not radio-collared and survival could only be confirmed if they were resighted.

Predators, Parasites and Diseases Interactions with other carnivores are best considered in terms of dominance and competition rather than predation. The Striped Hyaena is subordinate to Lions and Spotted Hyaenas, although Kruuk (1976) described a mutual 'attraction' between the two hyaenas. There is also suggestive evidence that competition with Spotted Hyaenas may be important in circumscribing the habitat used by Striped Hyaenas (H. Kruuk pers. comm.). Outcomes of encounters with Cheetahs and Leopards *Panthera pardus* are not as predictable, but adults of those species are likely to dominate Striped Hyaenas. Skinner & Ilani (1979) reported that a Caracal *Caracal caracal* dominated three subadult Striped Hyaenas of about 29 kg each.

The importance of the Striped Hyaena as a reservoir or vector for domestic animal and human disease has not been well evaluated. The spatial overlap with humans and domestic animals in many parts of the Striped Hyaena's range may be significant in this regard.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Humans are consistently indicated as the major source of mortality throughout the evaluated range (Hofer 1998a) and were responsible for 50% of recorded deaths in C Kenya (Wagner 2006). Negative perceptions of the species persist throughout its range and collection of human remains ('grave robbing') and incidents of damage to agriculture and livestock perpetuate negative attitudes. Striped Hyenas are very susceptible to accidental or targeted poisoning as they readily accept strychnine-poisoned bait. For example, along the Mediterranean coast in Israel, the Striped Hyena was exterminated by strychnine poisoning during the rabies eradication campaign administered by the British government between 1918 and 1948. The Striped Hyenas ate poisoned donkey carcasses that were provided to control Golden Jackals *Canis aureus*, then the main carrier of rabies (Hofer 1998a). The population in Niger is apparently declining as a result of officially sanctioned eradication or poisoning and indirectly by habitat destruction through overgrazing and agricultural encroachment (Hofer & Mills 1998b). Habitat destruction is also viewed as a threat in Kenya and effective protection is absent as hyenas are viewed with contempt. In this region, due to the lack of differentiation between the species, Striped Hyenas are often killed when Spotted Hyenas are the intended target (Wagner 2006).

Striped Hyenas are also subject to trade in skins and body parts, mainly for use in traditional medicine. In North Africa, the animal's brain is used as an aphrodisiac and hairs are used as a talisman (Ronnefeld 1969, Rieger 1979a, Osborn & Helmy 1980). In Morocco, where the species is commercially hunted for use in traditional medicine (and may fetch very high prices; F. Cuzin pers. comm.), the population has declined drastically and has withdrawn into the southern mountainous regions. In Egypt, Striped Hyenas are hunted for utilization of the whiskers and eyeballs as protection from the evil eye and the heart for courage (Osborn & Helmy 1980).

Striped Hyenas are present in numerous protected areas, including: Djurdjura N. P. and Mergueb N. R. (Algeria), 'W' N. P. and Arly N. P. (Burkina Faso), Waza N. P. (Cameroon), Awash N. P., Mago N. P., Omo N. P. and Yabello Sanctuary (Ethiopia), Masai Mara National Reserve, Tsavo East & West N. P., Samburu N. R. and

Lake Nakuru N. P. (Kenya), Boucle du Baoulé N. P. (Libya), Reserve integrale de Missou, Tazeka N. P. and Parc National de l'Oriental (Morocco), Boundou, Ferlo Nord, Ferlo Sud and Cayor Faunal Reserves (Senegal), and Serengeti N. P., Tarangire N. P., Ngorongoro Conservation Area and Mkomazi G. R. (Tanzania) (Hofer & Mills 1998a). Recent records also indicate the species occurs outside of protected areas in a number regions, including, for example, in Egypt, in the Nile Valley and near oases in the west, Mediterranean and Red Sea coastal areas, and, in Kenya, in Masailand, L. Natron, the central Highlands including Laikipia and Samburu Districts, L. Turkana region, and parts of Kajiado District (Hofer & Mills 1998a, Wagner 2006). Because they exist outside of formally protected areas in regions where pastoralism is the norm and the potential for human–carnivore conflict is very high, populations in Egypt and Kenya are exceptionally vulnerable to human population growth, habitat destruction and poisoning. Particular attention should be paid to ensuring the survival of the species in pastoral areas by identifying ways to reduce human–carnivore conflict through promotion of methods that ensure adequate numbers of prey persist and/or methods that reduce livestock killing by carnivores.

Aaron P. Wagner

GENUS *Crocota*

Spotted Hyena

Crocota Kaup, 1828. Oken's Isis 21. Encyclop. Zeit 21 (11), column 1145.

A monotypic genus, represented by the Spotted Hyena *Crocota crocuta*, and with adaptations to hypercarnivory and scavenging. The fossil history of *Crocota* (within as well as outside Africa) is complex, with at least three species present in Africa during the Plio–Pleistocene, in addition to the living one (Werdelin & Lewis 2005, 2008). These species document morphological changes in the *Crocota* lineage that suggest a transition from probably solitary scavenging in the Pliocene to the socially versatile, sometime group-hunting species of today. These changes imply modifications to ecology and behaviour that this species complex went through as it adapted to changes in climate and environment, as well as competition from an increasingly competent hunter and scavenger, *Homo* spp. (Lewis & Werdelin 1999, 2000).

Lars Werdelin

Crocota crocuta SPOTTED HYAENA

Fr. Hyène tachetée; Ger. Fleckenhyaena (Tüpfelhyaena)

Crocota crocuta (Erxleben, 1777). Syst. Regni Anim. 1: 578. 'Guinea, Aethiopia, ad caput bonae spei in terrae rupiumque caueis', restricted by Cabrera (1911) to 'Senegambia'.

Lateral view of skull of Spotted Hyaena *Crocota crocuta* with dental rooting exposed.

Taxonomy Monotypic. Very variable in morphology, size and pelage; Matthews (1939a) rejected all subspecies (and see Hollister 1918), as have later authors (Werdelin & Solounias 1996, Jenks & Werdelin 1998). However, significant variation in mitochondrial DNA between western, southern and eastern populations suggests that a re-evaluation in terms of at least three subspecies might be appropriate (Albert *et al.* 2000, Rohland *et al.* 2005); if these were to follow established taxonomic conventions, the West African form would be *C. crocuta crocuta*, the southern form *C. crocuta capensis* and an eastern form might be *C. crocuta habessinica*. Synonyms: *capensis*, *colvini*, *crocuta*, *cuvieri*, *encrita*, *felina*, *fisi*, *fortis*, *gariepensis*, *germinans*, *habessinica*, *kibonotensis*, *leontiewi*, *maculata*, *moltei*, *nyasae*, *nzoyae*, *panganensis*, *rufa*, *rufopicta*, *sivalensis*, *spelaea*, *thierryi*, *thomasi*, *togoensis*, *ultima*, *venustula*, *weissmanni*, *wissmanni*. Chromosome number: $2n = 40$ (Wurster-Hill 1973).

Description Largest extant hyaena. Head with a dog-like muzzle covered in short black hair with several rows of vibrissae. Ears rounded. Body strongly built, neck and shoulders muscular, back slightly sloping. Pelage colour light brown, beige, sandy or ginger. Prominent spots of variable size and density on neck, shoulder, back, flanks, rump, legs, base of tail and occasionally belly. Spots, initially black or dark brown, may turn light brown and fade with age. Pelage composed of fine underhair (15–20 mm) and longer, stouter, flat-sectioned bristle hairs (30–40 mm). Hair along back of neck and across shoulders is longer (70–80 mm), giving appearance of a mane. Tail thin and ending in long black hair at tip. Feet four-toed with short, blunt, non-retractable claws and broad and flattened naked pads. Characteristic loping gait when running.

Sexes very similar in appearance. Clitoris elongated and when erected similar in size to erected male penis. No vulva, as the outer labiae are fused (Matthews 1939b, Neaves *et al.* 1980, Cunha *et al.* 2003). No baculum in either sex. Sex can be determined from detailed morphology of the erect 'penis' (Frank *et al.* 1990). Male glans has pronounced incision at base, is asymmetrical and terminates in a tapering tip. In ♀♀ incision at base of clitoris is

Spotted Hyaena *Crocota crocuta*.

less pronounced and symmetrical, and tip is blunt. Erect clitoris usually straight or points forward; erect male penis usually curves backwards. In older ♂♂ belly line is V-shaped, in reproductively active ♀♀ udder is pronounced and belly line descends towards hindlegs. Four nipples are usually present, but typically only rear pair functional. Sex determination is possible by histological (Wurster-Hill *et al.* 1970, Yost 1977) and molecular methods (Schwerin & Pitra 1994).

Skull massively built and characterized by high sagittal crest extending backwards beyond occipital condyles. In some skulls the supra-occipital crest is represented by a backward sloping narrow flange; in others it is absent or just a low ridge. The rostrum is broad; zygomatic arches are robust and sweep out towards the back to provide ample room for the well-developed masseter and temporalis muscles (Skinner & Chimimba 2005). Dentition typically hyaenid, although upper first molars are often absent, unlike in the Brown Hyaena *Hyaena brunnea* where upper first molars are functional teeth and always present. Lower premolars massive, with rounded central cusps; upper first premolars small, the second and third rounded with high central cusps, while the fourth have distinct protocones on inner edges. Upper canines large, sharp, rounded and slightly recurved; lower canines are stout and recurved. Permanent teeth erupt at about 15 months. Wear of mandibular third premolar and cross-section of dentine lines of upper canines can be used as an index of age (Kruuk 1972, Lindeque & Skinner 1984, Van Jaarsveld *et al.* 1987), as can tooth eruption and replacement (Van Horn *et al.* 2003).

Geographic Variation No subspecies are currently recognized. Individual variation is considerable, and any non-molecular regional characteristics, if they exist, have yet to be identified.

Spotted Hyaena *Crocota crocuta* myology.

Similar Species

Hyaena brunnea. Sympatric in southern Africa, particularly in the west.

Ears long and pointed; pelage longer and dark brown without spots.

H. hyaena. Sympatric from Tanzania northwards. Long, erectile mane and dorsal crest, and prominent stripes (not spots) on body, legs and neck; ears longer and pointed.

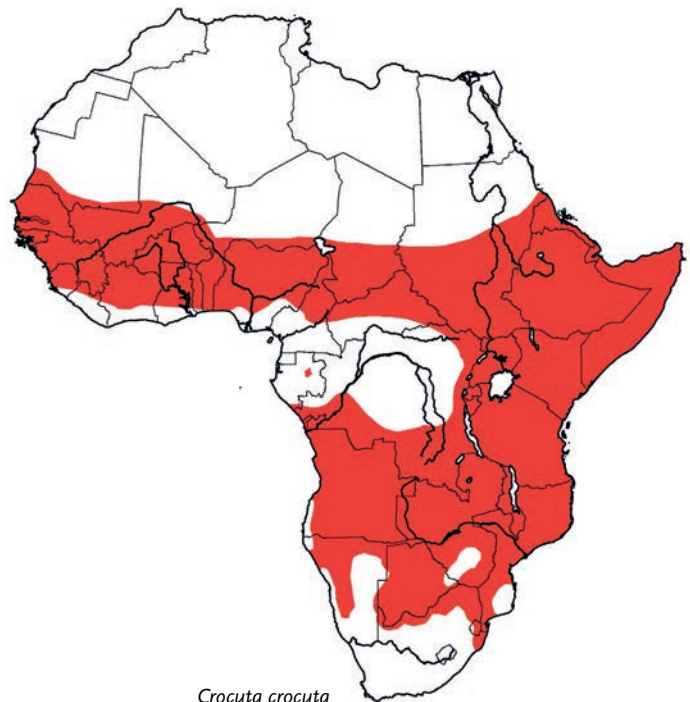

Distribution Endemic to Africa, south of the Sahara, although formerly with a geographic range across almost all of Africa and Eurasia (Werdelin & Solounias 1991). Current distribution is more patchy, especially in West Africa, with populations often concentrated in protected areas. More continuous distributions persist over large areas of Chad, Central African Republic, S Sudan, Ethiopia, Kenya, Tanzania, Botswana, Angola, Namibia and parts of South Africa. Hofer & Mills (1998a) reported the species as extinct in Algeria, where it may have occurred in the Ahaggar and Tassili d'Ajjer, although Kowalski & Rzebik-Kowalska (1991) noted that continued presence in the southernmost regions is not impossible. Hofer & Mills (1998a) also reported no recent records from Djibouti, Eritrea, Gabon, Gambia and Togo. Since then Künzel *et al.* (2000) have confirmed that Spotted Hyaenas are still widespread, albeit in small numbers, in Djibouti, Grubb *et al.* (1998) noted the same for Gambia, images of a single Spotted Hyaena inside Ivindo N. P., a rainforest site in Gabon, were recorded in 2003 (Henschel & Ray 2003) where the species had not been recorded since around 1950 (and see Juste & Castroviejo 1992), and Spotted Hyaenas were reported from Eritrea (P. D. Moehlman pers. comm.). There is no confirmed evidence of their occurrence in Egypt, Liberia or Lesotho.

Habitat Present in all habitats including semi-desert, savanna and open woodland, dense dry woodland and montane habitats, such as the Aberdares, Mt Kenya and the Ethiopian Highlands, up to 4100 m altitude (Young & Evans 1993, C. Sillero-Zubiri pers. comm.). It is absent from, or occurs at very low densities in, extreme desert conditions, the highest altitudes on mountains and tropical rainforests, though they may make deep incursions into forested areas where logging roads provide access (Kingdon 1977, Henschel & Ray 2003). In prime habitat, densities of Spotted Hyaenas are higher than those of other large carnivores (Hofer 1998b). In many parts of their range

Spotted Hyaena *Crocota crocuta* subadult.

they occur in close association with human habitations. Although long periods may elapse between drinking, Spotted Hyaenas are at least somewhat dependent on water, and Tilson & Henschel (1986) recorded an instance where a clan dispersed after the only water source in their range dried up.

Abundance Viable populations still exist in numerous countries and a tentative estimate of the total global population is between 27,000 and 47,000. The largest known populations occur in the Serengeti ecosystem (in the Tanzanian sector, 7200–7700; in the Kenyan sector, 500–1000) and Kruger N. P., South Africa (1300–3900). Significant numbers probably also occur in Selous G. R., Tanzania, and in the Okavango, Botswana. Population densities based on systematic censuses vary substantially, from 0.006 to 1.7 individuals per km² (Hofer & Mills 1998b; and see references therein). Low population

*Crocota crocuta*

densities occur in semi-desert areas in southern Africa (0.006–0.05 individuals per km²), such as the Namib (Tilson & Henschel 1986) and Etosha Pan (Gasaway *et al.* 1991). High densities occur in savanna and some open woodlands in Tanzania and Kenya, as well as in montane forest (0.32–1.7 individuals per km²), such as Selous G. R. (Creel & Creel 1996), Aberdare N. P. (Sillero-Zubiri & Gottelli 1992a) and Ngorongoro Crater (Kruuk 1972, Höner *et al.* 2005).

Adaptations The sagittal crest of the Spotted Hyaena skull provides the upper attachment for a hugely enlarged temporalis muscle. The bowed zygomatic arch also accommodates this muscle and provides the upper attachment for the masseter muscle. Both muscles are attached to posterior processes on the mandible and, together with an extremely hard, vice-like complex of cheekteeth embedded in dense mandibular bone (the mandibles are buttressed beneath the premolars) represent one of the most extreme forms of bone-shattering dentition known for any living land mammal (Biknevicius & Ruff 1992, Biknevicius & Van Valkenburgh 1996). The feeding behaviour of juvenile Spotted Hyaenas has been studied in terms of the development of a powerful bite and individual independence (Binder & Van Valkenburgh 2000). Adult skull size and full feeding performance is not achieved until sexual maturity at 24 months of age (Watts *et al.* 2009). Acidic digestion permits extraction of nutrients from bone fragments; digested bone results in pale-coloured faeces. Undigested matter (hair, bone and hooves) is regurgitated.

Spotted Hyaenas can pursue prey for long distances at speed with a unique form of galloping gait and can feed immediately once prey is captured. This is possible because the heart is exceptionally large in relation to body size and because of efficient heat loss through the rostrum. Excess heat is also lost through panting, by coating front legs and neck in copious saliva and by lying in water or mud. Young animals reduce energetic costs of thermoregulation and probably water loss by huddling together or resting underground in communal dens. Adults cannot enter the small burrows of the communal den and avoid daytime heat by resting in dense vegetation or large underground burrows of species such as warthogs *Phacochoerus* spp.

The most celebrated peculiarity of this species is its ‘hermaphroditism’. Several hypotheses have sought to explain female mimicry of male external genitalia:

- 1 Mimicry was an incidental by-product of selection for elevated androgen levels to increase aggression, social dominance and body size of adult ♀♀ over ♂♂ (Gould 1981, Frank *et al.* 1991, 1995a). Several facts do not conform to this theory. Large body size is not related to social rank in ♂♂ or ♀♀ (Holekamp *et al.* 1996, East & Hofer 2002, Hofer & East 2003). Androgen (testosterone and androstenedione) concentrations in non-pregnant ♀♀ are not elevated, are similar to those in many other non-pregnant female mammals, including Brown and Striped Hyaenas, and are considerably lower than androgen levels in ♂♂ (Goymann *et al.* 2001, Dloniak *et al.* 2004). Androgen-independent mechanisms contribute to the development of the penile clitoris, as anti-androgen treatment of ♀♀ during foetal development resulted in ♀♀ with an enlarged clitoris (Drea *et al.* 1998). Elevated levels of androgens in neonates of both sexes may be linked to selection for intense sibling rivalry (East *et al.* 1993) leading to facultative siblicide when food resources are low (see below).

Lateral, palatal and dorsal views of skull of Spotted Hyaena *Crocota crocuta*.

- 2 Mimicry occurred as a by-product of selection for androgenized, larger, aggressive ♀♀, and then the clitoris was incorporated into greeting ceremonies, favouring selection for its enlargement (Hamilton *et al.* 1986).
- 3 Mimicry provided the direct selective advantage of a conspicuous structure that facilitated the re-establishment of social bonds among clan members (Wickler 1965, Kruuk 1972).
- 4 After the evolution of female dominance, mimicry and presentation of male-like genitalia facilitated social relations by offering an appeasing, diversionary signal. Such a signal would benefit any animal (regardless of age and sex) seeking to reduce intra-specific aggression (Wickler 1965, Kruuk 1972, Kingdon 1977).
- 5 Mimicry of male external genitalia provided a selective advantage by decreasing infanticide of female cubs belonging to competing adult female clan members (Muller & Wrangham 2002).
- 6 Mimicry was a by-product of genetic translocation (Van Jaarsveld & Skinner 1987).

The reason why ♀♀ have an elongated clitoris remains a matter of debate. Passage of the firstborn cub or litter through the clitoris often results in cases of still-birth (Glickman *et al.* 1992, Frank *et al.* 1995b, Drea *et al.* 2002). This not only implies a reduction in life-time reproductive success of at least 5%, but also positive counter-selection pressure to maintain this costly trait (East *et al.* 1993). One benefit of a penile clitoris might be control over the mechanics of copulation, as this would have favoured selection for active submission by immigrant ♂♂ and therefore provided ♀♀ with a

Spotted Hyaena *Crocuta crocuta*.

high degree of mate-choice and the benefit of maternal investment being dedicated to offspring sired by high-quality or genetically compatible ♂♂ (East *et al.* 1993, 2003, East & Hofer 2002).

Foraging and Food Although often considered scavengers, Spotted Hyaenas are effective and flexible hunters. They prefer prey within a body mass range of 56–182 kg (with a mode of 102 kg) (Höner *et al.* 2005, Hayward 2006), a dietary niche breadth similar, but not identical, to that of the Lion *Panthera leo* (Höner *et al.* 2002). In Kruger N. P., the most important prey items are the Common Wildebeest *Connochaetes taurinus*, African Buffalo *Syncerus caffer*, Plains Zebra *Equus quagga*, Greater Kudu *Tragelaphus strepsiceros* and Impala *Aepyceros melampus*; preferred prey are all resident herbivores, namely the Impala, Greater Kudu, and Common Warthog *Phacochoerus africanus* (Henschel & Skinner 1990a). In the Namib Desert, Gemsboks *Oryx gazella* made up more than 80% of the diet (Tilson *et al.* 1980) and in Etosha N. P. Springboks *Antidorcas marsupialis* were most commonly hunted (Gasaway *et al.* 1991). In the S Kalahari, the principal prey are Gemsboks (the most common resident herbivore), Common Wildebeests and Springboks, followed by Common Eland *Tragelaphus oryx* and Hartbeest *Alcelaphus buselaphus* calves (Mills 1984, 1990). In Chobe they principally hunt migratory Plains Zebras and resident Impalas (Cooper 1990). In the Serengeti ecosystem and the Ngorongoro Crater, Spotted Hyaenas primarily hunt Common Wildebeests, Thomson's Gazelles *Eudorcas thomsonii* and Plains Zebras (Kruuk 1972, Hofer & East 1993a, Höner *et al.* 2002, 2005). In its northern extension in the Masai Mara, they feed mainly on Topis *Damaliscus lunatus* and Thomson's Gazelles when migratory species are absent. Upon arrival of the migratory herds from the Serengeti N. P., they switched to feeding on Common Wildebeests for about three months, until the migratory animals return to the Serengeti N. P. (Cooper *et al.* 1999). In the Aberdare Mts (Kenya) the dominant prey items are Bushbucks *Tragelaphus scriptus*, Sunis *Nesotragus moschatus* and African Buffalo (Sillero-Zubiri & Gottelli 1992b).

The diet of Spotted Hyaenas in West and Central Africa is less well known. In Niokolo-Koba N. P., Senegal, they feed mostly on large and medium-sized ungulates, with African Buffalo the most

frequently consumed prey species; Hartbeests and Common Warthogs were also eaten more often than expected (Di Silvestre *et al.* 2000). In contrast, in Faro N. P., N Cameroon, mainly medium-sized prey were taken, with the main prey being Buffon's Kobs *Kobus kob*, the most abundant prey species in the area (Breuer 2005).

Spotted Hyaenas are opportunistic, occasionally taking larger prey such as Giraffes *Giraffa camelopardalis*, juveniles of Common Hippopotamus *Hippopotamus amphibius*, Savanna Elephants *Loxodonta africana* and White Rhinoceroses *Ceratotherium simum*. They also consume a wide range of small mammal prey, including small carnivores and rodents up to the size of springhares *Pedetes* spp., as well as other vertebrate prey (such as birds, fish, reptiles), insects, crabs, snails, Ostrich *Struthio camelus* eggs, fruits and the faeces of herbivores, carnivores and omnivores (Hirst 1969, Pienaar 1969, Kruuk 1972, Bearder 1977, Cooper 1990, Henschel & Skinner 1990a, Mills 1990, Gasaway *et al.* 1991, Sillero-Zubiri & Gottelli 1992b, Skinner *et al.* 1992, Hofer & East 1993a, Holekamp *et al.* 1997, Cooper *et al.* 1999, Di Silvestre *et al.* 2000, Salnicki *et al.* 2001, Höner *et al.* 2002, Breuer 2005).

Despite being a highly social carnivore that may live in large groups, individuals hunt mostly on their own or in small groups (Kruuk 1972, Gasaway *et al.* 1989, Mills 1990, Skinner *et al.* 1992), although one case of mass killings of Thomson's Gazelles by a group of 19 was recorded in East Africa (Kruuk 1972). Prey is detected by sight, hearing and odour and carrion by smell, the noise of other carnivores feeding, or by watching vultures descending on a carcass. Adult solitary Spotted Hyaenas of around 5–6 years of age can be very efficient hunters, and, in the Masai Mara, are responsible for over 75% of hunting attempts on Common Wildebeest and Topi (Holekamp *et al.* 1997). Spotted Hyaenas are active mostly at night, dawn and dusk, but can forage at any time during the day. During hunts, prey may be chased over several kilometres (the longest recorded chase was 24 km in pursuit of a Common Eland; Mills 1990) at speeds of up to 60 km/h (Hofer 1998b). Spotted Hyaenas have been observed to drown prey, such as Southern Lechwe *Kobus leche* (Child & Robbel 1975), and even to run down Lesser Flamingoes *Phoenicopterus minor* in shallow soda lakes (Brown & Root 1971). Food is cached, mostly in water.

Average adult daily food consumption is estimated at 2.0–4.0 kg/day (Kruuk 1972, Green *et al.* 1984, Henschel & Tilson 1988). An adult Spotted Hyaena can consume approximately 18 kg in one meal (Kruuk 1972, Bearder 1977), equal to up to one-third of adult body mass. They are rapid feeders, an adaptation to strong feeding competition with conspecifics and Lions (Kruuk 1972). At large carcasses, female clan members and their offspring feed before immigrant ♂♂, and high-ranking ♀♀ and their offspring before lower-ranking ♀♀ and their offspring (Frank 1986a). Spotted Hyaena cubs show a remarkable resilience to a lack of regular supply of food or fluids (Hofer & East 1997).

Spotted Hyaenas may travel long distances (30–80 km) in search of prey or water (Eloff 1964, Tilson & Henschel 1986, Mills 1990). In Etosha N. P., migratory movements of main prey species (Springbok, Plains Zebra, Common Wildebeest) to the north-west at the start of the wet season results in a considerable decline in prey density. In response, clans in areas of low prey density follow the migratory herds, thus shifting their activities to the wet season range of the migratory herbivores (Trinkel *et al.* 2004). In contrast, Spotted Hyenas in Serengeti N. P. leave their clan territory (individually or

Serial silhouettes of running/galloping Spotted Hyaena *Crocota crocuta*.

in small groups) on frequent short-term, long-distance (80–140 km return distance) foraging trips (termed commuting trips) to areas containing high densities of migratory herbivores (Hofer & East 1993a,b,c). Low-ranking group members commute more often than socially dominant members. These trips last on average three days for lactating ♀♀ (who frequently return to the clan territory to nurse their young) and 9–10 days for non-lactating ♀♀, and ♂♂. Some 46–62% of the year is spent foraging by commuting between the clan's territory and herds of migratory prey. Lactating ♀♀ may make up to 40–50 trips and commute as much as 3680 km per year (Hofer & East 1993c). As the proportion of each year increases, during which lactating ♀♀ commute, the survival of her offspring decreases (Hofer & East 2003, 2008). Aggression towards commuters by resident clan members is context-specific. Animals in transit through an area are usually ignored, whereas commuters at food resources are attacked if they fail to submit to residents (Hofer & East 1993b).

The Spotted Hyaena is an efficient scavenger of carrion, including the kills of other Spotted Hyaenas and other carnivores like Lions (Kruuk 1972, Henschel & Skinner 1990a, Mills 1990), although in both Masai Mara (Cooper *et al.* 1999) and the Ngorongoro Crater (Kruuk 1972, Höner *et al.* 2002), Spotted Hyaenas obtained most of their annual intake from hunting rather than scavenging. It is also an effective kleptoparasite on other carnivores. The proportion of its diet derived from or lost to other predators varies between ecosystems (Kruuk 1972, Cooper 1991, Mills & Biggs 1993, Höner *et al.* 2002). Lions usually displace Spotted Hyaenas at kills, unless Spotted Hyaena group size is large and male Lions are absent (Cooper 1991, Höner *et al.* 2002). In Etosha N. P., clan sizes of Spotted Hyaenas are small and territories large; consequently, preventing kleptoparasitism by Lions or recruiting sufficient clan members to take over Lion kills is difficult (Trinkel & Kastberger 2005). In some areas, Spotted Hyaenas may kill domestic livestock, domestic cats, domestic dogs and people (Hofer 1998b, East *et al.* 2012). In some areas Spotted Hyaenas are, or used to be, relied upon to dispose of human corpses.

Assemblages of bones are often found at Spotted Hyaena communal dens where all clan offspring are placed, although not to the same degree as in the Brown Hyaena or the Striped Hyaena, because Spotted Hyaenas infrequently carry food back to their young. A variety of items, mostly long bones or skulls of medium- to large-sized ungulates, have been found in dens; bone assemblages tend to reflect the ungulate fauna in an area (Bearder 1977, Mills & Mills 1977, Henschel *et al.* 1979, Skinner *et al.* 1986, Lam 1992; and see Skinner 2006).

Social and Reproductive Behaviour A highly social species that lives in groups (clans) and defends group territories. Clans are a 'fission–fusion' society, and although clan members often operate independently, there is a high degree of cooperation in the defence

of the territory, of food resources and the communal den. Clan social structure consists of a linear dominance hierarchy amongst adult ♀♀, and a separate linear dominance hierarchy amongst immigrant ♂♂, all of which are socially subordinate to clan ♀♀ (Frank 1986a). The mechanisms by which adult ♀♀ and immigrant ♂♂ acquire social status differ (see below).

The average number of adults and subadults in a clan varies from three in desert and semi-desert areas of southern Africa to 90 individuals in the savanna areas of East Africa (Kruuk 1972, Hofer 1998b). Territory size and the density of prey inside a clan's communal territory may limit clan size, unless clan members regularly feed on migratory herds outside their territory (Hofer & East 1993a, b, Höner *et al.* 2005). Clans split if current clan size exceeds a threshold above which the food base of the territory is insufficient (Mills 1990), or if a territory in the neighbourhood has become vacant (Holekamp *et al.* 1993, Höner *et al.* 2005).

Females usually remain in their natal clan; therefore, large clans contain several matriline (Frank 1986b). When ♀♀ attain adulthood, they typically acquire a rank immediately below that of their mother (Smale *et al.* 1993, Hofer & East 2003). Dloniak *et al.* (2006) suggested that rank-related exposure of fetuses to different concentrations of maternal androgens during pregnancy resulted in high-ranking mothers producing more assertive offspring than lower ranking mothers, and that this maternal effect during gestation significantly influenced the rank achieved by offspring at adulthood. However, when individuals were adopted as young cubs and reared by a surrogate mother, they acquired a rank at adulthood close to and below that of their surrogate mother (East *et al.* 2009), similar to the behavioural mechanism termed rank 'inheritance' which explains rank acquisition in many primates and which has previously been described for Spotted Hyaenas (Smale *et al.* 1993). This behavioural mechanism is based on the social support a mother provides to her offspring. During their development, Spotted Hyaena cubs learn that with maternal support they can dominate all clan members socially dominated by their mother, and to submit to all group members that their mother submits to. As a result, they usually acquire a rank at adulthood immediately below that of their mother, but can significantly decline in social status should their mother die (Hofer & East 2003). Adult ♀♀ seek to stabilize their position in the dominance hierarchy by fostering relationships with ♀♀ holding ranks adjacent to their own in the hierarchy, and by supporting such ♀♀ during interactions with other clan member (East *et al.* 1993, Smale *et al.* 1995, Hofer & East 2000, Engh *et al.* 2000).

Males are considered mature at two years of age and typically (but not always) disperse from their natal clan after reaching maturity, immigrating into another clan at approximately 3–4 years of age (Höner *et al.* 2010). At immigration, they join the immigrant male hierarchy at the lowest rank. Because their social status increases as their tenure

in the clan lengthens and as $\delta\delta$ above them in the hierarchy die or leave the clan, the male hierarchy functions like a social queue (East & Hofer 2001). Queuing $\delta\delta$ observe strict conventions, and so rarely 'jump the queue' or use physical contests to advance in social status. Queuing $\delta\delta$ stabilize their social position in relation to lower ranked $\delta\delta$ by forming long-term alliances with $\delta\delta$ immediately in front and behind them in the queue (East & Hofer 2001). In large clans, such as those in the Serengeti N. P., social queues may contain more than 15 immigrant $\delta\delta$, and queuing $\delta\delta$ require several years to progress from the bottom to the top of the male hierarchy (East & Hofer 2001). Males sometimes undertake multiple dispersals, as observed in the Masai Mara National Reserve where eight of 20 $\delta\delta$ whose fates were known lived in three clans over time (Van Horn *et al.* 2003).

Males with long tenure mostly seek to foster amicable relationships with older adult ♀♀ , whereas recent immigrant $\delta\delta$ more often do so with younger adult ♀♀ . Females aggressively reject unwanted $\delta\delta$. Genetic paternity analyses have revealed that ♀♀ exercise a high degree of mate-choice (East *et al.* 2003, Höner *et al.* 2007). Because younger ♀♀ mostly reject close advances by longer tenured $\delta\delta$, they avoid inbreeding with close relatives, such as their father (East & Hofer 2001, Höner *et al.* 2007). As a result, the offspring of younger ♀♀ are mostly sired by $\delta\delta$ that were not clan members when the ♀♀ was born. Males that start their reproductive careers in a clan containing an above average number of younger adult ♀♀ gain a significant reproductive advantage, indicating that female mate-choice preferences drive male dispersal patterns (Höner *et al.* 2007). In the Ngorongoro Crater, sons of high-ranking ♀♀ reproduce at a younger age (4.8 yrs) than sons of both mid-ranking (5.9 yrs) and low-ranking ♀♀ (6.8 yrs), probably because of their privileged upbringing in their natal clan (Höner *et al.* 2010).

Male reproductive tactics range from extreme harassment to high investment in friendly (affiliative) behaviour with ♀♀ (Kruuk 1972, East & Hofer 2001, Szykman *et al.* 2001, East *et al.* 2003). Females also operate effective counter-tactics against $\delta\delta$ which attempt to harass or monopolize them, including behaviours likely to confuse paternity, such as multiple mating and mating when not in oestrus (East *et al.* 2003). A ♀ may mate with several $\delta\delta$ when in oestrus, with the result that a high proportion (about 35%) of twin litters are sired by two different fathers (Engh *et al.* 2002, East & Hofer 2002).

Territory size in the Spotted Hyaena is variable, ranging from 9 km² in the Ngorongoro Crater (Höner *et al.* 2005) to over 1000 km² in the Kalahari (Mills 1990). Clans defend communal territories against encroachment from neighbouring conspecifics through vocal displays, scent-marking (Gorman & Mills 1984) and boundary patrols (Kruuk 1972). Adult ♀♀ initiate and lead most cooperative territorial behaviours, although border patrols were occasionally conducted by groups composed exclusively of resident $\delta\delta$. Most territory intruders were $\delta\delta$. Resident ♀♀ were more likely to attack intruding ♀♀ than intruding $\delta\delta$, whereas resident $\delta\delta$ were more likely to attack intruding $\delta\delta$ (Boydston *et al.* 2001).

Spotted Hyaenas of both sexes produce a fatty, strongly smelling secretion in anal glands situated on either side of the rectum which discharge at an opening above the anus. During scent-marking ('pasting'), this scent gland is partially protruded and dragged along a grass stalk or herb by bending the hind legs to adopt a semi-crouched position (Kruuk 1972). Scent scattered throughout a clan's territory, termed 'hinterland' scent-marking (Gorman & Mills 1984), may be

Genital inspection ceremony in Spotted Hyaena *Crocuta crocuta*.

a way of optimizing the distribution of scent-marks over a large area with a limited amount of scent and time (Mills 1990). Anal gland scent contains a mixture of fatty acids and other organic compounds (Hofer *et al.* 2001, Burgener *et al.* 2009). Despite previous emphasis on the role of pasting in territory defence, recent studies have demonstrated that it is an important component of communication between clan members (Burgener *et al.* 2009, East *et al.* in press). The anal gland scent of natal animals and immigrant $\delta\delta$ from the same clan have similar chemical signatures, suggesting the presence of an olfactory clan membership badge (Hofer *et al.* 2001, Burgener *et al.* 2009), probably concocted by the remote exchange of scent between clan members when one individual over-pastes a scent mark of another clan member (Burgener *et al.* 2008). Spotted Hyaena anal gland scent also contains olfactory signatures that communicate the identity of the individual that deposited the scent. Female clan members are more likely to respond to scent marks deposited by top-ranking female clan members than ♀♀ of lower social status (Burgener *et al.* 2009). Spotted Hyenas also display behaviour similar to pasting but without protruding the anal gland and thus without depositing scent ('dry pasting'). Dry pasting anoints the body fur with scent deposited on grass stalks (Burgener *et al.* 2008). Juveniles start dry-pasting over scent marks at the communal den when less than two months of age and only start pasting scent when close to adulthood (Theis *et al.* 2008, East *et al.* in press). Spotted Hyaenas also scent-mark by depositing a secretion from their inter-digital glands when they scratch the ground, and by defecating in communal latrines (Kruuk 1972, Mills 1990, East *et al.* in press).

Clan members participate in ritualized greeting ceremonies during which two individuals stand parallel and face in opposite directions, lift their hindleg nearest their partner and sniff or lick the anogenital region of the other. The unique aspect of greetings between individuals is the prominent role of the erect 'penis' in animals of both sexes, and the fact that an erect 'penis' signals submission. Greetings occur between all ages and both sexes, although greetings between adult ♀♀ and immigrant $\delta\delta$ are rare. Cubs can erect their penis or clitoris within several weeks of birth (Frank *et al.* 1990), and engage in greeting ceremonies as early as four weeks of age. Greeting ceremonies are an important element in the maintenance of social status and the formation of alliances with other clan members and thus serve a similar social function to grooming in primates (East *et al.* 1993).

Spotted Hyaenas also have a complex system of acoustic communication (Kruuk 1972, Mills 1990). The loud-call or whoop can

be heard over several kilometres. Animals whoop with their muzzle bent towards the ground. Spotted Hyaenas can recognize the whoops of other members of their clan (East & Hofer 1991a, Holekamp *et al.* 1999) and possibly members of neighbouring clans. Whoops can function as a rallying call to gather scattered clan members together to feeding sites, the communal den and sites of conflict, and as an individual display for ♂♂ and ♀♀. High-ranking animals of both sexes whoop more often than lower-ranking clan members of the same sex and ♂♂ whoop more frequently than ♀♀ (East & Hofer 1991b). Whoops show pronounced non-linear phenomena, predominantly subharmonics, which may enhance individual recognition by adding structural complexity to calls (Peters *et al.* 2004). The laugh or giggle is produced when individuals are nervous, as when challenged by a Lion or when signalling submission to a dominant clan member. Like whoops, giggles contain acoustic signatures which may communicate individual identity (Mathevon *et al.* 2010).

Much of the social life of a clan occurs in the vicinity of the communal den. Communal dens may be used for years, or den sites may be changed several times within a year. A clan may simultaneously have several communal dens separated by up to 7 km (Hofer & East 1993a). Dens are dug by other species, mostly warthog, Aardvark *Orycteropus afer* and Bat-eared Fox *Otocyon megalotis* and then are modified. Cubs excavate underground burrows and adult ♀♀ enlarge the den entrance. The structure of dens does not normally permit the access of adult animals and cubs must emerge at the den entrance to interact with their mother (Golla *et al.* 1999). Small underground burrows may protect cubs from predation by Lions and non-clan members (Kruuk 1972), and may also reduce infanticide by adult ♀♀ and immigrant ♂♂ clan members (Hofer & East 1995, East *et al.* 2003).

Mating in the Spotted Hyaena is facilitated by retractor muscles that allow the ♀ to retract the clitoris on itself, thereby forming an opening into which the ♂ inserts his penis. In order to achieve intromission, the ♂ tucks his rump under the ♀, only assuming an erect posture behind her once engaged (Frank 1996). Females give birth through their penile clitoris that ruptures to permit the passage of the young, creating a large wound of several centimetres. Females may give birth in a private birth den or at the communal den (East *et al.* 1989, Henschel & Skinner 1990b). Communal dens may contain numerous young of different sizes and ages from many litters; Hofer (1998b) reports up to 30. Mothers probably use private birth dens so that they can maintain continuous access to their newborn cubs; at the communal den this is only feasible for top-ranking mothers. Mothers may also use birth dens so that both mother and offspring can learn to identify each other before they move to the communal den (East *et al.* 1989). Young cubs that emerge from a den due to the presence of a ♀ that is not their mother risk infanticide, and mothers that nurse cubs that are not their own risk compromising the growth and survival of their litter. Females usually nurse only their own cubs and reject approaches by other cubs; however, exceptions to this rule do occur (East *et al.* 2009). As there are often several animals present at the communal den, cubs benefit from the vigilance of adults that can alert young to the presence of predators. Social interactions at the communal den between cubs and adult clan members play an important role in the integration of juveniles into the dominance structure of the clan (East *et al.* 1993, Holekamp & Smale 1993). Cubs remain at the communal den for a period of approximately

Spotted Hyaena *Crocuta crocuta* two months old.

12 months and during this period their major source of food is milk provided by their mother (Hofer & East 1993c, Frank *et al.* 1995b).

At birth the eyes are open and deciduous canines and incisors are fully erupted (Pournelle 1965). Litter-mates engage in aggressive interactions immediately after birth, leading to the establishment of a dominance hierarchy between siblings within the first few days of life (Smale *et al.* 1995, Golla *et al.* 1999). When litters are suckling, the dominant cub skews access to maternal teats in its favour by using aggressive behaviours to train its sibling to respond submissively and to stop suckling when challenged (Benhaïem *et al.* in press). If the amount of milk provided by a mother is insufficient for both littermates, dominant littermates increase their monopolization of access to maternal teats. When well fed, subordinate cubs observe social dominance conventions, respond submissively and stop suckling for lengthy periods than when they are hungry and behave more assertively (Benhaïem *et al.* in press). As a result of their reduced submissiveness, the rate of aggression is high in hungry litters (Golla *et al.* 1999). When mothers provide insufficient milk to a twin litter for an extended period, dominant cubs may skew consumption of maternal milk in their favour to such an extent that their subordinate siblings die of enforced starvation (Hofer & East 1997, 2008, Golla *et al.* 1999). Siblicide is therefore facultative and rarely occurs in habitats where mothers have access to sufficient food resources (Smale *et al.* 1999, Wachter *et al.* 2002). A cub that manages to starve its sibling obtains significant benefits, as growth rates of singletons are higher than those of twins, and cubs with a higher growth rate have a better chance of surviving to the age of independence (Hofer & East 1993c, 2003, 2008). It is probable that high maternal investment in litters, a lack of communal suckling and the substantial benefits associated with being the dominant member of a twin litter (or the survivor after the subordinate sibling has been dispatched due to starvation) favoured selection for high neonatal aggression, and elevated levels of androgens in young neonates have been selected to produce cubs primed for sibling rivalry at birth (East *et al.* 1993).

Reproduction and Population Structure Breeding takes place throughout the year, with little evidence for seasonality of births (Kruuk 1972, Mills 1990, Holekamp & Smale 1995, East & Hofer 2002). The gestation period is approximately 110 days, oestrus is thought to last for one day and females cycle every 14 days (Matthews 1939b, Schneider 1952). Females give birth to litters of one, two or rarely three cubs (Holekamp & Smale 1995, Hofer & East 1997, 2008). Triplets typically do not survive, as ♀♀ normally only lactate through two nipples, but

one triplet litter is known to have survived in the Ngorongoro Crater (O. P. Höner pers. comm.). Birth-weight is approximately 1.5 kg (Pournelle 1965). At birth cubs are uniformly black, with ears folded backwards over the head, eyes partially open and deciduous teeth erupted (Pournelle 1965, East *et al.* 1989). Eyes develop white rings at approximately six weeks of age. Lighter hair spreads across the face to the neck and shoulders and eventually the body, and spots emerge. At the age of 6–12 months cubs develop a longer and lighter coloured pelage before assuming the shorter, darker adult coat.

Cubs are nursed for a prolonged period and may not be weaned until 14–18 months of age (Hofer & East 1993c). The milk of Spotted Hyaenas in Serengeti N. P. has the highest protein content (mean 14.9%) recorded for any terrestrial carnivore, a fat content (mean 14.1%) exceeded only by that of Palearctic bears and the Sea Otter *Enhydra lutra*, and a higher gross energy density than the milk of most terrestrial carnivores (Hofer & East 1995). Owing to their milk's high energy content and the long nursing period, the Spotted Hyaena has the highest energetic investment per litter of any carnivore (Oftedal & Gittleman 1989). As high-ranking mothers nurse their offspring more often than subordinate ♀♀, their offspring grow faster (Hofer & East 2003) and survive better than cubs of subordinate mothers (Frank *et al.* 1995b, Hofer & East 1996, 2003). This privileged upbringing provides the important fitness benefit of an early start to reproduction to adult daughters and sons of high-ranking mothers (Hofer & East 2003, Höner *et al.* 2010).

Age at first parturition varies substantially between two and five years (Holekamp *et al.* 1996, Hofer & East 2003). Inter-birth intervals are shorter in dominant ♀♀ than subordinate ♀♀, probably as a result of the dominant female's priority of access to food resources in the clan territory (Holekamp *et al.* 1996, Hofer & East 2003, Höner *et al.* 2005). In the Ngorongoro Crater, the average inter-birth interval of ♀♀ that rear a litter is approximately 18 months (Höner *et al.* 2005). Inter-birth intervals for ♀♀ that lose a litter are likely to be shorter, as Henschel (1986) reported inter-birth intervals of about 135 days in one ♀ in Kruger N. P. that lost five litters in succession.

Sex ratios amongst adults are usually even or slightly female-biased (Mills 1990, Hofer & East 1993a, Frank *et al.* 1995b). Significant deviations in offspring sex ratios in singleton and twin litters have been found in some populations (Frank *et al.* 1991, Holekamp & Smale 1995, Hofer & East 1997, Golla *et al.* 1999), but not in others (Wachter *et al.* 2002). For example, of 114 twin litters recorded by Hofer & East (1997), 16 were female–female, 29 male–male, and 69 male–female. Such deviations in the sex ratio from the expected distribution may either be a consequence of changes in the sex ratio at conception (Holekamp & Smale 1995) or of post-natal sex-specific facultative siblicide (Hofer & East 1997, Golla *et al.* 1999, Wachter *et al.* 2002).

Average annual mortality rates are around 13–15% within protected areas. Approximately 50–60% of Spotted Hyaena cubs survive their first 12 months of life (Hofer 1998b; and references therein). A study conducted over a four-year period in one clan in Kenya found that peaks in cub mortality coincided with life-stage events, including mean age of arrival at a communal den, and age at which cubs began visiting kills (White 2005). Longevity in captivity is in the order of 40 years (Weigl 2005).

Predators, Parasites and Diseases The only major predators of the Spotted Hyaena are Lions (Kruuk 1972, Schaller 1972, Mills

1990, Trinkel & Kastberger 2005), although they do not generally consume the hyaenas they kill. Leopards *Panthera pardus* occasionally kill individual hyaenas (Bailey 2005). Other sources of natural adult mortality include violent encounters between conspecifics (Kruuk 1972, Henschel & Skinner 1991), injuries sustained while hunting, and disease (see below). An estimated 9–18% of ♀♀ may die during their first birth from complications arising during parturition (Frank & Glickman 1994, Frank *et al.* 1995b). Infanticide by adult female clan members, diseases and facultative siblicide are important sources of cub mortality (Mills 1990, Hofer & East 1995, White 2005). White (2005) described selective litter reduction by mothers via partial litter abandonment, a mechanism of filial infanticide not previously described in this species. Cubs may also starve to death when their mothers die. Other sources of cub mortality include predation by Lions and the collapse of communal dens after heavy rain.

Infection with microfilaria, *Dipetalonema dracunculoides*, at least three species of cestodes in the genus *Taenia*, a protozoan parasite in the genus *Hepatozoon* and trypanosomes have been reported (Hofer 1998b; and references therein). An examination of faecal samples from Spotted Hyaenas in the Masai Mara recorded a total of nine parasite genera; most individuals were infected with *Ancylostoma* sp. and *Spirometra* sp., and these had the highest median intensity of infection. Other parasites identified include *Isoospora* sp., Taeniidae, Spirurida, *Toxocara* sp., *Mesocostoides* sp., *Dipylidium* sp. and *Trichuris* sp. (Engl *et al.* 2003). Ectoparasites recorded include ixodid ticks of the genera *Amblyomma*, *Boophilus*, *Haemaphysalis*, *Ixodes* and *Rhipicephalus* from animals taken in the Kruger N. P. and in NE KwaZulu–Natal, South Africa (Horak *et al.* 1987, 2000).

Serological evidence suggests that Spotted Hyaenas survive exposure to many viral diseases. Antibodies against rabies, canine distemper virus, canine herpes, canine brucella, canine adenovirus, canine parvovirus, feline calysi, leptospirosis, feline immunodeficiency virus, coronavirus, calicivirus, feline herpes virus 1, bovine brucella, rinderpest, anaplasmosis and African horse sickness virus have been reported (Hofer & East 1995, Hofer 1998b, East *et al.* 2001, 2004, Harrison *et al.* 2004, Troyer *et al.* 2005). Over 70% of Spotted Hyaenas in the Serengeti N. P. and Masai Mara National Reserve are exposed to coronavirus infection (East *et al.* 2004, Harrison *et al.* 2004).

Between 1993 and 1994 an outbreak of canine distemper virus (CDV) increased mortality among Spotted Hyaena cubs less than 12 months of age in Serengeti N. P. (Haas *et al.* 1996). Mothers that lost cubs produced replacement litters that did not succumb to CDV. The hyaena CDV strain (Haas *et al.* 1996) was similar to that from dead Lions from the same area (Carpenter *et al.* 1998), African Wild Dogs *Lycaon pictus* that died in a captive-breeding facility in Mkomazi N. P. in 2000 (Van de Bildt *et al.* 2002), and from a pack of African Wild Dogs that died close to the Serengeti N. P. in 2007 (Goller *et al.* 2010). The 1993–1994 CDV outbreak spread to Masai Mara National Reserve, but did not affect Spotted Hyaena mortality (Alexander *et al.* 1995). Serological evidence of a subsequent CDV outbreak in Spotted Hyaena in the Masai Mara was not associated with increased mortality (Harrison *et al.* 2004).

Rabies may play an important role in the population dynamics of the Spotted Hyaena in the Kalahari (Mills 1990), and rabies in Spotted Hyaena has been reported in several African countries. A high proportion (37%) of Spotted Hyaena in Serengeti N. P. had significant rabies-specific antibody titre levels, without suffering mortality (East *et al.* 2001).

Many carnivore species have sub-clinical infections with the tick-borne blood parasite *Hepatozoon* sp. Young Spotted Hyaena cubs in Serengeti N. P. can suffer lethal *Hepatozoon* infections, suggesting that this blood parasite may be an important cause of juvenile mortality (East *et al.* 2008).

A *Streptococcus equi ruminatorum* outbreak in Spotted Hyaenas in the Ngorongoro Crater in 2001–2002 caused clinical signs similar to those described for ‘Strangles’ in domestic horses and led to increased mortality (Höner *et al.* 2006). Individuals were observed with clinical signs when prey abundance in their clan territory was low and mortality during the outbreak mostly occurred in animals of low social status and those likely to experience poor nutrition. Infection reduced population growth rate in the Ngorongoro Crater from 13.6% prior to the outbreak to a 4.3% decline during the outbreak. After the outbreak, population growth recovered to 13.9% (Höner *et al.* 2012).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although the total world population is relatively large and contains sub-populations that exceed 1000 individuals in several countries, it is declining outside protected areas, largely as a result of human persecution through shooting, trapping and poisoning, some of it officially led or sanctioned. Mortality from wire snares set to catch wild herbivores is the most important cause of adult mortality in Serengeti N. P., where snares kill around 400 adult hyaenas each year and are responsible for more than half of all adult mortality (Hofer *et al.* 1993, 1996). Entire clans may be killed by poisoning (Holekamp *et al.* 1993), and many individuals are killed when hit by vehicles.

Most populations in protected areas in southern Africa, such as Kruger N. P. (South Africa), Kgalagadi Transfrontier Park (South Africa and Botswana), Hluhluwe-iMfolozi (South Africa) and Etosha N. P. (Namibia), are considered to be stable, whereas populations in eastern and West Africa, even in protected areas, are considered to be declining because of snaring and poisoning (Hofer & Mills 1998b). The population in the Ngorongoro Crater has significantly increased in recent years (Höner *et al.* 2005, 2012). The Spotted Hyaena may be able to respond rapidly to changing ecological conditions. At the edge of Masai Mara National Reserve, increased human activity during a ten-year period was associated with increased use of daytime resting areas in dense vegetation, and avoidance of areas containing the highest abundance of prey, as these were the areas where intensive livestock grazing by pastoralists was concentrated (Boydston *et al.* 2003).

Official attitudes towards the Spotted Hyaena vary from a legal classification as ‘vermin’ (Ethiopia) to fully protected in conservation areas. There are still countries where farmers may kill hyaenas at their discretion (Hofer & Mills 1998b). The Spotted Hyaena is not an important item in the diet of humans (though it is occasionally harvested as a food source in some countries), or an important species for trophy hunters, although it is killed for body parts for traditional medicines and body parts and live hyaenas are used for witchcraft. Licensed sport hunting is permitted in several countries, but numbers killed for this purpose are probably small. Habitat loss and degradation has reduced the habitat available to species that are suitable prey for the Spotted Hyaena and led to declines in populations (Hofer & Mills 1998b).

Measurements

Crocota crocuta

TL (♂ ♂): 1587 (1465–1735) mm, n = 9
 TL (♀ ♀): 1572 (1440–1794) mm, n = 8
 T (♂ ♂): 249 (227–280) mm, n = 9
 T (♀ ♀): 249 (130–315) mm, n = 8
 HF c.u. (♂ ♂): 230 (220–245) mm, n = 9
 HF c.u. (♀ ♀): 228 (215–250) mm, n = 5
 E (♂ ♂): 112 (100–125) mm, n = 8
 E (♀ ♀): 114 (110–120) mm, n = 7
 Sh. ht (♂ ♂): 802 (775–870) mm, n = 10
 Sh. ht (♀ ♀): 794 (735–845) mm, n = 9
 Ht hq. (♂ ♂): 669 (605–720) mm, n = 9
 Ht hq. (♀ ♀): 648 (575–680) mm, n = 8
 WT (♂ ♂): 62.5 (54.0–70.0) kg, n = 11
 WT (♀ ♀): 68.2 (55.0–81.0) kg, n = 9
 Kruger N. P. (Henschel 1986)

In the Serengeti N.P., average weight for ♂ ♂ is 48.4 kg (range 40.0–58.0, n = 27) and for ♀ ♀ 55.6 kg (range 39.0–74.0, n = 40) (M. L. East & H. Hofer pers. obs.)

Note that published sex differences in weight may be misleading, unless standardized for the amount of food contained in the stomach because ♀ ♀ have priority of access to food and Spotted Hyaenas may consume as much as one-third of their body weight (up to 18 kg) in one meal (Kruuk 1972, Hofer 1998b)

Spotted Hyaena *Crocota crocuta*.

GENUS *Proteles*

Aardwolf

Proteles I. Geoffroy St.-Hilaire, 1824. Bull. Sci. Soc. Philom. Paris 1824: 139.

A monotypic genus represented by the Aardwolf *Proteles cristatus*, a species having specialized adaptations for feeding on social insects, especially the termite genera *Trinervitermes* and *Hodotermes*. The origin and evolution of the Aardwolf are not known. The species is a mixture of very primitive and highly derived anatomical features, making phylogenetic evaluation on this basis very difficult. The recent molecular study by Koepfli *et al.* (2006) dates the split of *Proteles* from other Hyainidae to the earliest late Miocene, which is plausible but leaves no clues as to the geographic origin of the genus. It has been commonly suggested (Thenius 1966, Werdelin & Solounias 1991) that *Proteles* derives from the small, hypocarnivorous genus *Plioiviverrops*. However, this genus is of too ancient an origin to fit with the date proposed by Koepfli *et al.* (2006), who instead resurrect a proposal

by Ewer (Ewer & Cooke 1964, Ewer 1973) that *Proteles* derives from the *Lycyaena* lineage of cursorial hypercarnivorous hyaenas. The fossil record at present gives no support for either hypothesis, as the earliest fossil of the genus is from Swartkrans in South Africa, dated ca. 1.5 mya (though skeletal material of a small hyaenid from ca. 4 mya old deposits at Laetoli, Tanzania, may represent *Proteles*; Werdelin & Dehghani 2011). This South African fossil has been given the name *Proteles amplidentus*, but in all respects is very similar to the modern species and does not represent a transitional form (Hendey 1974c, Werdelin & Solounias 1991). Other fossils are younger and indistinguishable from the living species.

Lars Werdelin

Proteles cristatus AARDWOLF

Fr. Protèle; Ger. Erdwolf

Proteles cristatus (Sparrman, 1783). Resa Goda-Hopps-Udden. I. 1: 581. English translation (Sparrman 1786) of original locality: 'Agter-Bruntjes hoogte ... which takes in the upper part of Kleine Visch-rivier, and is separated from Camdebo by Bruntjes hoogtens ...'; listed in G. M. Allen (1939) as 'Near Little Fish River, Somerset East, Cape Colony' [South Africa].

Aardwolf *Proteles cristatus*.

Taxonomy Two Aardwolf subspecies are recognized (Coetzee 1977, Meester *et al.* 1986). Jenks & Werdelin (1998) provisionally retained the subspecies, while noting that there have been no genetic or morphometric studies done to confirm their validity. Synonyms: *canescens*, *harrisoni*, *hyenoides*, *lalandii*, *pallidior*, *septentrionalis*, *termes*, *transvaalensis*, *typicus*. The diploid number of chromosomes is $2n = 40$, with 72 autosomal arms; the X chromosome is metacentric and the Y chromosome is submetacentric. The chromosomes are similar in number and configuration to the hyaenas, providing further evidence for classifying the Aardwolf in the Hyainidae (Ulbrich & Schmitt 1969). Similarly, haemoglobin of the Aardwolf has the same electrophoretic mobility as that of the hyaenas (Seal 1969).

Description Medium-sized carnivore, larger than a jackal, standing about 0.47 m at the shoulder. Height accentuated by long mane hairs, which are erected when stressed. Face usually greyer than rest of body, while throat is a paler grey-white. Ears long and pointed; brown-black behind, white in front. Hair on the face short (10–15 mm) and grey, muzzle almost hairless and grey-black. Muzzle has minute, delicate light-coloured downy hairs, with a few longer hairs on the upper lip. Seven or eight strong, black vibrissae. Neck long and slender, sometimes with black spots or stripes present (Roberts 1951, Richardson & Bearder 1984, Koehler & Richardson 1990, Skinner & Chimimba 2005).

Background colour of the body varies from yellowish-white or buff to rufous. There are three vertical black stripes on the body and one or two diagonal stripes across the fore- and hindquarters. Body stripes run from mid-back and tail out towards the underparts. Most of the body consists of dense, soft, crinkled underfur interspersed with coarser guard hairs. Hair relatively short, not more than about

10–15 mm; individual hairs are dark at base, then broadly white, with black tips. In South Africa length and density of pelage increases during winter (Anderson 1994, 2004, Anderson *et al.* 1997). Hairs of the mane, which runs from back of head to base of tail, are broadly black-tipped and show as broad black band down mid-back. Mane hairs coarse and long (longest of all carnivores; Wemmer & Wilson 1983), being about 70 mm on back of head, increasing to about 200 mm on shoulders. These hairs have broad white bases, then alternating black and white annulations, terminating in black tips (Koehler & Richardson 1990, Skinner & Chimimba 2005).

Legs long, with regular horizontal stripes, which are darker towards the feet. Stance digitigrade (Sclater 1900). Five digits on the front feet, four on the hind. Presence of the first digit (pollex) on the front feet is one of the characters in which the Aardwolf differs from hyaenas. Claws strongly built and non-retractile (Sclater 1900). Claws on the first digits of the front feet are well developed and distinctly curved, the remaining four only slightly so. Viewed from above the claws are narrow, but in side view they are broad at the bases and strongly built and about 20 mm long over the curve. Claws on the hindfeet are similar, but slightly more curved. The tips of the claws show clearly in the Aardwolf's spoor (Koehler & Richardson 1990, Skinner & Chimimba 2005). Tail bushy and broadly black-tipped. Hair on the tail is long and wiry like that of the crest. Individual hairs are up to 150 mm long, broadly whitish at base and for about two-thirds of their length, remainder black (Skinner & Chimimba 2005). No sexual dimorphism in size (Richardson 1985, Koehler & Richardson 1990), although in overall length (and length of tail) ♀♀ appear slightly larger than ♂♂ (Smithers 1971). The ♀ has two pairs of inguinal nipples (Richardson 1985).

The skull is flat in profile, but falls off abruptly in front of the eye orbits flattening out towards the nasals. The supra-occipital crest is well developed and heavily built, rising 6–7 mm from the braincase; a short sagittal crest joins it at right-angles. The zygomatic arches are broad and heavily built, suggesting well-developed masseter muscles. Orbits are incomplete, although the two postorbital processes approach quite closely. The front chamber of the ear bulla is tiny compared with the hind chamber, which is elongated and swollen, rising high from the braincase when viewed from below. The broad palate accommodates the broad spatulate tongue, while the lower jaw, when viewed from above, is bowed out in front for the same reason. The dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{1/1} = 32$. Although the canines are well developed (the upper canines being long and curved, the lower canines slightly recurved), the cheekteeth are peg-like and much reduced (Koehler & Richardson 1990, Skinner & Chimimba 2005).

Geographic Variation

P. c. cristatus: southern Africa.

P. c. septentrionalis: eastern and north-eastern Africa.

Similar Species

Hyaena hyaena. Sympatric in East and north-east Africa. Also has vertical body stripes, but is >50% larger in size and the stripes are more irregular (Roberts 1951, Richardson & Bearder 1984). Gingerich (1975) suggested that the Aardwolf mimics the Striped Hyaena *Hyaena hyaena* to reduce predation by Leopards *Panthera pardus* and other carnivores. However, as the Aardwolf is half the size of the hyaena and as other animals (including several species of smaller carnivores) seem unperturbed by an Aardwolf, mimicry

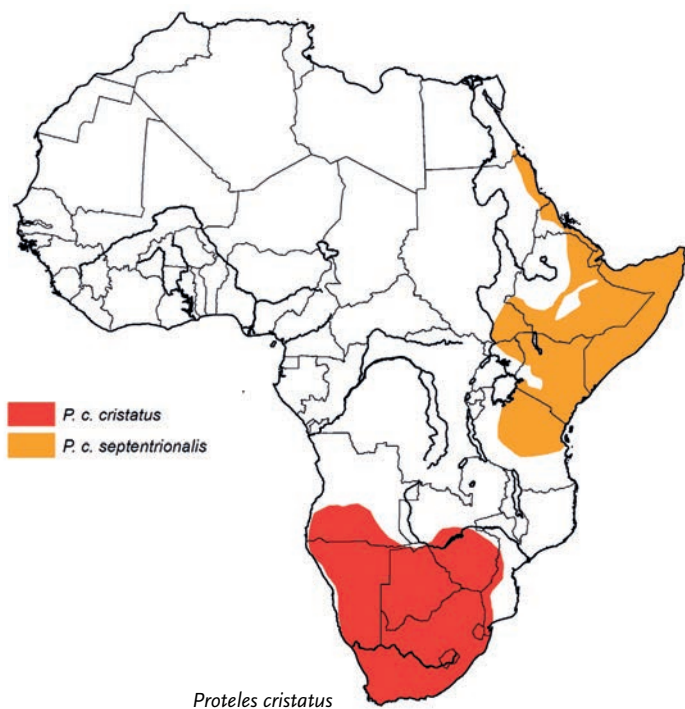

Lateral, palatal and dorsal views of skull of Aardwolf *Proteles cristatus*.

Aardwolf *Proteles cristatus* facial myology (note large salivary glands).

seems an unlikely explanation for Aardwolf stripes (Kingdon 1977, Koehler & Richardson 1990).

Distribution Endemic to Africa, with two discrete distributional areas, 1500 km apart, one in East and north-eastern Africa and one in southern Africa. During the Pleistocene epoch, when the climate in central Africa was often drier, the range of the Aardwolf was probably continuous (Coe & Skinner 1993).

The northern population extends from CTanzania to NE Uganda, Ethiopia (including the central Rift Valley; Yalden *et al.* 1996) and Somalia, then narrowly along the coast of Eritrea and Sudan to extreme SE Egypt (in the Sudan Government Administration Area; Hoath 2003) (Hofer & Mills 1998a). Their presence in Djibouti is unclear: no confirmed records are mentioned by Hofer & Mills (1998a) or Künzel *et al.* (2000), although it is mentioned by Simoneau (1974). A road kill from near Mbatwa in the Udzungwa Mts in 2002 may represent the most southerly record for the *P. c. septentrionalis* subspecies (De Luca & Mpunga 2005).

The southern population ranges over most of southern Africa, extending just into SW Angola, S Zambia (apparently south of the Kafue R.) and SW Mozambique (Smithers & Lobão Tello 1976, Ansell 1978, Crawford-Cabral 1989a). It is therefore absent from Malawi, STanzania and most of Zambia (Koehler & Richardson 1990, Hofer & Mills 1998a). The Aardwolf occurs throughout Namibia, except along the Namib Desert coast, Botswana, Zimbabwe (except the north-east), Swaziland, and throughout South Africa, except the forested areas in the south along the coast (Skinner & Chimimba 2005). It is not recorded from Lesotho, but may well occur (Lynch 1994). There are unconfirmed reports of occurrence in NE Central African Republic and Burundi (Koehler & Richardson 1990).

The distribution of the Aardwolf is largely determined by the distribution of *Trinervitermes* termites, which constitute their principal food (von Ketelhodt 1966, Kruuk & Sands 1972, Cooper & Skinner 1979, Richardson 1987a, 1990). The Aardwolf's absence in West

Africa is related to a scarcity of suitable termites (Kruuk & Sands 1972). The surface-foraging *Trinervitermes* termites that occur in West Africa (*T. oeconomus* and *T. occidentalis*) are relatively uncommon and prefer bushy habitats rather than open grassland (Sands 1961, Kruuk & Sands 1972, Ohiagu 1979).

Habitat The Aardwolf's prime habitat is open, grassy plains, although most habitats having a mean annual rainfall of 100–800 mm are occupied (Koehler & Richardson 1990). The Aardwolf is most common in the 100–600 mm range and does not occur in forests or pure desert (Skinner & Chimimba 2005). In southern Africa Aardwolves occupy diverse habitats, ranging from the karroid habitats of the Western Cape and Eastern Cape, the grasslands and scrub of Botswana, the open savanna woodlands of Zimbabwe, and the inland gravel plains of the Namib Desert in Namibia (Skinner & Chimimba 2005). In East Africa the habitat occupied by Aardwolves includes open grassland with virtually no trees (Kruuk & Sands 1972). They are recorded to 2000 m in Ethiopia (Yalden *et al.* 1996).

Abundance Although fairly widely distributed in Africa, the Aardwolf is not common within this range. In prime habitat (open grassland and scrub regions), Aardwolf densities may reach 1 adult/km² on farms with good populations of *Trinervitermes* termites and no persecution by farmers (Richardson 1984, 1985, Skinner & Van Aarde 1985, Koehler & Richardson 1990). In Serengeti N. P. the centres of Aardwolf ranges appeared to be 1–2 km apart (Kruuk & Sands 1972).

Adaptations Despite genetic, morphological and behavioural evidence that the Aardwolf is closely related to the hyaenas, its diet and dentition are clearly different from the hyaenas. Hyaenas have strong dentition and are able to crush bones, while the Aardwolf has a slender skull and the cheekteeth are reduced to small, widely spaced, redundant pegs. Unlike the hyaenas, elongated frontal sinuses are conspicuously absent in the extant Aardwolf (Joeckel 1998). Hyaena-like features include: large pointed ears, long erectile mane, sloping back with forelegs longer than hindlegs, and a well-developed anal gland for scent-marking grass stalks (Roberts 1951, Koehler & Richardson 1990, Skinner & Chimimba 2005).

The Aardwolf possesses none of the obvious external physical features of a termite feeding style, characteristics that are typical of other myrmecophagous mammals (Griffiths 1968, Anderson *et al.* 1992). Behaviourally, the Aardwolf differs from the other typical myrmecophages in that it does not dig for its prey, but licks them off the soil surface. Nevertheless, the Aardwolf does have a number of anatomical features that are clear adaptations to this diet (Flower 1869a, Anderson *et al.* 1992, Anderson 2004). The Aardwolf is probably one of the most specialized carnivores and myrmecophagous mammals (Richardson 1987b).

Sight, hearing and smell appear to be well developed in the Aardwolf. Externally the eyes and ears are noticeably large, while internally the auditory bulla and olfactory lobes also are well developed (Flower 1869a, Kruuk & Sands 1972, Richardson 1985, Koehler & Richardson 1990, Skinner & Chimimba 2005). The Aardwolf has a large and hairless muzzle, which prevents the soldier termites' defensive secretions, and hence dirt, from adhering to the same extent as they would if the muzzle was haired (Kruuk & Sands 1972). The most noticeable features of the Aardwolf skull are the widely spaced and small-

Aardwolf *Proteles cristatus* myology.

peg-like teeth, the contrastingly large canines, and the broad and parallel-sided palate (Anderson *et al.* 1992). Therefore, although the Aardwolf probably has the ability to kill vertebrate prey with its large canines, because of a lack of developed molars and premolars it would not be able to process the prey. The canines are used in territorial disputes against other Aardwolves and in defence against predators (Richardson 1985, 1987a, b). The relatively well-developed incisors are almost certainly used for grooming.

An interesting aspect of the Aardwolf's musculature is the relatively large digastric muscle, compared with that of a domestic dog (Turnbull 1970; illustrated in Kingdon 1977). As the digastric muscle is used for opening the jaw, its enlarged size may be explained by the Aardwolf's need to open its mouth rapidly and frequently while feeding (Anderson *et al.* 1992). This is a development that parallels, on a more modest scale, the enlarged digastric of the Bat-eared Fox *Otocyon megalotis* (another myrmecophagous carnivore), where just such a function is unambiguous. Other features of the skull are the well-developed postorbital processes and the extraordinarily large tympanic bulla (Anderson *et al.* 1992).

The Aardwolf has a broad spatulate tongue (117–123 mm long, and 30–32 mm wide) covered with large, hardened papillae (one type, 'incisiform' papillae, may be unique to the Aardwolf) (Flower 1869b, Richardson 1985, Anderson *et al.* 1992). This tongue is used to lick termites from the soil surface and the papillae are adaptations to protect the tongue against abrasion by sand. The broad palate accommodates the rapid licking movements of the broad tongue. It also has posteriorly directed transverse ridges, which presumably act as a catchment area for termites as the tongue is again extruded.

The mandibular salivary glands are very large (about twice the size of the mandibular salivary glands of a similar-sized dog) (Flower 1869b, Richardson 1985) and they are serous and mucous secreting, while the parotid, sublingual and zygomatic glands are serous or mixed. The mucous secretions provide a relatively thick and sticky substrate and facilitate the licking up of termites. In addition, the mucus could provide protection for the oral cavity and oesophagus from the termites' terpene secretions, as has been speculated to be the case in myrmecophagous sengis (Kratzing & Woodall 1988). Like other nasute termites (Nasutitermitinae), *Trinervitermes* possess a highly

effective means of chemical defence: the soldiers have well-developed frontal glands from which they can squirt threads of very sticky and noxious, terpene-based secretions (Prestwich 1983, Braekman *et al.* 1984). It is not known whether the saliva may play a role in the detoxification of the terpene secretions, i.e. similar to the tannin-binding proteins found in the saliva of browsing ruminants (Austin *et al.* 1989). The ability of the Aardwolf to tolerate these terpenes secretions must be its most significant adaptation, as this has made these termites readily available and virtually without competition from any other mammal (Kruuk & Sands 1972, Melton 1976, Kingdon 1977, Richardson 1987b, Richardson & Levitan 1994). It has been suggested that, as the Aardwolf evolved from civet-like viverrids, such as the African Civet *Civettictis civetta*, which has the ability to feed on noxious food items, it was pre-adapted to tolerate the terpenes secretions of *Trinervitermes* (Richardson 1987b, Richardson & Levitan 1994).

The gastrointestinal tract of the Aardwolf follows the typical carnivore pattern and consists of a stomach, small intestine, caecum and colon (Anderson *et al.* 1992). The smooth-walled pyloric region of the stomach has a few irregular folds and the walls are thick and muscular. As *Trinervitermes* termites are small and soft-bodied, chewing is unnecessary and the termites are probably pulverized by the muscular region of the stomach. A similar structure is found in the stomach of anteaters (Myrmecophagidae) and pangolins (Manidae) (Chivers & Hladik 1980). Chewing would not only limit the amount of termites that could be ingested, but also rupture the soldier termites' heads and thus release the terpene contents into the Aardwolf's buccal cavity. The pulverization of termites in the stomach is probably aided by sand and other debris that is incidentally ingested with the termites (up to 50% of the faeces contain sand; Cooper & Skinner 1979). The small intestine is short, a characteristic of animals that feed on soft, easily digestible material. Aardwolf digestion may be more geared to processing large volumes of material and the rapid digestion of the workers' abdomens, as opposed to the more efficient digestion of the whole termites. The small caecum may play a role in the absorption of water and electrolytes. The descending (distal) colon is characterized by thick walls with distinct longitudinal bands. This enables the distal colon to distend, allowing the accumulation of a large volume of faeces (over periods as long as 18 hours). Soon after emergence from their den in the late-afternoon/early-evening, Aardwolves walk to a nearby midden and defecate, with the first defecation of the evening weighing up to 1 kg (Kruuk & Sands 1972, Richardson 1987a). As Aardwolves obtain most of their water from termites and thus very rarely drink (Richardson 1985), the distal colon may also play an important role in the absorption of water (Anderson *et al.* 1992).

There are diel and seasonal variations in the body temperatures (T_b) of Aardwolves in South Africa (Anderson 1994). During winter active Aardwolves maintain an average T_b of approximately 37.3 °C but after returning to their dens their T_b decreases through the rest of the night and early morning until the middle of their inactive period (08:00–10:00h) (Anderson 1994). At 09:00h their average T_b is 34.1 ± 1.6 °C. The lowest T_b recorded during winter was 31.2 °C in one ♀ at 09:00h (Anderson 1994). Hypothermia in the Aardwolf during winter translates to a ca. 18% energy saving (Anderson 1994). The Aardwolf does not fully exploit the energetic advantages of hypothermia, but perhaps the T_b at which Aardwolves rest during the day facilitates the lowest rate of energy expenditure needed to

maintain physical agility for predator avoidance. The Aardwolf's size and the cost of rewarming may preclude it from lowering its T_b below 31–33 °C. A lowered T_b also has adaptive potential for water conservation by a reduction of evaporative water loss (Anderson 1994, 2004). The evaporative water loss rates and rates of water flux are lower than predicted for similar-sized eutherian mammals (Chew 1965, Anderson *et al.* 1997, Williams *et al.* 1997).

Aardwolves have reduced basal and field metabolic rates, further reduced during winter, thus reducing energy requirements during the stressful winter months when termites are generally not available (McNab 1984, Anderson 1994, Anderson *et al.* 1997, Williams *et al.* 1997). The main advantage of a low metabolic rate is that it reduces energy expenditure and thus reduces the minimum energy requirements per feed and/or increases the maximum intervals between feeds (McNab 1983). McNab (1984) suggested that ant- and termite-eating mammals have evolved a low BMR in order to survive on a diet of termites, which are not only nutritionally poor (Phelps *et al.* 1975, Redford & Dorea 1984, Anderson 1994), but also have a patchy distribution in both space and time (cf. Richardson 1985, Anderson 1994).

Aardwolves spend the majority of their inactive period in their dens (Richardson 1985, Anderson 1994). Richardson (1985) found that an average of 5.8 dens (range 2–9) were used by a pair of Aardwolves in a territory each year, with each den being used for about 6–8 weeks at a time before a different den was used. A den may be re-occupied 6–18 months later (Richardson 1985).

The time of departure from, and time of retirement to, dens is highly variable throughout the year but fairly consistent within a specific season (Richardson 1987a, Anderson 1994, Williams *et al.* 1997), with Aardwolves spending a greater proportion of time in their dens during winter. During a study in South Africa, denning times were 19.1 ± 1.2 hours and 15.8 ± 1.72 hours during winter and summer, respectively (Anderson 1994, 2004). The extended period spent in the den during winter, coupled with a reduced metabolic rate, results in Aardwolves conserving at least 639 kJ/day while in their winter dens (Anderson *et al.* 1997). Aardwolf activity patterns and hence den usage are largely determined by the availability of termites. The den also has an important anti-predatory function, especially as it provides a safe refuge for the cubs from predators, such as Black-backed Jackals *Canis mesomelas* (Richardson 1985).

Dens usually have only one entrance, with the entrances being randomly orientated (Anderson 1994). Most den entrances are oval-shaped, being about 320 mm high and 420 mm wide at the entrance, but rapidly narrowing down to about 200×300 mm inside the tunnel (Richardson 1985). Two excavated Aardwolf dens were narrow and well defined with no side tunnels and no obvious enlargements at the end. In contrast, a den excavated by Richardson (1985) had a slight chamber enlargement. The two excavated burrows narrowed into smaller burrows of the Southern African Springhare *Pedetes capensis*, with a tunnel height and width of approximately 100 mm and 155 mm, respectively (Anderson 1994). As Aardwolves do not possess well-developed and powerful limbs to excavate a subterranean den (Anderson *et al.* 1992), they apparently rather enlarge those dug by springhares (Smithers 1971, Anderson 1994, Anderson & Richardson 2005). The Aardwolf may also use old Aardvark *Orycteropus afer* and Cape Porcupine *Hystrix africae australis* burrows (Smithers 1971, Richardson 1985, Anderson 1994). Although it has been stated that Aardwolves may excavate their own

burrows (Smithers 1971, Skinner & Chimimba 2005), there is no conclusive evidence to support this.

In South Africa, the temperature of Aardwolf burrows (T_d) is relatively constant during summer, averaging 27.2 ± 0.2 °C, despite large daily fluctuations at the soil surface where temperatures range from a maximum of 39.5 °C at 11:00h to a minimum of 15.0 °C at 05:00h (Anderson 1994, Anderson & Richardson 2005). The T_d s during summer are high but still within the thermoneutral zone of the Aardwolf (McNab 1984, Anderson *et al.* 1997). During winter, mean burrow temperatures are also constant, averaging 12.2 ± 1.2 °C, substantially lower than that recorded during summer (Anderson 1994, Anderson & Richardson 2005). Although the T_d during winter is below the thermoneutral zone of the Aardwolf, it is still considerably warmer than the T_a s outside the den. It is likely that the relatively low T_d , together with a CO₂ build-up in the den during winter (exacerbated by the extended period spent underground, and den sharing) (Anderson 1994), may stimulate temporal heterothermy in the Aardwolf (see Kuhn 1986).

It has been found that during winter young Aardwolves frequently shared their dens with siblings or one of their parents (Richardson 1985, Anderson 1994). Huddling reduces the Aardwolves' effective surface area, resulting in a reduction in heat loss (Anderson 1994, Anderson *et al.* 1997). Owing to the small size of the den chamber, heat produced by the occupant(s) will also raise the T_d to some extent, so the T_d of the Aardwolf chamber may therefore rise above the lower critical temperature of the thermoneutral zone. The dens are not lined with insulative materials (such as grass, litter or fur) (Richardson 1985, Anderson 1994).

The histopathology of the Aardwolf penile pad, anal pouch and forefoot scent-marking glands have been described by Stoeckelhuber *et al.* (2000). The anal gland is situated immediately above the anus, sharing a common external aperture, and consists of a T-shaped reversible pouch of sebaceous tissue (Flower 1869b, Pocock 1916c, Stoeckelhuber *et al.* 2000). The anal pouch can be everted and retracted again (Stoeckelhuber *et al.* 2000) and is characteristic of all Hyaenidae (Macdonald 1985). A yellowish-orange sebaceous and apocrine secretion is produced, which turns black when it oxidizes (Richardson 1985, Stoeckelhuber *et al.* 2000). The gland structure is very similar to that in the Striped Hyaena and Spotted Hyaena *Crocuta crocuta* (Pocock 1916c) and scent-marking behaviour is similar to Spotted Hyaenas (Kruuk & Sands 1972). Glandular tissue in the forefoot (Stoeckelhuber *et al.* 2000) may have scent-marking functions. At the base of the penis is a pair of oblong clusters of pale sebaceous glands separated by non-glandular tissue (Flower 1869b), the penile pad (Stoeckelhuber *et al.* 2000), present only in the ♂, which is not present in hyaenas. The function of this gland is not very clear (Flower 1869b, Richardson 1985), although it may be used to mark the genitals of the ♀ during copulation to inform other competing ♂♂ that she has already copulated (Sliwa 1996, Stoeckelhuber *et al.* 2000).

Foraging and Food The Aardwolf's diet is the best documented aspect of its biology, with this specialization initially being noted by Sclater (1900), Roosevelt & Heller (1914), Shortridge (1934), Wells (1968) and Smithers (1971). Throughout its distribution, it has been found to feed primarily on nasute harvester termites (genus *Trinervitermes*) and, in any particular region, mainly on one species (Skinner & Chimimba 2005). These include *T. bettonianus* in East Africa

(Kruuk & Sands 1972), *T. rhodesiensis* in Zimbabwe (Smithers & Wilson 1979) and Botswana (Smithers 1971) and *T. trinervoides* in South Africa (Cooper & Skinner 1979, Richardson 1987a). These termites are ecological equivalents: they forage in dense aggregations completely exposed on the soil surface while browsing or collecting dry grass (Richardson 1987a). Most other African termites forage underground, under the protection of mud galleries, or are very irregular in their surface foraging and therefore present a much less reliable food source (Kruuk & Sands 1972). Unlike the Aardwolf, other myrmecophagous generalists (such as the Aardvark and the Ground Pangolin *Manis temminckii*) typically have powerful claws with which they can dig into ant and termite nests, and long, thin tongues for licking up the termites in their tunnels. In contrast, the Aardwolf has a large, broad tongue ideal for licking termites off the flat soil surface (Richardson 1987a, b). Richardson (1987a) estimated that an Aardwolf in the Northern Cape, South Africa, consumes as many as 300,000 termites (1.2 kg) per night, amounting to about 105 million termites per year. Of these, *Trinervitermes* constitute the vast majority, with *Hodotermes mossambicus* being of limited importance during the winter months.

Aardwolves are almost exclusively solitary foragers, except when accompanying their young cubs (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1995, 1987a). When foraging, Aardwolves move slowly (speeds of 1–3 km/h) and quietly, head bent slightly forward and ears cocked forward, constantly moving (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1987a). An irregular route is followed, but upwind movements predominate (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1985). Aardwolves cover 8–12 km/night during summer and 3–8 km/night during winter (Richardson 1985, 1987a). There is one record of an Aardwolf walking 25 km in 10 hours and remaining active until the temperature had dropped to zero, 4 hours after it had last fed on termites (Richardson 1987a).

Patches of termites are found either fortuitously or, more commonly, after the Aardwolf has turned sharply upwind from whatever direction it happened to be walking in (Kruuk & Sands 1972). The upwind turn indicates that food location takes place primarily by scent, or by hearing, or both (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1985, Koehler & Richardson 1990), but hearing is probably the most important sense used (Kruuk & Sands 1972). The large bulbus oticus in the Aardwolf skull is indicative of a comparatively well-developed sense of hearing, although sight may be important at close range (Kruuk & Sands 1972, Richardson 1985, Koehler & Richardson 1990, Skinner & Chimimba 2005). The *Trinervitermes* concentrations generate a noise that can be heard by humans at 15–30 cm distance (Kruuk & Sands 1972). Olfaction also plays a role, since the soldiers' defensive secretion has a strong resinous smell, first observed by Kemp (1955) (and see Kruuk & Sands 1972). It is likely that sporadic attacks by small predators (such as ants) on the foraging termites would also cause scattered discharges of terpenoids (Kruuk & Sands 1972).

Having located termites, the Aardwolf licks them off the soil surface with its very broad tongue, pushing the front part of the snout into the vegetation and close to the ground (Kruuk & Sands 1972, Richardson 1987a). Feeding is rapid, with many quick licks and somewhat jerky pushing and rotating head movements. The ears, which are cocked forward until feeding begins, are now laid back. One of the front paws is occasionally used to push aside the vegetation, but during foraging and feeding the feet are never used for digging (Kruuk & Sands 1972).

A female Aardwolf in East Africa fed 44 times in 65 min, on average once every 98 sec (Kruuk & Sands 1972). The mean feeding time per termite patch is between 20 and 28 sec (Kruuk & Sands 1972, Richardson 1985, 1987a). On a second occasion she fed 35 times in 51 min, on average every 87 sec, with the mean feeding time per termite patch being 22 sec. The longest feed was 70 sec, the shortest 3 sec (Kruuk & Sands 1972). Foraging times per termite patch in the Namib Desert are significantly longer (Bothma & Nel 1980). Examination of termite foraging patches after Aardwolf feeding reveals that large numbers of termites are still milling around in a dense concentration (Kruuk & Sands 1972). Aardwolves stop feeding on a termite patch after a critical change in the soldier/worker ratio. The disturbance of the termite patches increases the percentage of unpalatable soldiers as the worker termites go underground and soldier termites emerge to defend the foraging termites (Bothma & Nel 1980).

Aardwolves are primarily nocturnal, although they may be active during the late afternoon, especially during the winter months (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1987a). During summer in the Northern Cape, they generally become active 30–60 min after sunset and retire to the dens 1–2 hours before dawn (Richardson 1987a). The winter pattern is more flexible, with Aardwolves on some nights retiring to the den earlier than they had left on others, with these variations being explained by ambient temperature and the activity of termites (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1985, 1987a).

A feature of *T. trinervoides* (and probably most nasute termites) is that they are very poorly pigmented and consequently cannot tolerate direct sunlight (Hewitt *et al.* 1972). They are almost entirely nocturnal (Richardson 1987a, b). By contrast, the larger harvester termites, *Hodotermes mossambicus*, are pigmented and are mainly active by day and during winter (Nel & Hewitt 1969, Hewitt *et al.* 1972). This is serendipitous for the Aardwolf, because during winter in southern Africa (May–Aug) it is frequently too cold for *T. trinervoides* to forage at night (they become inactive when air temperature drops to about 9 °C; Richardson 1987a, b), so the Aardwolf becomes more diurnal and frequently feeds on *Hodotermes* during the afternoon (Richardson 1987a). In spite of the utilization of this alternative food source, the Aardwolf consumes only one-fifth the amount of termites per month that it does outside the winter months (Richardson 1987a). This places great stress on the animals, which lose up to 20% of their body weight during winter (Richardson 1987a, b, Anderson 1994, 2004). Through winter, Aardwolves deplete their deposits of subcutaneous fat. This suggests that Aardwolves are very dependent on *Trinervitermes* and unable to feed successfully on alternative sources of food (Richardson 1987a, b). In East Africa, *T. bettonianus* is less active during the wet season (Mar–May), and the diet of the Aardwolf is more varied during this period (Kruuk & Sands 1972).

During the summer months Aardwolves foraged for significantly longer periods than in winter, but the percentage activity over the total foraging period was significantly lower (Richardson 1987a). This is because during winter, with the termites being active for a very limited period each night, Aardwolves made maximum use of the opportunity to feed and therefore did not rest during the night (Richardson 1987a). They did sometimes rest during the afternoon if they had become active earlier, but found no *Hodotermes* foraging (Richardson 1987a). More time is spent foraging on termite patches earlier in the night (Bothma & Nel 1980). Bothma & Nel (1980)

suggested that den emergence in the Namib Desert reflected the success of the previous night's foraging activities.

Aardwolves rest during the night for various lengths of time, from brief grooming bouts (30–60 sec) to 2 h 17 min (Bothma & Nel 1980). They usually cease foraging when it rains (Kruuk & Sands 1972). The sound of raindrops striking the grass may blanket termite activity and this may affect the use of sound in the location of food, or it is possible that during rain termites simply disappear underground (Kruuk & Sands 1972). At the end of the night's foraging session, Aardwolves retreat to their dens, which provide a more equable climate and protect them against the cold nights of winter and the daytime heat of summer (Anderson 1994).

As noted, Isoptera form the main portion of the Aardwolves diet: *Trinervitermes* spp. in the Namib (Bothma & Nel 1980), *Fulleritermes contractus* in SAngola (Dean 1978), *T. trinervoides* in South Africa (Bothma 1965, Cooper & Skinner 1979, Richardson 1997a), *T. rhodesiensis* in Botswana (Smithers 1971) and *T. bettonianus* in Serengeti N. P. (Kruuk & Sands 1972). Across Africa, the dominant food species is replaced by a closely related and ecologically similar member of the same termite species (Kruuk & Sands 1972). Other prey items that have been recorded in very small amounts in the Aardwolf's diet include: Coleoptera, Hymenoptera, Lepidoptera, Diptera, Dictyoptera, Odonata and Orthoptera, Arachnida and Acarina (Smithers 1971, Kruuk & Sands 1972, Kingdon 1977, Dean 1978, Cooper & Skinner 1979, Bothma & Nel 1980, Kok 1996, Matsebula *et al.* 2009, de Vries *et al.* 2011). The beetles in the scats may occupy the faeces after deposition, possibly in search of Diptera larvae (Bothma & Nel 1980). The Diptera pupae are not indicative of carrion consumption and are probably the result of post-deposition fly breeding (Cooper & Skinner 1979). Aardwolf hairs identified in the stomachs of several individuals are probably ingested during grooming (Cooper & Skinner 1979, Kok 1996).

Trinervitermes termites are small, so the Aardwolf's method of feeding results in the simultaneous ingestion of large amounts of debris, indigestible soil and vegetable matter (Kruuk & Sands 1972, Dean 1978, Kok 1996). The sand content of faeces may vary from negligible amounts to 40% in very sandy areas (Cooper & Skinner 1979, Bothma & Nel 1980), or when termites are unavailable (Richardson 1985). Smithers (1971) noted that the stomach contents of three Aardwolves contained 15%, 30% and 31% of indigestible matter including sand. In a study on Aardwolves in the Namib Desert it was found that sand formed 42.4–65.5% of the total dry faecal mass, while plant material formed 3.1% of the total dry organic mass (Bothma & Nel 1980).

Unconfirmed reports of Aardwolves eating lambs, carrion, eggs (even Ostrich *Struthio camelus* eggs), small rodents and reptiles (Sclater 1900, Shortridge 1934, Maberly 1960) are not substantiated by studies of gut or faecal contents and probably result from mistaken identity (cf. Cooper & Skinner 1979, Richardson 1987a, b), with the statements probably referring to hyaenas and/or jackals (Kruuk & Sands 1972). Although Bothma (1965) found that 80% of the contents of one Aardwolf stomach was carrion, in addition to the remains of a rodent and some small pieces of tortoise shell, it is possible that this specimen was a misidentified Black-backed Jackal. The reports of Aardwolves scavenging on carrion (Sclater 1900) are probably the result of Aardwolves feeding on maggots and carrion insects on the carcass, which the Aardwolf will eat when food is scarce (Cooper & Skinner 1979).

Aardwolves occasionally feed on termitaria opened by Aardvarks, especially during the winter months when food is scarce (Kingdon 1977, Bothma & Nel 1980, Taylor & Skinner 2000, M. D. Anderson pers. obs.).

Aardwolves are generally independent of surface water as they get all their water requirements from termites (Skinner & Chimimba 2005). However, during prolonged cold spells during winter, when termites are not active, Aardwolves may walk long distances in search of water. This is the only time of year when they have been observed to drink (Richardson 1985).

Social and Reproductive Behaviour Aardwolves are socially monogamous, with a mated pair occupying a perennial territory with their most recent offspring. Although usually seen singly, pairs and small aggregations of Aardwolves have been reported foraging together (Roberts 1951, Smithers 1971, Kingdon 1977). There are observations during winter of Aardwolves from the same territory coming together in a loose 'colony', spread over 100 m or more, to feed on the harvester termite, *H. mossambicus* (Skinner & Chimimba 2005); however, the reported aggregations of larger numbers (up to 14 individuals; Roberts 1951) is disputed. Usually one Aardwolf occupies a den at a time, although on occasions, especially during winter, cubs will share the den with one of their parents (Bothma & Nel 1980, Richardson 1985).

Aardwolves occupy territories that vary between 1 and 4 km², depending on the density of termite mounds (Kruuk & Sands 1972, Bothma & Nel 1980, Richardson 1985, Skinner & Van Aarde 1985). Territory maintenance is by means of overt aggression and scent-marking (Kruuk & Sands 1972, Richardson 1985, 1987b, c, Sliwa & Richardson 1998). Territory maintenance is energetically expensive (36.6% of daily energy expenditure during summer) (Williams *et al.* 1997). Territory sizes vary according to the density of *Trinervitermes* mounds, with each territory having approximately 3000 termitaria, each containing an average of 55,000 termites (Richardson 1985). The standing crop of these mounds provides approximately half the annual consumption of a family of Aardwolves, so it is presumed that these termites must have a high production/biomass ratio in order to accommodate their high predation rate (Richardson 1985, 1986, 1987a). Aardwolves avoid each other on the boundary of the range, with little overlapping of ranges (Kruuk & Sands 1972, Richardson 1990, 1991).

Paste-marking is the predominant form of communication in Aardwolves, functioning as territorial advertisements, mainly to intimidate intruders and to synchronize mating (Richardson 1985, 1990, 1991, 1993, Sliwa & Richardson 1998). Scent-marks help to maintain territorial integrity in the temporary absence of the resident Aardwolf (Richardson 1991, 1993), being used as an unambiguous cue advertising territory ownership, thereby establishing an asymmetry of contest between residents and intruders (Gosling 1982, Richardson 1990). There is a higher density of scent-marks in smaller Aardwolf territories, possibly because the smaller territories have a higher density of resources and, as such, attract the highest intruder pressure (Richardson 1991).

When scent-marking, Aardwolves straddle a single grass stalk, then rapidly crouch while everting the anal pouch and wiping a smear of secretion, ca. 6 mm in length, onto the grass (Kruuk & Sands 1972, Nel & Bothma 1983, Richardson 1985, 1990). The secretion colour varies and this is related to age, sex and mating season (Stoeckelhuber

et al. 2000). The colour of the male secretion is dark brown to bluish-black while the female secretion is orange, greenish to light, or dark brown (Sliwa 1996). The different scent-mark colours may have a communicatory function (Stoeckelhuber *et al.* 2000), but as Aardwolves are primarily nocturnal and the scent marks soon oxidize to a black colour (Apps *et al.* 1989b), a visual stimulus is unlikely (Stoeckelhuber

et al. 2000). The chemical properties of the Aardwolf scent-mark have been described by Apps *et al.* (1989b).

Scent-marking is observed from an early age, with the young animals having a yellowish-translucent (2 months) to light brown (4–5 months) secretion colour (Sliwa 1996). Both sexes scent-mark, although ♂♂ tend to paste more frequently than ♀♀, at mean

Aardwolf *Proteles cristatus*.

intervals between scent-marks of ca. 1 min (Kruuk & Sands 1972). Scent-marking rates do not differ significantly between the sexes (Sliwa 1996). Territorial marking by male Aardwolves plays an important role in the defence of access to their ♀♀ and food resources, while ♀♀ defend feeding territories only (Stoesselhuber *et al.* 2000). Scent-marking plays an important role in the mating season in both sexes (Sliwa 1996, Sliwa & Richardson 1998); however, during the three-month mating season territorial borders are frequently trespassed by both sexes, especially before and during female oestrus (Sliwa & Richardson 1998). Aardwolves scent-mark in neighbouring territories in order to advertise their presence to the resident pair to initiate extra-pair copulations (Richardson 1987c, Sliwa 1996). Pastings are concentrated along the territory boundary and at dens and middens (Kruuk & Sands 1972, Richardson 1987c). Richardson (1985, 1987b) believed this behaviour to be related to territoriality and mate acquisition. Male and female Aardwolves overmark more frequently, change their dens more often and increase their scent-marking rate more when they encounter scent marks of same-sex individuals than opposite-sex individuals, except during the mating season (Sliwa & Richardson 1998). Along territorial borders and at middens, marks are sniffed at for shorter periods and overmarked, with overmarking seeming to assert territorial ownership (Sliwa & Richardson 1998). Aardwolves seldom overmark scent-marks at dens and sniff at them longer, often showing flehmen (Sliwa & Richardson 1998). After locating a neighbour's scent-mark, the resident Aardwolf usually increases its rate of marking and often moves directly to the respective border, demonstrating individual scent-mark recognition (Sliwa & Richardson 1998). This has been confirmed by the different chemical properties of different individual's scent-marks (Apps *et al.* 1989b). Nel & Bothma (1983) reported that in the Namib Desert the Aardwolf makes a second type of pasting in which a very small spot of secretion is deposited; apparently this is related to advertising areas that have been traversed while feeding. This form of pasting has not been recorded elsewhere (Kruuk & Sands 1972, Richardson 1987c, Sliwa 1996).

Upon emergence from a den, Aardwolves either start feeding immediately, scent-mark, or run rapidly to a midden and defecate, and then start feeding or marking (Bothma & Nel 1980). Aardwolves defecate mainly at middens, although they sometimes defecate at random (Kruuk & Sands 1972, Nel & Bothma 1983, Richardson 1985, Koehler & Richardson 1990). Middens are usually 1–2 m in diameter and often are made up of soft, bare sand from frequent digging by the Aardwolves. There may be as many as 20 middens located throughout the territory, but those near the territory boundary seem to be used more frequently (Kruuk & Sands 1972, Richardson 1985, 1990). Up to four middens are used in a territory at one time (Kruuk & Sands 1972). To defecate, a narrow trench is dug with alternating strokes of the forepaws, after which the animal turns around and squats over the trench. The expulsion of the faeces during feeding involves considerable straining (Kruuk & Sands 1972). After defecating the equivalent of one-tenth of its body weight (Kruuk & Sands 1972, Richardson 1990), it scratches the hole closed with its forepaws and moves off (Richardson 1990). Subsequent defecations through the night are smaller. After defecating the Aardwolf usually deposits a few scent-marks before leaving (Richardson 1985, Koehler & Richardson 1990). Aardwolves always urinate in the same hole used for defecating. However, when termites are abundant they

may urinate 5–6 times per night, and simply stop foraging, squat, urinate and then continue foraging (Richardson 1985).

Fresh Aardwolf faeces carry a smell reminiscent of the smell of termites, possibly undigested defence secretions of the soldier termites, and so it is an advantage to concentrate the faeces in middens (Kruuk & Sands 1972, Richardson 1985, 1987a, b, 1990). If scent plays a role in food location, it would be confusing during foraging for the animal to encounter its own faeces (Kruuk & Sands 1972). The middens may also facilitate the decomposition of the dung, as, in East Africa, they contain large numbers of the termite *Macrotermes virescens* (Kruuk & Sands 1972). The middens may also have a territorial function (Richardson 1990, 1991).

Aardwolves will fiercely defend their territories and interactions can result in aggressive altercations. When territorial intruders are detected the resident immediately raises its mane of hair and chases the intruder, usually right to the territory border (Richardson 1985). If an intruder is caught, both animals fall to the ground and bite each other's necks while resting on their carpals (Richardson 1985, Koehler & Richardson 1990). Although the cheekteeth are small and redundant, the canines are well developed and the Aardwolf is capable of inflicting a severe bite (Ewer 1973, Skinner & Chimimba 2005). These anatomical features have almost certainly been retained for fighting (Ewer 1973), as Aardwolves have very aggressive territorial disputes and frequently chase jackals from their breeding dens (Richardson 1985). The use of canines in fighting is reflected clearly in their wear, as in old animals they are broken down to rounded stumps (Richardson 1985, Koehler & Richardson 1990). Generally, however, if another Aardwolf from the same territory is encountered during a foraging bout, both individuals raise the mane of hair along the back as they slowly approach each other (Skinner & Chimimba 2005). Once the other individual is recognized the hair is lowered and they pass by each other without any further greeting (Skinner & Chimimba 2005). Occasionally, particularly in a greeting between a mother and her cubs, the two individuals may sniff each other's noses briefly before separating (Koehler & Richardson 1990, Richardson 1995). Although it is quite widely reported that the Aardwolf ejects the contents of its anal gland as a form of defence when attacked or when it is stressed (Roberts 1951, Smithers 1971), the secretions are not noxious (Kingdon 1977), and such behaviour has not been confirmed.

Although the mated pair occupies the same territory throughout the year, copulations are not necessarily exclusive within the pair (Richardson 1987c, Richardson & Coetsee 1988, Koehler & Richardson 1990, Sliwa 1996). Extra-pair copulations regularly occur between the most aggressive ♂♂ and ♀♀ of less aggressive neighbours (Richardson 1987c). Access is gained to ♀♀ in neighbouring territories by rigorous scent-marking of the adjacent territory during the prooestrous period of the ♀ and then by defeating the resident ♂ in a fight (Richardson 1987c, Sliwa & Richardson 1998). Cuckoldry has evolutionary implications, especially as paternal care, guarding of the cubs from jackals, is energetically expensive and ♂♂ may not have a genetic investment in this generation. Females may accept extra-pair copulations after mating with the resident ♂ (Richardson 1987c, Richardson & Coetsee 1988), possibly resulting in mixed paternity (P. R. K. Richardson pers. comm.). The cuckolded ♂ may then guard the cubs, unless he has the rare opportunity of a ♀ with whom he can breed exclusively. He may desert his promiscuous ♀ to mate with an alternative ♀ (Richardson & Coetsee 1988).

Cubs are born and raised in dens, from which they emerge after about one month. From 4–6 weeks of age they play around the den for short periods when adults are present. From 6–9 weeks they venture further afield to play, but usually remain within 30 m of the den. From 9–12 weeks they may go foraging with an adult and start feeding on termites, but usually remain within 100 m of the den. From 12 weeks to four months, they may forage throughout the territory, but are usually accompanied by a parent. Cubs are weaned at the end of this period. Males help in rearing the young by guarding the den against Black-backed Jackals. Paternal care varies, but during the first two months some fathers may spend up to 6 h/night guarding the cubs while the ♀ is away foraging (Richardson 1985, 1987b, Richardson & Coetzee 1988). The cubs may still be accompanied by a parent for a short period of the night up to seven months of age, but thereafter forage alone. At about one year old the cubs make excursions into neighbouring territories and generally have left the territory by the time the next year's cubs have emerged from the den. Once they have finally left their natal territory, cubs seldom return, becoming transients in a search of vacant territories elsewhere in the region. There is one record of an Aardwolf moving 35.4 km three weeks after it was marked (Bothma 1971b). If a parent dies, a cub of the same sex usually remains in its natal territory (Richardson 1985, 1987c).

Although generally silent, the Aardwolf utters a number of different sounds (Kingdon 1977, Koehler & Richardson 1990, Estes 1991). Although it relies mainly on olfactory communication, it uses diverse acoustic signals (nine sound types) when interacting with conspecifics at close and medium range (Peters & Sliwa 1997). The acoustic signal repertoire is very different to that of the closely related hyaenas. The Aardwolf lacks long-range vocalizations (Peters & Sliwa 1997). Vocalizations during agonistic interactions are most diverse (Peters & Sliwa 1997). Peters & Sliwa (1997) have described the Aardwolf's various vocalizations as: Purring, Whine, Jaw Click, Lip Smack, Growl, Snarl, Bark, Squeal and Whizzing Sound. The Aardwolf is particularly vociferous when under stress, varying from a soft, clucking sound, to a deep-throated growl. During fights or when suddenly surprised Aardwolves may give a surprisingly loud and explosive roar (Smithers 1971, Richardson 1985, Koehler & Richardson 1990, Estes 1991). The cubs are said to make a clicking sound very much like the warning clicks of termites (Bartlett & Bartlett 1967).

As noted earlier, the Aardwolf has been observed to chase Black-backed Jackals from their breeding dens (Richardson 1985, 1987c, Richardson & Coetzee 1988), possibly using their well-developed canines during aggressive encounters. No aggression was observed between Aardwolves and Bat-eared Foxes that foraged 10 m apart (Bothma & Nel 1980). An Aardwolf and two Cape Foxes *Vulpes chama* were once observed chasing each other, but this was thought to be in the context of play, as immediately afterwards the foxes continued chasing one another (Bothma & Nel 1980). Associative feeding has been observed between Aardwolves and Southern Anteater-chats *Myrmecocichla formicivora* (Anderson 1992) and between Aardwolves and Aardvarks (Taylor & Skinner 2000). On one occasion, an Aardvark and an Aardwolf fed simultaneously from the same excavated termitarium, with no antagonistic interactions between the two individuals (Taylor & Skinner 2000).

Reproduction and Population Structure In the Northern Cape, ♀♀ come into proestrus during the last weeks of Jun

(Koehler & Richardson 1990). Mating usually takes place during the last days of Jun and the first two weeks of Jul (Koehler & Richardson 1990, Sliwa 1996). Copulation may last from 1 to 4 hours, with ejaculation, indicated by pelvic thrusting and tail bobbing, occurring after 1 hour and again at approximately hourly intervals (Koehler & Richardson 1990). There is no bulbus glandis (Wells 1968) and thus no copulatory tie (Koehler & Richardson 1990). Females remain receptive for 1–3 days, but normally are not receptive after a copulation lasting >3 hours (Koehler & Richardson 1990), although A. Sliwa (pers. comm.) saw ♀♀ copulate repeatedly after previous 3-hour copulations. A ♀ will recycle if she is not fertilized (Richardson 1985, 1987c). The gestation period is approximately 90 days (Koehler & Richardson 1990), not 60 days as suggested by Richardson (1985). In South Africa the young are born from Oct to Dec (Shortridge 1934, Stuart 1981, Richardson 1985), although with warmer winters further north in Botswana and Zimbabwe, the breeding season seems to be less restricted, as gravid ♀♀ have been found in May, with others lactating in Apr (Smithers 1971, Skinner & Chimimba 2005).

Most litters have 2–4 young, usually three (Roberts 1951), but litters of five have apparently been recorded in zoos (Koehler & Richardson 1990, Skinner & Chimimba 2005). The birth-weight and size of the cubs are not known, although an emaciated 25-day-old cub weighed 350 g (Spinelli 1970). The cubs are born with their eyes open (Meltzer 1993). Asymptotic growth rate is approached by 1.8 years, but may be reached as early as 3–6 months in some individuals (Van Jaarsveld *et al.* 1995). Maximum growth rate is achieved at three months of age (Van Jaarsveld *et al.* 1995). The daily food intake of captive Aardwolf cubs is about 18–20% of their body mass (Meltzer 1993). Litters are born annually.

The Aardwolf has an above average weight and a below average age of maturity (Van Jaarsveld *et al.* 1995). They reach final weight before sexual maturity, an uncharacteristic feature for mammalian species (Van Jaarsveld *et al.* 1995). Aardwolves tend towards an iteroparous life-style, which serves to reduce juvenile mortality. However, species-specific constraints do not allow it to pursue this strategy by maximizing growth rate. Instead, growth is sustained using an extended lactation period and intensive parental care to enable final body size to be reached as soon as possible (Van Jaarsveld *et al.* 1995).

Richardson (1985, 1987b) found that between 1981 and 1984 the survival rates of cubs up to the age of 12 months in the Northern Cape was 68%. However, most of this recorded mortality was during the height of the drought in 1984 when 55% of the cubs died during winter. Record longevity in captivity is about 20 years (Weigl 2005).

Predators, Parasites and Diseases The Aardwolf is probably prone to predation by most large carnivores. However, in the small-stock farming areas of South Africa, where Lions *Panthera leo* and other large carnivores no longer occur, the Black-backed Jackal is probably the only important predator of Aardwolf cubs (Richardson 1985). Although the Aardwolf shares its habitat with many other termite-eating animals, the variety of their feeding habits and specializations reduces competition between them (Kruuk & Sands 1972).

Little information is known on the parasites carried by Aardwolves (Koehler & Richardson 1990). Although intra-erythrocytic piroplasms have been identified from the blood of free-ranging Aardwolves, the collected material was not adequate to identify the parasites to species

(or even genus) level, although they were suspected to be a new species of *Babesia* (Peirce *et al.* 2001). The vectors for the above haematozoa have not been identified; however, three species of ticks that have been collected from Aardwolves are possibilities: *Haemaphysalis spinulosa* (Peirce *et al.* 2001) and *H. zumpti* and *H. leachi/zumpti* (Horak *et al.* 2000). *Felicola intermedius intermedius* and *F. i. hyaenae* (Mallophaga) have been only found on the Aardwolf and Brown Hyaena *Hyaena brunnea*, respectively (Hopkins 1960, Ledger 1968). Although most species of *Babesia* are host-specific, it is not known whether babesiosis could be transmitted from Aardwolves to other carnivores, such as domestic dogs. Blood from a pet Aardwolf with babesiosis was inoculated into a splenectomized dog and cat, but no parasitaemia developed (B. L. Penzhorn pers. comm., Peirce *et al.* 2001). There is no evidence from free-ranging Aardwolves that the haematozoan causes any morbidity; however, under certain conditions (such as with the pet Aardwolf), clinical piroplasmiasis may occur (Peirce *et al.* 2001). Macchioni (1995) recorded *Ancylostoma braziliense* from an Aardwolf in Somalia, and also recorded a new species, *A. protelesis*.

Rabies and rabies-related viruses have been confirmed in specimens sampled from southern Africa (Swanepoel *et al.* 1993). The Aardwolf is reported to be susceptible to canine distemper and canine parvovirus (Meltzer 1993).

Conservation IUCN Category: Least Concern. CITES: Appendix III (Botswana).

In South Africa the Aardwolf was previously persecuted by some farmers for the mistaken belief that it was a predator of livestock, chickens and Ostrich eggs (Sclater 1900, Roberts 1951, Smithers 1966, Richardson 1984, Anderson 1988). This was based on (a) its aggressive behaviour when cornered; (b) its fierce appearance when its mane is raised and when it growls; (c) its well-developed canines; (d) the collection of livestock bones outside their burrows (generally, the remnants of those collected by Cape Porcupines); and (e) the occasional observations of Aardwolves feeding on blowfly maggots at livestock carcasses (Roberts 1951, Smithers 1971, Anderson 1988). This perception has now changed and most farmers actively conserve Aardwolves. They are, however, also the occasional inadvertent victims of problem animal control operations, especially those using gin traps (M. D. Anderson pers. obs.). Aardwolves are probably killed indiscriminately by packs of dogs used to hunt jackals and foxes (Koehler & Richardson 1990).

Loss of habitat, through urbanization and the transformation of natural habitats to agricultural lands, may be having an important negative impact. Some farmers in South Africa destroy termitaria, using a plough or poisons, and these areas then become unsuitable for Aardwolves (M. D. Anderson pers. obs.). Poisons used for termite control reduces food availability and may have an effect on Aardwolves. Aardwolves may be sensitive to some locust-control poisons, especially organochlorines and organophosphates (M. D. Anderson pers. obs., P. R. K. Richardson pers. comm.). Other mortality factors include predation by carnivores and accidental road casualties, which are not uncommon, as Aardwolves fail to move out of the way of oncoming vehicles at night (Smithers 1971, Richardson 1984, M. D. Anderson pers. obs.). Aardwolves were previously hunted with dogs for sport (Sclater 1900).

Some indigenous tribes in Africa feed on Aardwolves and also use parts of the body for medicinal purposes (Richardson 1984, Koehler

& Richardson 1990, M. D. Anderson pers. obs.), but the extent of this usage as a cause of mortality is unknown (Von Ketelhodt 1966, Richardson 1984, Anderson 1988).

Aardwolves are present in numerous well-managed protected areas across their range, and as their nocturnal and shy and retiring nature make them difficult to observe they are probably more common than usually believed (Koehler & Richardson 1990). Grassland burning and overgrazing by ungulates results in a gross increase in the population of *Trinervitermes* (Coaton 1948, Hartwig 1955), so the population of Aardwolves would thus benefit in areas where such management took place (Kruuk & Sands 1972).

Measurements

Proteles cristatus

TL (♂ ♂): 909 (840–990) mm, n = 10

TL (♀ ♀): 924 (900–970) mm, n = 5

T (♀ ♀): 245 (223–280) mm, n = 5

HF c.u. (♂ ♂): 156 (149–162) mm, n = 10

HF c.u. (♀ ♀): 151 (149–156) mm, n = 5

E (♂ ♂): 97 (90–101) mm, n = 10

E (♀ ♀): 98 (91–102) mm, n = 5

WT (♂ ♂): 8.9 (7.8–10.0) kg, n = 10

WT (♀ ♀): 8.7 (7.7–10.0) kg, n = 5

Zimbabwe (Smithers & Wilson 1979)

Anderson (1994) gave mean body mass for ♂ ♂ as 8.6 ± 1.2 kg (n = 72) and ♀ ♀ as 9.0 ± 1.2 kg (n = 64). Adult body mass varies seasonally with the availability of termites, but maintains an average of 8–12 kg (Richardson & Bearder 1984, Koehler & Richardson 1990, Van Jaarsveld *et al.* 1995). The body mass of individuals during late summer (9.6 ± 1.2 kg, n = 33; Feb, Mar and Apr) differs significantly from the body masses of individuals during mid-winter (8.4 ± 1.1 kg, n = 55; Jun–Aug) (Anderson 1994). Kingdon (1977) gave body masses of up to 14 kg in East Africa

Family HERPESTIDAE
MONGOOSES

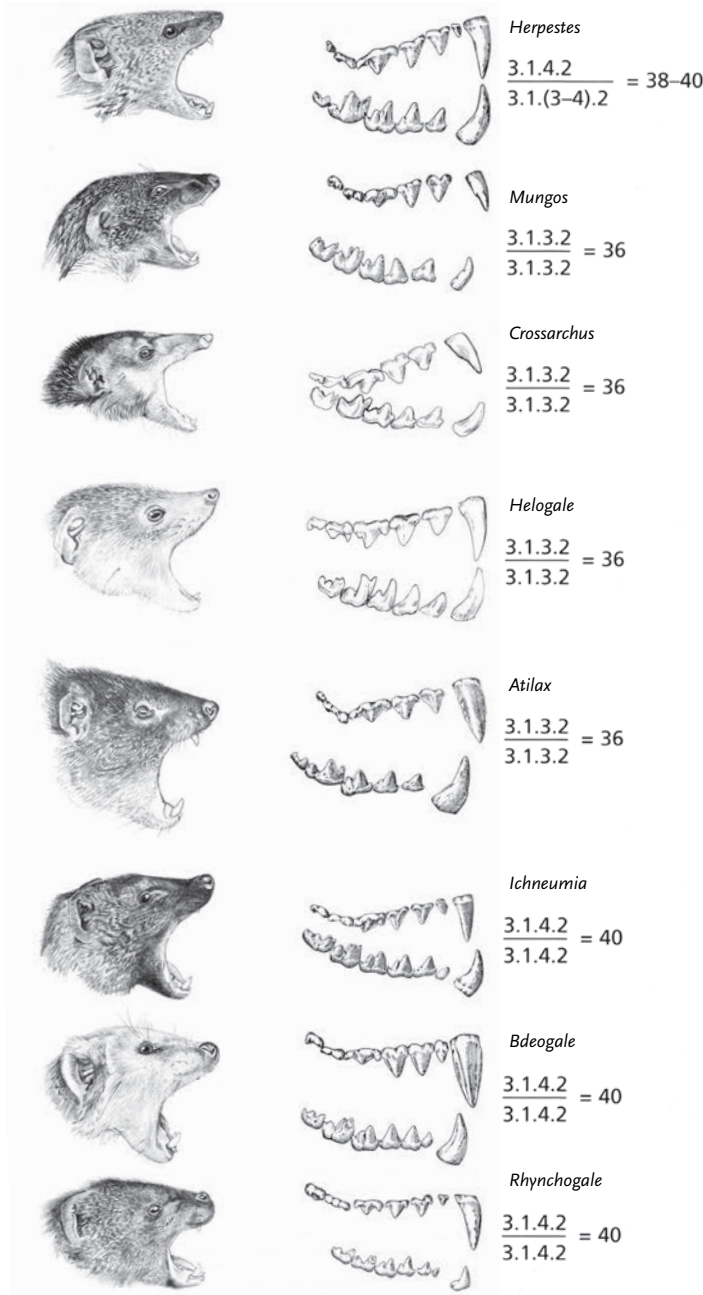

Herpestidae Bonaparte, 1845. Cat. Meth. Mamm. Europe, p. 3.

Table with 3 columns: Subfamily, Species, and Page. Rows include Herpestinae (Xenogale, Atilax, Herpestes, Bdeogale, Rhynchogale, Cynictis, Paracynictis, Ichneumia) and Mungotinae (Suricata, Mungos, Liberiictis, Dologale, Helogale, Crossarchus).

Herpestidae represent a homogeneous family of small to medium-sized carnivores. They are found almost exclusively in Africa, with only the genus Herpestes ranging into southern Europe and throughout Asia. The taxonomy of the family has long been disputed. Traditionally, the family has been held to comprise two subfamilies (Wozencraft 1993): Herpestinae (ca. 14 genera, 32 species) and the exclusively Malagasy Galidiinae (ca. four genera, five species) (see, for example, Wozencraft 1993), with herpestines occasionally being further subdivided into two groups, Herpestinae and Mungotinae, each being accorded subfamilial status together with Galidiinae (e.g. Wozencraft 1989a). However, molecular findings seriously challenge the inclusion of Galidiinae in the family (see below).

Together with the family Viverridae, Herpestidae strongly resemble the putative ancestor of the Carnivora as represented by Miacoidea. Both families tend to have long, slender body plans with relatively short legs, and skulls that are somewhat elongate in the facial region. Herpestids are distinguished from viverrids by the more complex morphology of their anal scent glands, a relatively shorter tail (only one-half to three-quarters of body length), more uniform coat colouration, non-retractile claws, rounded pinnae that protrude only slightly from the head, slightly less elongate and more robust skull, and largely terrestrial habitat.

Herpestids range in size from the Dwarf Mongoose Helogale parvula (average values: head and body length 250 mm, tail length 190 mm, weight 0.25 kg) to the White-tailed Mongoose Ichneumia albicauda (average values: head and body length 680 mm, tail length 442 mm, weight to 5.52 kg). Extralimital specimens can exceed these values. Sexual dimorphism, when apparent, is minimal, with males being slightly larger than females. Males possess a baculum; females have two or three pairs of abdominal nipples. Pelage colour tends to be uniform and generally grizzled, with banding (e.g. Banded Mongoose Mungos mungo and Meerkat Suricata suricatta) being present in very few species (Ortolani 1999). Differential tail colouration, tail tip patterning and eye contouring and patches are similarly limited (Ortolani 1999). The dental formula for the family is I 3/3, C 1/1,

A key to dental formulae for some major mongoose genera.

PM 3-4/3-4, M 2/2 = 36-40, with the carnassial teeth developed, but the canine teeth relatively small. The general form of the teeth varies according to the diet (e.g. omnivory, insectivory). In particular, the carnassial teeth are better developed in the more carnivorous species. Karyological investigations of the family date back to the pioneering work of Karl Fredga (Fredga 1972). Diploid numbers in the family range from 2n = 36 (the most common) to 2n = 40, 42 or 44, with the changes in number being easily accounted for through centric fission or fusion events. Of more note is that Marsh

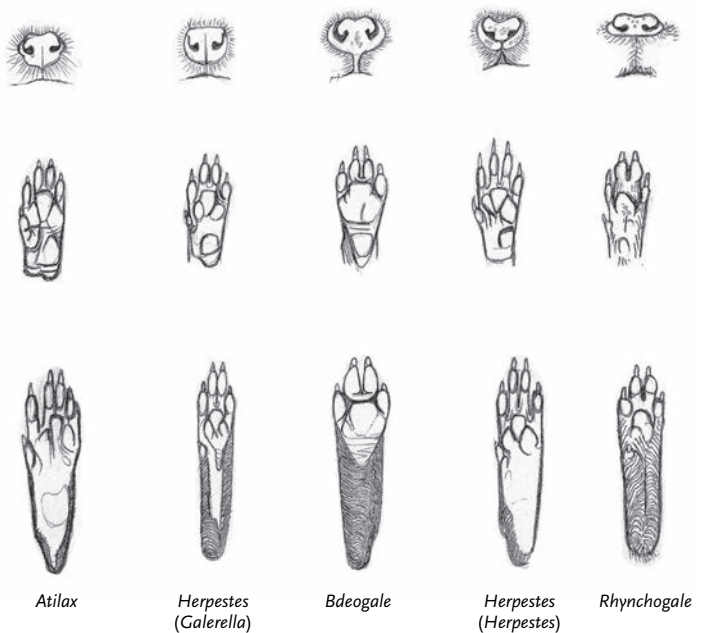

Tentative phylogenetic tree for African Herpestidae (after Patou *et al.* 2009).

Mongoose *Atilax paludinosus* and various species of *Herpestes* possess a 'pseudo-XO-XX' sex-chromosome mechanism, whereby the functional Y-chromosome has been translocated to an autosome (as such, diploid numbers in these species are better represented as $2n = 35/36$, for example.) This feature is unique among carnivores and Fredga (1972) gave two evolutionary scenarios as to its possible origin: 1) a shared derived feature uniting the species in question, or 2) the trait being ancestral for the family, with the typical condition of a separate Y-chromosome being regained by the remaining species. Interestingly, current estimates of the phylogeny of the family (e.g. Perez *et al.* 2006, Patou *et al.* 2009) tend to support the latter, more complex scenario, indicating either multiple independent gains of the trait or its acquisition and subsequent loss. Fredga (1972) concluded that the chromosomal data supported recognition of herpestids, commonly subsumed within Viverridae at the time, as a distinct family.

Herpestids are small opportunistic omnivores, with small vertebrates, insects and other invertebrates constituting the bulk of the diet. They occur in all major habitat types on the African continent, from forests to open woodland, savanna, semi-desert and desert. Unlike many other small carnivores, about half of all species live in pairs or small social groups (notably Dwarf Mongooses, Banded Mongooses and Meerkats). *Herpestes* spp. tend to be uniformly solitary. Social species tend to be diurnal. More species are diurnal than not, in contrast to viverrids, which are almost exclusively nocturnal or crepuscular.

The fossil history of herpestids is cogently summarized by Hunt (1996). Fossil evidence is sparse, with the best records being from Plio-Pleistocene deposits of Africa, mostly the East African Rift

Herpestid noses and fore- and hindfeet.

Valley and South Africa. The first 'modern' herpestid morphotype in Africa (referred to *Galerella sanguinea* = *Herpestes sanguineus*) dates to the late Miocene (7 mya; Peigné *et al.* 2005). The earliest putative herpestid is from the early Miocene deposits at Rusinga and Songhor in Kenya and Uganda (20–18 mya), with many authorities recognizing *Leptoplesictis* from the Rusinga site as being the first definite herpestid. *Leptoplesictis* also comprises the first European herpestid, dating from the middle Miocene. However, the known material for *Leptoplesictis* is admittedly fragmentary (some tooth and mandible fragments) and it cannot be ruled out that the observed similarities with true herpestids comprise primitive (plesiomorphic) features only. In any case, the diversity of the fauna at this time argues for an arrival before the earliest record at ca. 20 mya. It is thought that Herpestidae originated in and emigrated from southern Asia, although fossil herpestid remains are unknown in Asia before the late Miocene. This was followed by an early Miocene migration into Africa from Europe (Hunt 1996). Today, most Herpestidae are located in Africa proper, with *Herpestes* extending significantly back into Asia and Europe.

The phylogenetic relationships of Herpestidae have long been contentious. Most importantly, molecular evidence strongly suggests that Herpestidae as traditionally delineated (see Wozencraft 1993) is paraphyletic, with all the Malagasy carnivores (i.e. the traditional herpestid subfamily Galidiinae and those genera traditionally assigned to Viverridae: *Cryptoprocta*, *Eupleres* and *Fossa*) forming a monophyletic clade within the group (Yoder *et al.* 2003, Flynn *et al.* 2005). This supports earlier suggestions that the enigmatic Malagasy Fossa *Cryptoprocta ferox* is closely related to herpestids, possibly forming a monotypic subfamily (Veron & Catzeflis 1993, Veron 1995). The recent tendency has been to place all the Malagasy carnivores in their own family (Eupleridae; see Wozencraft 2005), which forms the sister group to the redefined Herpestidae (= the traditional Herpestinae). As noted earlier, the family is sometimes (e.g. Wozencraft 1989a) broken down further into two subfamilies: the larger, mainly solitary Herpestinae (*Atilax*,

Xenogale, *Herpestes*, *Bdeogale*, *Cynictis*, *Paracynictis*, *Rhynchogale*, and *Ichneumia*) and Mungotinae for the social species (*Crossarchus*, *Helogale*, *Dologale*, *Liberiictis*, *Mungos* and *Suricata*). Recent molecular work (Veron *et al.* 2004, Perez *et al.* 2006, Patou *et al.* 2009), in particular, appears to support this split. Molecular studies also reveal that *Herpestes* is likely polyphyletic and might need to be restricted taxonomically to only the Egyptian Mongoose *Herpestes ichneumon* (Patou *et al.* 2009).

Within the clade of feliform ('cat-like') carnivores, herpestids have been linked traditionally with viverrids, often as a subfamily of the latter. However, such a placement was typically assumed rather than tested directly, and few primary studies provide strong evidence for such a pairing (see Wozencraft 1989b, although see Radinsky 1975a, Wayne *et al.* 1989a). Instead, both morphological and molecular evidence advocates a sister group relationship with

the Malagasy euplerids and then with hyaenids (Hunt 1987, Veron & Catzeflis 1993, Werdelin 1996a, Flynn & Nedbal 1998, Yoder *et al.* 2003, Flynn *et al.* 2005, Eizirik *et al.* 2010).

Together with Galidiinae, Herpestidae is typified by phenotypic characters such as the absence of a marker chromosome, the structure of the anal glands and presence of a storage pouch located outside the anus proper, and numerous features associated with the auditory bulla and surrounding area (Wozencraft 1989b, Hunt 1996). However, in light of recent phylogenetic evidence, these characters must be regarded as being primitive. Instead, features distinguishing Herpestidae from their close relatives include their more uniform coat colouration, the lack of ear bursae on the lateral margins of the ear flap, and the lack of perineal glands.

Olaf R. P. Bininda-Emonds

Subfamily HERPESTINAE – Solitary Mongooses

Herpestinae Bonaparte, 1845. Cat. Meth. Mamm. Europe, p. 3.

Subfamily Herpestinae includes the larger, mainly solitary, mongooses of the genera *Atilax*, *Xenogale*, *Herpestes*, *Bdeogale*, *Cynictis*, *Paracynictis*, *Rhynchogale* and *Ichneumia*.

GENUS *Xenogale*

Long-nosed Mongoose

Xenogale J. A. Allen, 1919. J. Mammal. 1: 26, 28.

The genus contains only one species, the Long-nosed Mongoose (3–4 kg), which is restricted to equatorial rainforests from Gabon through the Congo basin to DR Congo. On the basis of cranial and external differences, Gregory & Hellman (1939), Simpson (1945) and Orts (1970) retained the genus *Xenogale*, used by Allen (1924), for this species, followed by Rosevear (1974) and Colyn & Van Rompaey (1994a). However, because these differences are no greater than those between the geno-typical Egyptian Mongoose *Herpestes*

ichneumon and several Asiatic *Herpestes* species, Wozencraft (1993, 2005) included *naso* under *Herpestes* in order to avoid paraphyly. The results of genetic studies (Veron *et al.* 2004, Perez *et al.* 2006, Patou *et al.* 2009) reveal an association between *X. naso* and *Atilax*, suggesting that its placement in *Herpestes* has to be reconsidered. Consequently, the species is here returned to the genus *Xenogale*.

Harry Van Rompaey & Marc Colyn

Xenogale naso LONG-NOSED MONGOOSE (LONG-SNOUTED MONGOOSE)

Fr. Mangouste à long museau; Ger. Langnasenichneumon

Herpestes naso De Winton, 1901. Bull. Liverpool Mus. 3: 35. Cameroon River, West Africa [Cameroon].

Lateral view of skull of Long-nosed Mongoose *Xenogale naso*.

Taxonomy Monotypic. Taxonomic status confused, due in large part to ongoing revision of the genus *Herpestes*, but here retained in genus *Xenogale* following Colyn & Van Rompaey (1994a). The species has occasionally been treated as a subspecies of *Atilax* and *Ichneumia*. Synonyms: *almodovari*, *nigerianus*, *microdon*. Chromosome number: not known.

Description A large, long-muzzled, dark-coloured mongoose. Muzzle long with very short, dark brown hairs up to the eyes; rhinarium black. Iris very dark brown. Ears round, broad, low-set and finely haired. Cheeks, forehead and neck greyish and more grizzled than body. Chin with very short, speckled hairs. Throat with longer,

Long-nosed Mongoose *Xenogale naso*.

forwardly directed hairs. Dorsal pelage long, rough, glossy brownish-black, speckled with yellow to orange. Dorsal hairs 50–60 mm long, irregularly ringed with pale and dark zones. Underfur greyish-brown to orange-brown; the fine hairs are 10–15 mm long with a pale tip. Ventral pelage sparser and paler. Fore- and hindlimbs deep brown to black. Digits webbed. Underparts of fore- and hindfeet fully haired up to the pads. Tail long-haired and tapered, coloured as back. Sexes similar in colour. Males slightly larger than ♀♀. Nipple numbers not recorded.

The rear part of the braincase is less horizontal than in the Egyptian Mongoose and the nasal bones are slightly concave, whereas in the Egyptian Mongoose they form a straight line or are slightly convex. The rostrum of the Long-nosed Mongoose is relatively longer (ratio CBL/ROL in *H. ichneumon*: 3.8 [3.6–4.2], $n = 50$; *X. naso*: 2.9 [2.7–3.2], $n = 42$) and broader (ratio CBL/ROB in *H. ichneumon*: 5.2 [4.8–5.6], $n = 47$; *X. naso*: 4.0 [3.8–4.3], $n = 40$) than that of the Egyptian Mongoose. In addition, the interorbital breadth in the Long-nosed Mongoose is relatively wider (ratio CBL/IOB in *H. ichneumon*: 6.1 [5.4–6.7], $n = 45$; *X. naso*: 5.1 [4.5–5.8], $n = 38$) than in the Egyptian Mongoose (H. Van Rompaey pers. obs.).

The dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$. The Long-nosed Mongoose is distinguished from *Herpestes* species by teeth characters: an extra posterior-lingual cusp on P_4 , a longer M_1 talonid, and large M^2 and M_2 (Barry 1983). Orts (1970) and Rosevear (1974) remarked on the significant differences of proportion in comparison with the Egyptian Mongoose.

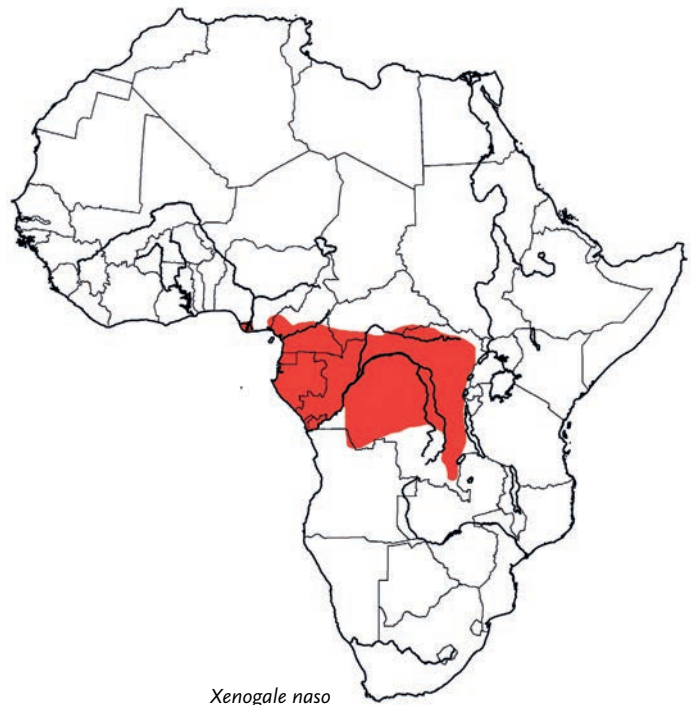

Geographic Variation Examination of a large number of specimens ($n = 103$) shows that the species is geographically more evenly distributed than previously thought and that none of the three described subspecies, *X. n. naso*, *X. n. almodovari* and *X. n. microdon*, can be characterized by any specific cranial character (Colyn & Van Rompaey 1994a).

Similar Species

Atilax paludinosus. Sympatric in western and central Africa. Hindfoot plantar surface naked; feet unwebbed; snout shorter; tail shorter; and dentition more massive.

Crossarchus spp. Smaller with legs much shorter; tail shorter; pelage shaggy; more grizzled and speckled; social, and group-living.

Distribution Endemic to Africa, ranging from the Cross R. in SE Nigeria through the central African forest block eastward to

*Xenogale naso*

Cameroon and Central African Republic and southward to Gabon, Equatorial Guinea, Congo and DR Congo to ca. $10^{\circ} 30' S$. In 1994, what is probably a relic population was discovered in the Niger Delta, Nigeria, approximately 200 km west of the Cross R. (Colyn & Van Rompaey 1994a, Angelici *et al.* 1999b) and a specimen was recovered being sold as bushmeat in Ibeno, just west of the Cross R. (Angelici *et al.* 1999c). Wozencraft (1993, 2005) gives the species as occurring in Kenya, Niger and Tanzania, but there are no museum records or literature to corroborate this statement; Niger may be a lapsus for Nigeria.

Habitat Occurs in forest near swampy places or near streams and stream-beds (Bates 1905, Ray 1995a, 1997). Found in bare parts of the forest floor in recesses of the high deciduous forest in Cameroon (Sanderson 1940). In Dzanga-Sangha Reserve, Central African Republic, they prefer the dense and tangled understorey in forest, avoiding the very open understoreys of the stands of mono-dominant *Gilbertiodendron dewevrei* forest (Ray 1995a, 1997). At least sometimes forages (on dark nights) more than 50 m from the forest edge on open, recently burnt, grassland (T. M. Butynski pers. comm.). Collected from sea level to 600 m (Eisentraut 1963), and observed at 640 m altitude in N DR Congo (T. M. Butynski pers. comm.).

Abundance In SW Central African Republic, the Long-nosed Mongoose is the numerically dominant small carnivore, possibly by virtue of its sole occupancy of the diurnal, terrestrial, predominantly insectivorous niche (Ray 2001). Bates (1905) noted that this species was the small animal most frequently killed by hunters in S Cameroon. In other areas, they are not as abundant relative to other forest carnivores (especially *Crossarchus* spp.), and they are rare in the Niger Delta.

Adaptations Although terrestrial, a semi-captive, subadult female specimen climbed onto chairs and shelves, and tried to climb up

table legs by wrapping limbs around them and 'shimmying up' (Van Rompaey & Powell 1999). When nervous or afraid, the tail fur is erected, showing the pale colour of the underfur.

Although several authors (Rosevear 1974, Depierre & Vivien 1992) state that the Long-nosed Mongoose is nocturnal, data on captive and radio-collared individuals seem to indicate that it is diurnal. In SW Central African Republic, they are strictly diurnal with peak movements at midday (12:00h) but otherwise with little variation, except for smaller peaks at 08:00h and 15:00h (Ray 1995a, 1997). A semi-captive, subadult female specimen was mainly diurnal with sleeping spells during the day (Van Rompaey & Powell 1999). One foraging adult was observed two hours after dark on a moonless night in N DR Congo (T. M. Butynski pers. comm.).

Foraging and Food Omnivorous. In the Niger Delta, Nigeria, stomachs ($n = 2$) contained a centipede, a snail and some remains of fruits and berries (F. M. Angelici pers. comm.). In Dzanga-Sangha, 91% of 346 scats contained arthropods (mostly beetles and orthopterans, followed by termites, ants and millipedes), 52% held mammalian prey (mostly shrews and rodents, occasionally bats [Hutterer & Ray 1997]), 8% anurans, 8% snakes, 4% lizards and skinks, 8% fruit (at least 18 species), 7% birds and 0.3% fish (Ray 1996, 1997, Ray & Sunquist 2001). A high incidence of shrews was notable in the diet (which were almost as frequently consumed as small rodents). Several rodent species were selectively preyed upon in closed and structurally complex micro-habitats (Ray 1998). Mammal prey of more than 5 kg is rarely taken; Blue Duiker *Philantomba monticola* were the most common large prey found in scats (Ray 1996, 1997). They are said to eat crabs (Bates 1905).

As for several other species of mongooses (Banded Mongoose *Mungos mungo*, Gambian Mongoose *M. gambianus*, White-tailed Mongoose *Ichneumia albicauda*, Marsh Mongoose *Atilax paludinosus*), the Long-nosed Mongoose carries hard prey (such as snails) to a favourite spot where it breaks them against a tree or rock by throwing them backwards through the hindlegs with the forefeet. Vernacular names in the Niger Delta ('Norgbene' and 'Lalabene') translate as 'snail breaker' (Van Rompaey & Powell 1999).

Social and Reproductive Behaviour Usually solitary, sometimes in pairs. Home-ranges of 48 ha and 8 ha were estimated for two adult ♂♂, and 41 ha for a subadult ♂ (Ray 1995a, 1997). Mean distance travelled per 30 min during daylight hours by these three ♂♂ was 92 m ($n = 309$). During two 24-hour follows, one individual covered 2324 m (71% of its home-range) and another covered 4605 m (29% of its home-range) (Ray 1997). Night-time resting places are never in the same spot, and there is no evidence for latrine-use (Ray 1997).

A captive specimen was at all times perfectly silent (De Winton 1901). In the wild, loud, repetitive snarling chatter vocalizations are given during aggressive interactions between ♂♂ (J. C. Ray pers. comm.).

Reproduction and Population Structure A juvenile of ca. 2–3 months of age was obtained mid-Mar in Nigeria (Van Rompaey & Powell 1999). Allen (1924) recorded three young in one litter. The

young are full-grown at ca. seven months and permanent dentition is attained at around one year. A captive lived to a little over 11 years (Weigl 2005).

Predators, Parasites and Diseases Remains were found in one Black-legged Mongoose *Bdeogale nigripes* scat (probably scavenged) and one Leopard *Panthera pardus* scat in Dzanga-Sangha (Ray & Sunquist 2001). Larvae of a tongue worm *Porocephalus moniliformis* were found in a specimen from Cameroon (Schäfer 1912). A captive specimen died from myeloid leukaemia (Hamerton 1945).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although not currently threatened, numbers probably are declining as a result of forest fragmentation and forest loss by logging, mining, slash and burn farming, and from bushmeat hunting. In a study in NE DR Congo, the Long-nosed Mongoose made up 5% of the carnivore bushmeat (Colyn *et al.* 1987).

Skeleton of Marsh Mongoose *Atilax paludinosus*.

GENUS *Atilax*

Marsh Mongoose

Atilax F. G. Cuvier, 1826. In: E. Geoffroy Saint-Hilaire and F. G. Cuvier, Hist. Nat. Mammifères, pt. 3, 5 (54), 'Vansire,' 2 pp.

The genus contains only one species, the Marsh Mongoose *Atilax paludinosus*, which is distributed throughout much of sub-Saharan Africa in well-watered habitats with adequate vegetation cover. The unique character among the family Herpestidae of possessing unwebbed toes makes the Marsh Mongoose indisputably generically independent (Allen 1924, Rosevear 1974). Other distinguishing characters include its short and broad muzzle, entirely naked soles of the hindfeet, relatively wide zygomatic breadth and narrow braincase with a well-developed surpaoccipital crest. Unlike other mongooses, *Atilax* has a marked preference for aquatic habitats. Molecular studies have shown *Atilax* to be closer to the Long-nosed Mongoose *Xenogale naso* (Veron *et al.* 2004, Perez *et al.* 2006, Patou *et al.* 2009) than to any species in the genus *Herpestes*.

Fossil remains found both at Kromdraai (Ewer 1956) and Olduvai (Petter 1973) indicate that this genus derives from the Pliocene, but no details are available about whether the number of species within it has increased or declined.

Marsh Mongoose *Atilax paludinosus* in 'basking' posture. (See previous page for an illustration of the skeleton of Marsh Mongoose.)

Carolyn M. Baker & Justina C. Ray

Atilax paludinosus MARSH MONGOOSE

Fr. Mangouste des marais; Ger. Sumpfichneumon (Wasser Manguste)

Atilax paludinosus (G. Cuvier, 1829). Le Règne Animal 1: 158. 'une grand des marais du Cap'
[South Africa, Western Cape Prov., Cape of Good Hope].

Taxonomy Ten subspecies have been recognized (Coetzee 1977), but their validity is doubtful (Rosevear 1974). Synonyms: *atilax*, *galera*, *macrodon*, *mitis*, *mordax*, *nigerianus*, *paludosus*, *pluto*, *robustus*, *rubellus*, *rubescens*, *spadiceus*, *transvaalensis*, *urinatrix*, *vansire*, *voangshire*. Chromosome number varies with sex, with the diploid number for ♂♂ being $2n = 35$, and that of ♀♀ $2n = 36$; the fundamental number is 66. Fourteen pairs of autosomes are metacentric or submetacentric

and three pairs are acrocentric or subacrocentric; the X chromosome is a medium metacentric (Wurster & Benirschke 1968).

Description A large, dark, shaggy mongoose with an overall grizzled appearance conferred by the white or fawn annulated guard hairs. Muzzle short and pointed, terminating in a pink and black, or wholly black, naked, slightly upturned rhinarium. External nares

Marsh Mongoose *Atilax paludinosus*.

Lateral and palatal views of skull of Marsh Mongoose *Atilax paludinosus*.

dorsolaterally situated. Short, rounded ears partially concealed by hair and carried low on the head. Hair around mouth fawn-coloured. There is no step where the frontals and the nasals meet, thus indicating a smooth transition from the braincase to the nasal region, and the small eyes are positioned somewhat laterally, increasing the lateral field of vision. Overall colour varies from a deep russet to black. Dorsal pelage shorter in the anterior region and longer across the hindquarters; undercoat slightly paler in colour and usually thick and woolly. Ventral surface entirely covered in fur. Limbs and feet short in relation to head-body length and covered with very short, sleek, dark brown or black hair. Fore- and hindfeet bear five, well-defined, flexible digits that lack webbing (present in all other herpestids); each toe bears a stout, curved claw. Plantar surfaces entirely naked and very soft; soles of hindfeet naked to the heel. Tail shorter than head-body length (ca. 65%), with longer hairs (up to 56 mm) at the base, tapering towards the tip. Anal glands open on either side of the anus into an anal pouch. Cheek glands situated at base of genal vibrissae. Two pairs of abdominal nipples in specimens from KwaZulu-Natal (South Africa), although Skinner & Chimimba (2005) report on the presence of three pairs in Zimbabwe.

Skull broad with marked postorbital constriction, and with zygomatic breadth averaging approximately 58% of condylobasal length (Rosevear 1974), and condyloincisive length more than 100 mm in adults (Coetzee 1977). Dental formula usually $I^{3/3}$, $C^{1/1}$, $P^{3/3}$, $M^{2/2} = 36$; marked variation is found with respect to the presence of the first premolar in both upper and lower jaws and, if present in both jaws, the total number of teeth is 40 (Rosevear 1974). Upper and lower outer incisors larger than the others and the canines are robust. Upper canines bear narrow blade-like processes on front and back, these being less evident on lower canines. In older animals, canines usually wear to blunted points, and the fourth upper premolar wears flat (Skinner & Chimimba 2005).

Geographic Variation According to Coetzee (1977), West African specimens ('*pluto*') are virtually black, East African specimens ('*robustus*') more grizzled, and animals from southern Africa ('*paludinosus*') more brownish-black, but colour is not thought to be a reliable indication of subspecies.

Similar Species

Xenogale naso. Sympatric in western and central Africa. Webbed feet, soles of fore- and hindfeet fully haired to pads, longer brush-tail (less tapered) and more slender snout.

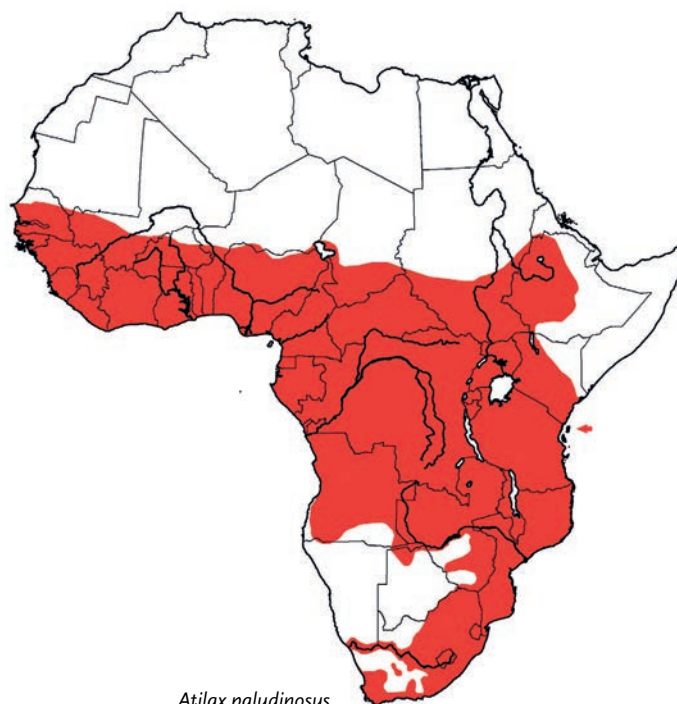

Herpestes ichneumon. Sympatric in most countries south of the Sahara. Paler overall pelage colour; longer tapered tail with black-tufted tip; more slender body-build.

Liberiictis kuhni. Sympatric only in NE Liberia and W Côte d'Ivoire. Medium-sized, with long snout, and distinctive dark neck-stripe; a whitish stripe extends from back of mouth to below the ear; very long curved claws.

Ichneumia albicauda. Woodland and savanna habitats from Senegal to north-east Africa southwards to SE South Africa. Large and distinctive, usually grey, with distal third of tail white (but sometimes black).

Rhynchogale melleri. Woodland habitat from N Tanzania south to NE South Africa. Smaller (less than 3 kg); individuals may have partially white tails, but pelage overall more brown; distinct crest-like parting on either side of neck.

Distribution Endemic to Africa, south of the Sahara, where it is widely distributed from Senegal, Guinea-Bissau, Sierra Leone and Liberia eastward through most West African countries to Cameroon, Equatorial Guinea, Gabon, Congo, Central African Republic, Sudan, DR Congo, Uganda, Rwanda, Burundi, Kenya, Ethiopia and Tanzania. In southern Africa, occurs mostly in the east in Zambia, Zimbabwe, Mozambique, South Africa, Swaziland and E Lesotho. Present in W Angola, but absent from most of Namibia, Botswana and large parts of C South Africa, wherever adequate water and cover are unavailable (Rosevear 1974, Baker 1992a, Skinner & Chimimba 2005). Present on Pemba I., but absent from Zanzibar (Pakenham 1984). Wozencraft (2005) lists this species as occurring in Algeria, presumably an error as there are no confirmed records from this country.

Atilax paludinosus

Habitat Usually restricted to riparian habitats, such as rivers, streams, swamps, marshes and dams, wherever the availability of vegetation cover and proximity of water are guaranteed. They may also be found along estuaries and in coastal areas. On occasion may be found away from water-courses, but for limited periods (Rosevear 1974, Baker 1987, Maddock & Perrin 1993). The degree of restriction to aquatic habitats varies from one locale to the next, and may depend on the relative abundance of other sympatric mongoose species (Ray 2001). Fast-flowing rivers may represent sub-optimal habitat (Louw & Nel 1986), although highest densities in Bwindi Impenetrable N. P., Uganda, were attained in large swamps with the largest river inflows (Andama 2000). Mostly recorded at altitudes from sea level to about 2700 m (e.g. Rowe-Rowe 1992a, Andama 2000), although they have been sighted at 3500 m on Mt Kenya (Young & Evans 1993) and up to 3950 m in Bale Mts N. P., Ethiopia (Yalden *et al.* 1996).

Abundance Marsh Mongooses are generally common in suitable habitat, although in some areas sightings may be uncommon due to their crepuscular habits. Their presence is evidenced near all water sources by means of their very distinctive spoor. One of the most common mongoose species represented in West African museum collections (Rosevear 1974) and the second most photographed species in a camera-trapping study in the Udzungwa Mts, Tanzania (De Luca & Mpunga 2005). In KwaZulu-Natal, density was recorded as 1.8/km² (Maddock 1988).

Adaptations Old individuals have a well-developed sagittal crest joining the supraoccipital crest at the rear of the braincase. It continues forwards to divide into two ridges, ending in the supraoccipital processes. Together with the rough surfaces of the sides of the braincase, these support a powerful set of temporalis muscles that facilitate the crushing action of the jaws. The carnassial teeth show a distinct adaptation to crushing rather than slicing (Petter 1969, Kingdon 1977, Skinner & Chimimba 2005).

Strictly terrestrial, and easily able to leap distances of 60–70 cm (Frese 1981). Forepaws of Marsh Mongooses are highly sensitive and adapted for feeling about under water, rocks and mud for terrestrial

and aquatic prey (Lombard 1958), and for holding and handling food and other items (Gläss & Sedlag 1980). Long, unwebbed digits increase the ability to feel into small crevices for food items as they move along stream edges (Baker 1989). They have been observed to waddle out of the water bipedally, while carrying a large snail in their forepaws (J. Kingdon pers. comm.). Dense underfur, particularly in the shoulder and flank regions, assists in keeping the skin surface dry should the mongooses venture into deeper water during foraging. Marsh Mongooses are excellent swimmers, and swim using lateral movements; they can remain submerged in the water after diving for up to 15 sec (Taylor 1970a). Advanced motor control and tactile sensitivity of the digits is supported by studies on neuroanatomy (Radinsky 1975a). Horizontal pupils increase the lateral range of vision, thus enhancing prey detection.

Glandular secretions from well-developed anal glands serve to inform conspecifics of the identity and sexual status of neighbouring mongooses, thereby enhancing communication in this solitary species. Scent deposition is via an anal drag or in cases of extreme agitation may be expelled more forcefully (Kingdon 1977, Baker 1988).

In KwaZulu-Natal, radio-collared mongooses became active ca. 30 min after sunset and remained active until 01:00–02:00h (Maddock & Perrin 1993). The latter authors found no evidence of diurnal activity, although Rowe-Rowe (1978a) did record them being active in the early morning and late afternoon. Similarly, activity peaks in one ♂ in Dzanga-Sangha, Central African Republic, were recorded in the early morning (04:00–06:00h) and in the evening (17:00–20:00h) (Ray 1997). In general, peaks of activity are linked to several factors such as food availability, reproductive condition, climate and season.

Different day-beds or burrows are used for resting each day; in Central African Republic they are located in dry areas on relatively high ground surrounded by water or deep mud, with dense cover provided by high grass or vine entanglements (n = 24; Ray 1997). Studies in central and southern Africa suggest that each home-range has a number of sites that are easily accessible from anywhere in the range (Maddock 1988, Ray 1997).

Foraging and Food Aquatic prey forms the bulk of the diet, and crustaceans (mainly crabs) usually dominate, which is unusual among herpestids. However, Marsh Mongooses are able to vary their diet quite considerably by including amphibians, fish, molluscs as well as terrestrial arthropods and rodents; birds, birds' eggs, reptiles and fruits are generally less important food items (Rowe-Rowe 1977a, Smithers & Wilson 1979; Du Toit 1980, Whitfield & Blaber 1980, Louw & Nel 1986, Maddock 1988, Baker 1989, Purves *et al.* 1994, Somers & Purves 1996, Avenant & Nel 1997, Ray 1997, Andama 2000, Angelici 2000, Stuart & Stuart 2003a, b).

The diet of this species has been very well studied in South Africa, where two major studies using scat analysis from the highlands (n = 210 scats; Rowe-Rowe 1977a) and lowlands (n = 349; Maddock 1988) of KwaZulu-Natal revealed the following relative percentage occurrence of prey: highlands – 43% crustaceans, 14% mammals, 14% amphibians, 14% birds, 2% fish and 2% insect; lowlands – 21% crustaceans, 15% mammals, 17% amphibians, 2% birds, 0% fish and 19% insects. Elsewhere in southern Africa, the percentage occurrence of items in 29 stomachs from Zimbabwe was 29% amphibians, 24% mammals, 24% crustaceans, 19% insects and 5% fish (Smithers & Wilson 1979).

Marsh Mongoose *Atilax paludinosus*.

Diets of inland-dwelling Marsh Mongooses tend to be more catholic in nature than those in coastal habitats (Louw & Nel 1986). In the Olifants R., most crabs (*Potamonautes perlatus*) consumed had a mean carapace width of 29 mm (range 9–48 mm), with an average weight of 9 g ($n = 85$; Purves *et al.* 1994), while in the Bushman's R., mean crab size was 24 mm (range 10–41 mm; $n = 65$; Somers & Purves 1996). Mean weight of fish (species not identified) consumed by Marsh Mongooses in Dzanga-Sangha was 28 g (3.5–72 g; $n = 39$; Ray 1996), and mean length of fish (*Tilapia sparrmanii*; $n = 8$) consumed in the Bushman's R. was 25 mm (21–39 mm; Somers & Purves 1996). Seasonal variations in dietary components may be associated with variations in local abundance of preferred food items (Avenant & Nel 1997). Some evidence of their scavenging on Water Chevrotain *Hyemoschus aquaticus* (Ray 1997) and domestic stock (e.g. Stuart & Stuart 1998b) has been recorded, and the latter authors recorded the presence of two small carnivores, Yellow Mongooses *Cynictis penicillata* and Cape Grey Mongooses *Herpestes pulverulentus*, in scats from S Namaqualand in the Northern Cape, South Africa; the same authors also recorded the presence of Cape Grey Mongooses in one scat from the central Great Karoo (Stuart & Stuart 2003a).

Marsh Mongooses forage principally in the littoral zones of water bodies, although they are known to dive for food on occasion (Baker 1989). They spend a great deal of their time walking along the water shore or wading in water searching for food (Rowe-Rowe 1978a). In Central African Republic, the average distance covered while travelling over 30-min periods was 320 m (Ray 1997). Both sound and touch have been reported as being the most important senses for locating food (Baker 1989), with vision facilitating prey capture. Prey are forked out with the forefeet from under stones, or from within holes and crevices, and crabs, rodents and other similar-sized prey are seized in the mouth and flicked sideways, presumably in order to stun the prey before killing (Rowe-Rowe 1978a, Rowe-Rowe & Somers 1998).

Prey items taken in water typically are carried out of the water before being eaten. Smaller crabs are eaten whole, while larger crabs are pinned to the ground and the nippers removed with the teeth (Baker 1989). The crab is then turned onto its back and the meat from inside the carapace is consumed first. The carapace usually is discarded (although see Angelici 2000), and the presence of these on river-banks often is an indication of the presence of this species (African Clawless Otters *Aonyx capensis* normally crunch up the carapace; Rowe-Rowe 1977a). Toads *Bufo* sp. are killed by a head bite and then palpated on the ground (perhaps to remove noxious substances; Baker 1989). Rodents are killed by means of a bite to the anterodorsal part of the cranium, parts of which are sometimes found in scats. Insects are captured in mid-flight by grasping them in the mouth or with the forefeet (Rowe-Rowe 1978a, Baker 1989, Rowe-Rowe & Somers 1998). Although small eggs are crushed in the jaws, large eggs are broken by rearing up on the hindlegs and smashing them on a hard substrate (Kingdon 1977, Gläss & Sedlag 1980); the same method may be used to break open mussels and snails.

Social and Reproductive Behaviour Marsh Mongooses are predominantly solitary, but may be seen in small family groups of two or three during the breeding season. Groups consist of mother and offspring, and it is seldom that an adult ♂ and ♀ remain together for any length of time beyond that required for mating. The offspring remain with their mother beyond weaning age until they

are able to fend for themselves at about 20 weeks of age. With the onset of sexual behaviour at about six months, the levels of agonistic behaviour between mother and offspring increase, thus promoting dispersion (Baker 1987).

Marsh Mongooses communicate with both scent and sound. Five different vocalizations are made, of which three are agonistic, accentuating the solitary nature of this species. Compared with some of the more sociable mongooses, the vocal repertoire is limited (Baker 1988). While communication at close quarters is effected by vocalizations and behavioural displays, distance communication is achieved through the deposition of scent, by both cheek and anal glands. Cheek marking is pronounced when mongooses are excited or threatened. Anal marking occurs more frequently and conveys information regarding the identity and sex of the owner, and is used particularly by the ♀ during the breeding season. Anal secretions are also deposited during defecation. Urination takes place in the squatting position in the ♀ ♀, while ♂ ♂ lift a leg. Marsh Mongooses use middens for scat deposition, which serve not only as a reservoir for scent communication, but also as a visual display for other mongooses. These communal defecation sites are particularly significant in this solitary species as conspecifics are able to identify the sex and status of other animals in the vicinity, thus facilitating long distance communication (Baker 1998). In central African forest habitats, middens are usually located on rocks or sandy beaches near streams and in marshy clearings (Ray & Sunquist 2001); in inland areas of southern Africa, they are usually found in areas covered by vegetation, often <10 m from the water edge, or above the high water mark in coastal areas, often on rocks (Louw & Nel 1986, MacDonald & Nel 1986, Purves *et al.* 1994).

On account of their dense pelage and undercoat and also their mode of life that necessitates spending some time in water, Marsh Mongooses groom themselves (and occasionally partners) by licking their fur and combing the fur with the incisors. This behaviour is neither systematic nor prolonged. Rowe-Rowe (1978a) suggested that this behaviour accounted for the presence of its own hair in 67% of the scats he examined.

Home-range sizes vary widely but are generally linear in shape, owing to fidelity to water-courses. One radio-collared adult ♂ in Dzanga-Sangha travelled up and down a stream ca. 5 km in length; its home-range was estimated at 54 ha (Ray 1997). In KwaZulu-Natal, the home-range of one ♂ was smaller (131 ha) than that of one ♀ (204 ha) (Maddock 1988). Ranges may overlap (Maddock 1988), although Kingdon (1977) has suggested that Marsh Mongooses are territorial. It is likely that the ♀ ♀ hold territories with the ♂ being more mobile.

Marsh Mongoose *Atilax paludinosus* myology.

Females tend to avoid ♂♂ until they are ready to be mated. Oestrus lasts for nine days. Mating sequences may last up to 29 min if successful, with copulation lasting for up to 6 min (Baker 1987).

Reproduction and Population Structure In southern Africa, breeding is seasonal occurring in the summer, with mating from as early as Aug through to Feb (Rowe-Rowe 1978a, Stuart 1981). There is no evidence of a breeding season in West Africa (Rosevear 1974). Mean gestation is 10.5 weeks (Baker 1987) and births in captive animals occurred mainly at night. Mean litter-size in the wild in South Africa is 2.5 (range 2–3, $n = 6$; Baker & Meester 1986), and 1.1 in captive individuals (range 1–2; $n = 15$; National Zoological Park, Washington, DC; Frese 1981). Mean birth-weight is 108.5 g (range 78–123, $n = 7$; Baker & Meester 1986). Newborn mongooses are fully furred with eyes and the auditory meatus closed; incisors one and two are present at birth and may function to ensure adequate nipple attachment during suckling (Baker & Meester 1986). Eyes open at around Day 11 (range 9–14, $n = 7$; Baker & Meester 1986) and hearing develops around Day 21 (Baker 1987). The earliest weaning commences is one month, but young continue sucking until eight weeks (Baker 1992a). Deciduous dentition is complete at about Day 44, after which replacement by the permanent set occurs; the permanent canines are only complete by about Day 243 (Baker & Meester 1986). The earliest that young mongooses can successfully capture and kill rodent prey varies around Day 121 (range 102–135; $n = 5$; Baker 1992b). Males have abdominal testis at birth, with descent ranging from Day 204 to Day 307 ($n = 2$; Baker & Meester 1986). Weight of young doubles by Week 4 and is more than eight times by Week 7 (Frese 1981); adult mass is attained at Week 27 (Baker & Meester 1986). A captive animal lived for more than 19 years (Nowak 1999).

Predators, Parasites and Diseases While young Marsh Mongooses are vulnerable to predation by a range of other small carnivores, there are few reports of predation on either juvenile or adult animals; they were recorded in the scats of Leopards *Panthera pardus* in several study sites in Gabon (Henschel *et al.* 2011). A range of parasites has been found on mongooses, including fleas (*Ctenocephalides felis* and *Echidnophaga gallinacea*), ticks (*Rhipicephalus simus*, *R. sulculatus*, *Haemaphysalis subterra*) and lice (*Trichodectes* sp.) (Loveridge 1923, De Meillon *et al.* 1961, Hoogstraal *et al.* 1992, Ntiamoa-Baidu *et al.* 2005). Alimentary parasites include nematodes and ascarids (Loveridge 1923, Stuart 1981). Some bone diseases in the hindfoot have been recorded in mongooses in East Africa (Taylor 1971b).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Dependence on riverine vegetation for shelter that is prone to destruction (Rosevear 1974, Andama 2000, Ray 2001) may have long-term implications. Drainage of swamplands to expand arable land has also been identified as a threat to Marsh Mongooses in eastern Africa (Andama 2000). The Marsh Mongoose is the most common carnivore appearing in bushmeat markets in SE Nigeria (Angelici *et al.* 1999c) and the species made up 5.6% of the carnivore bushmeat in NE DR Congo in one study, the fifth most common carnivore species to appear in markets (Colyn *et al.* 1987). It was also commonly recorded in bushmeat surveys in the Classified Forest of Diécké, Guinea (Colyn *et al.* 2004). They are otherwise present in numerous protected areas across their range.

GENUS *Herpestes*

Common Mongooses

Herpestes Illiger, 1811. Prodr. Syst. Mamm. Avium., p. 135.

The genus includes 14 species worldwide, five of which occur in Africa: Egyptian Mongoose *Herpestes ichneumon*, Cape Grey Mongoose *H. pulverulentus*, Slender Mongoose *H. sanguineus*, Kaokoveld Slender Mongoose *H. flavescens* and Somali Slender Mongoose *H. ochraceus*. The Long-nosed Mongoose *Xenogale naso*, sometimes included in *Herpestes* (Wozencraft 2005), is here included in the monotypic *Xenogale*. The Small Asian Mongoose *Herpestes auropunctatus*, from South and South-East Asia, has been reported as introduced on Mafia I., off the coast of Tanzania (Moreau & Pakenham 1941, Nellis 1989, Kock & Stanley 2009).

The Egyptian Mongoose (2–4 kg) is found widely through many habitats in much of sub-Saharan Africa. It has been associated with human habitation for millennia and mummified specimens have been found in Egyptian tombs. In much of non-coastal South Africa and S Namibia, it is replaced by the Cape Grey Mongoose (0.6 kg). Both species are relatively uniformly grizzled grey with a tapered tail, with that of the Egyptian Mongoose having a black tuft at the tip. The commonest of the *Herpestes* mongooses is the Slender Mongoose (0.6 kg), which usually has a grizzled pelage, although the colour appears to be associated with the habitats in which it occurs, with the darker colours occurring in the moister habitats. The Somali Slender Mongoose (0.6 kg) is found only in Somalia, and is distinguished by its relatively short broad skull and markedly inflated auditory bullae. The Kaokoveld Slender Mongoose (0.6 kg) is restricted to a semi-arid region of Namibia and S Angola near the coast, and is distinguished by its blackish to reddish pelage.

Mongooses in the genus *Herpestes* are distinguished from other African mongooses by the presence of five digits on fore- and hindfeet, and species in the subgenus *Herpestes* (*H. ichneumon*) have a generalized dentition of $I^{3/3}$, $C^{1/1}$, $P^{4/4}$, $M^{2/2} = 40$, while those in the subgenus *Galerella* (*H. pulverulentus*, *H. sanguineus*, *H. ochraceus* and *H. flavescens*) have $I^{3/3}$, $C^{1/1}$, $P^{4/3}$, $M^{2/2} = 38$. In all species, P^4 has the posterior lobe (metacone) elongated such that the tooth is a distinctive carnassial. The species have maintained a generalist body plan and display no obvious specializations for diet or locomotion (Petter 1969); all are omnivorous, eating more insects during wet times of the year and more vertebrates during dry seasons. This is in contrast to some of the other mongooses in Africa, many of which have evolved into specialist ecological niches such as the earthworm-eating Liberian Mongoose *Liberiictis kuhni* with a very elongated rostrum and short pointed teeth, and the Marsh Mongoose *Atilax paludinosus*, which specializes on aquatic vertebrates and invertebrates.

The basis for assigning species into subgenera is based on the absence of the first lower premolar in the adult of most species and the greater inflation of the auditory bulla (Wozencraft 1993). However, the presence of the lower first premolar is a variable feature and the Small Asiatic Mongoose *H. javanicus* has comparable auditory

Egyptian Mongoose *Herpestes ichneumon* myology.

bullae to the small African *Herpestes* (Taylor & Matheson 1999). There are allozyme differences between the Slender Mongoose, Cape Grey Mongoose and Egyptian Mongoose in southern Africa (Taylor *et al.* 1991), though the allozyme variation between all the other *Herpestes* has not been determined. In all *Herpestes*, diploid chromosome number ranges from $2n = 35$ in ♂♂ and $2n = 36$ in ♀♀ (Indian Grey Mongoose *H. edwardsi*) to $2n = 43$ for ♂♂ and $2n = 44$ for ♀♀ (Egyptian Mongoose). The Y chromosome has been translocated to an autosome, thus the chromosomal sexual mechanism (as in other *Herpestes*) affects two pairs of chromosomes (Fredga 1970, 1972, 1977).

The taxonomic position of *Galerella* relative to *Herpestes* has been the matter of some debate, and has been elaborated upon and discussed in detail elsewhere (e.g. Meester *et al.* 1986, Wozencraft 1993, 2005, Bronner *et al.* 2003, Skinner & Chimimba 2005). Chromosomal studies, including forms of *Herpestes* from Africa and Asia, indicate that recognition of *Galerella* would render *Herpestes* paraphyletic (Fredga 1972), while a craniometric study (again, including both Asiatic and African *Herpestes*; Taylor & Mattheson 1999) supported inclusion of *Galerella* in *Herpestes*. McKenna & Bell (1997) included *Galerella* in *Herpestes*, while Wozencraft (2005) continued to recognize *Galerella*. Recent molecular studies (Veron *et al.* 2004, Perez *et al.* 2006, Patou *et al.* 2009) have shown that *Herpestes* is polyphyletic, with the Long-snouted Mongoose grouping with *Atilax*, the Egyptian Mongoose *H. ichneumon* grouping with the species traditionally assigned to *Galerella*, and the Asian *Herpestes* forming a monophyletic clade. Clearly, further investigations are needed, but it certainly seems possible that *Herpestes* could be restricted to *H. ichneumon*, and *Galerella* may need to be raised to genus level and the Asian *Herpestes* assigned to other genera (Patou *et al.* 2009).

Herpestes flavescens KAOKOVELD SLENDER MONGOOSE (ANGOLAN SLENDER MONGOOSE)

Fr. Kaokoveld Mangouste Rouge; Ger. Kaokoveld Rotichneumon

Herpestes flavescens Bocage, 1889. J. Sci. Math. Phys. Nat. Lisboa, ser. 12, 1: 179. 'Benguella' [Angola].Kaokoveld Slender Mongoose *Herpestes flavescens*.

Taxonomy Included in subgenus *Galerella*. The Kaokoveld Slender Mongoose has a confusing taxonomic history. The species was first described as a subspecies of the Slender Mongoose *Herpestes gracilis* var. *flavescens* (Bocage 1889) from Benguela, SW Angola, although the type specimen was subsequently lost in a fire in the Museu Bocage (Crawford-Cabral 1996). Later, Thomas (1928a) identified specimens from the Kaokoveld in Namibia as a distinct species (*Myonax nigratus*), the holotype of which is in the British Museum of Natural History. Shortridge (1934) also considered *nigratus* a distinct species, including the form *shortridgei* (described by Austin Roberts in 1932 from NW Ovamboland), which he considered an erythristic form. Subsequently, *nigratus* was assigned to subspecific rank in the Cape Grey Mongoose *H. pulverulentus* by Ellerman *et al.* (1953), who suggested that *nigratus* represented a melanistic form of this species, with *shortridgei* an erythristic form of it; this classification was in turn followed by others (e.g. Coetzee 1977, Meester *et al.* 1986, Cavallini 1992; but see Lynch 1981 who referred *nigratus* to *sanguineus*). Meanwhile, Coetzee (1977) assigned the form *flavescens* to *sanguineus*, a form not even mentioned by Meester *et al.* (1986) or Watson & Dippenaar (1987).

Three separate studies using different cranial data sets have confirmed the distinctiveness of *nigratus* as a separate species using multivariate analyses (Watson & Dippenaar 1987, Watson 1990, Taylor & Goldman 1993, Crawford-Cabral 1996). Crawford-Cabral (1989b) noted that *nigratus* should be considered conspecific with the earlier *flavescens* (Bocage 1889) from Angola. However, Taylor & Goldman (1993) considered that available evidence suggested that most Angolan specimens belong to *H. sanguineus*, and proposed that in the absence of cranial material from Angola demonstrating that *H. flavescens* is synonymous with *H. nigratus*, a change in name was not warranted. Wozencraft (1993), without the benefit of the study of Taylor & Goldman (1993) published the same year, accepted the conclusions of Crawford-Cabral (1989b). A subsequent analysis

(Crawford-Cabral 1996) of cranial measurements of specimens from SW Angola found that these agree with *H. nigratus*, reinforcing the proposed synonymy (and this classification was adopted by Bronner *et al.* 2003 and Wozencraft 2005). That the issue is far from resolved is highlighted by Rathbun & Cowley (2008), who consider that animals in N Namibia (referred to these authors as *nigratus*) are a different species than those in SW Angola. The latter authors comment on the occurrence of black (*nigrata*) and chestnut-coloured (*flavescens*) forms in the Kunene R. area that are apparently spatially segregated with no intermediate colour forms, the apparent absence of *flavescens* forms in Namibia, and remark on possible ecological differences. Clearly, a careful reassessment of the taxonomic status of these mongooses is in order, but in the interim we provisionally follow the classification of Wozencraft (2005).

Besides *nigratus* and *shortridgei*, the species also includes the form *annulata* Lundholm 1955a (Watson & Dippenaar 1987, Crawford-Cabral 1989b, Watson 1990, Taylor & Goldman 1993), also previously regarded as an uncertain subspecies of *H. pulverulentus* (Meester *et al.* 1986). However, the status of *annulata* remains uncertain because the holotype and only known specimen is an immature specimen. Synonyms: *annulata*, *nigratus*, *shortridgei*. Chromosome number: not known.

Description A small diurnal mongoose of variable colouration, usually either black or dark brown (*nigrata*) or else a reddish-brown. As name suggests, species is slender in body shape, with long tapered tail about 85% of head and body length. Hair in dark or black individuals not grizzled, although grizzled in erythristic form *shortridgei*. The latter has upper parts chestnut-red to yellowish-orange and yellowish-orange tail has black tip with underparts buffy to yellowish-buff (Crawford-Cabral 1996). Ears small and rounded. Skull intermediate in size between that of Slender Mongoose and Cape Grey Mongoose. Nipple numbers not recorded; probably two or three pairs.

Geographic Variation See Taxonomy.

Similar Species

Herpestus sanguineus. Sympatric in N Namibia. Smaller; dorsal colour greyish-yellow to bright reddish-brown.

H. pulverulentus. Allopatric, occurring only in S Namibia. Larger.

Helogale parvula. Largely allopatric, although both are present in the Erongo Mts of Namibia where this species is also black and is often confused with the Kaokoveld Slender Mongoose (G. Rathbun & M. Griffin pers. comm.). Smaller, with rounder head, relatively shorter tail and less shaggy pelage; social species, diurnal, largely insectivorous and sleeping in old termite mounds (whereas Kaokoveld Slender Mongoose is solitary, diurnal and consumes more vertebrate prey).

Distribution Endemic to Africa. Confined to SW Angola and NW and NC Namibia (Feller 1990, Crawford-Cabral 1996, Skinner & Chimimba 2005). The type locality is Benguela (12° 35' S) in the

Herpestes flavescens

north (Crawford-Cabral 1996) and it ranges from there to the Erongo Mts (Coetzee 1969) and Spitzkoppe (M. Griffin pers. comm.) in NC Namibia, with an eastward extension into the Otavi Highlands in Namibia (M. Griffin pers. comm.). It does not extend inland much beyond the Chela Escarpment in Angola (Crawford-Cabral 1996).

Habitat Inhabits arid hills and kopjes away from water (Shortridge 1934) and appears to be confined between the coastal strip and the interior plateau. In Namibia the species has a restricted distribution to the interior plateau not extending into the pro-Namib Desert. The black form of this mongoose (*nigratus*) seems to be restricted to habitats dominated by large granitic boulders (petrophily), and the drainages and woodlands connecting these, which results in a highly fragmented distribution (Shortridge 1934, Rathbun & Cowley 2008). Animals radio-tracked in the Erongo Mts virtually never ventured into surrounding bushveld, and if they did it was to visit isolated boulders near the main rock area (G. Rathbun pers. comm.).

Sympatric with the Slender Mongoose and Dwarf Mongoose in parts of its range, as in the Erongo Mts. It appears to occur in the more arid habitats, when it is sympatric with the Slender Mongoose, which prefers the more vegetated parts.

Abundance Little information is available, but it is assumed that the species is locally common in arid regions of south-western Africa.

Adaptations The erythristic colour of some forms is assumed to be a camouflage feature in the reddish rocky area of some of its habitats. The black form (*nigrata*) is strictly diurnal and unquestionably camouflaged to hunting in the deep shadows of the rocky habitat that it occupies (Rathbun 2004, Rathbun & Cowley 2008). Kaokoveld Slender Mongooses have been recorded using crevices and small caves among boulders as nocturnal den sites, with no evidence of nesting material in those examined; animals denned alone, using multiple sites haphazardly from night to night (Rathbun & Cowley 2008).

Foraging and Food In Namibia, the species has been recorded feeding on small diurnal rodents (especially Noki *Petromus typicus*; see Rathbun & Rathbun 2006), birds, lizards and insects, and may also feed on freshwater crabs and other aquatic animals (Shortridge 1934, Rathbun & Cowley 2008). In an analysis of 126 scats, insects made up the greatest proportion of scat content (Warren *et al.* 2009).

Cowley & Cunningham (2003) recorded the Namibian Rock Agama *Agama planiceps* as a prey item. Both Nokis and Namibian Rock Agamas are common, diurnal, boulder-dwelling animals typical of the habitat in which the species lives (Rathbun & Cowley 2008). The latter authors also recorded a mongoose unsuccessfully stalk a group of Rock Hyraxes *Procavia capensis*, an attempted capture of a Red-billed Francolin *Francolinus adspersus*, and the successful capture of Helmeted Guineafowl *Numida meleagris*. Remains of reptilian eggs were identified in one scat examined by Warren *et al.* (2009) and the species is also suspected to forage on the eggs and nestlings of the Chatsrike *Lanioturdus torquatus* (Rathbun & Cowley 2008). Adult flies (Sarcophagidae) attracted to rotting carcasses (see below) may be an important (ephemeral) source of food (Rathbun *et al.* 2005).

Social and Reproductive Behaviour There is limited information available, with the most detailed study to date being that of Rathbun & Cowley (2008), who radio-collared six animals in the foothills of the Erongo Mts. Although largely solitary, they were sometimes found in pairs or threes. Mongooses did not maintain exclusive home-ranges or defend these areas as territories, and the home-range of some animals overlapped nearly 100%.

Rathbun *et al.* (2005) reported on a Greater Kudu *Tragelaphus strepsiceros* that died within the home-range of a radio-collared mongoose. Up to seven mongooses fed on adult, larval and pupal sarcophagid flies attracted to the rotting antelope. While one animal fed, others in the vicinity usually waited 5–25 m away and only moved in to feed when no others were present. On a few occasions mongooses arrived as well-coordinated pairs or triads, and if these animals fed on the carcass at the same time they remained at different locations or one animal waited nearby while the other fed. However, five intra-specific fights, lasting about 10–15 seconds, were observed within about 30 m of the kudu. These encounters included initial growling followed by face-to-face biting, rapid rolling about on the ground, and loud screeching or squealing. Intra-specific aggression near the carcass probably produced a dominance hierarchy that determined when individuals fed at the Greater Kudu carcass and reduced further aggression between individuals. Rathbun *et al.* (2005) also recorded the home-range size of the mongoose during the entire observation period (May to Jul 2003), which measured some 145 ha (based on 95% minimum convex polygon method). However, the pre- and post-kudu home-range areas were quite different, roughly 158 ha pre-kudu and 60 ha post-kudu.

Rathbun & Cowley (2008) observed potential scent marking behaviour in the form of urination, defecation, and throat-chest rubbing, but did not observe marking with cheeks or anal glands. These authors also recorded single animals basking in the early morning sun on several near-freezing mornings. Basking was associated with auto-grooming, including licking the abdominal, peri-anal and tail region; allogrooming was not observed (Rathbun & Cowley 2008).

Reproduction and Population Structure No information available.

Predators, Parasites and Diseases Diurnal raptors, such as African Hawk-eagle *Hieraaetus spilogaster*, are potential predators (Rathbun 2004, Rathbun & Cowley 2008).

Conservation IUCN Category: Least Concern. CITES: Not listed.

In Namibia, the species is found in both the Skeleton Coast and Etosha National Parks (M. Griffin pers. comm.), as well as on a number of conservancies, such as the Erongo Mountains Conservancy. Reports of black mongooses from the Waterberg Plateau Park refer to a black form of Dwarf Mongoose (M. Griffin pers. comm.). In Angola, they may occur in Iona N. P., though none of the specimens examined by J. Crawford-Cabral (pers. comm.) from the Namibe Province was collected from inside the Park.

Measurements

Herpestes flavescens

HB (♂ ♂): 343 (335–355) mm, n = 3

HB (♀ ♀): 310, 330 mm, n = 2

T (♂ ♂): 344 (325–362) mm, n = 3

T (♀ ♀): 340, 345 mm, n = 2

HF c.u. (♂ ♂): 70 (69–72) mm, n = 3

HF c.u. (♀ ♀): 64, 66 mm, n = 2

E (♂ ♂): 27.5 (27–28) mm, n = 3

E (♀ ♀): 24, 25 mm, n = 2

GLS (♂ ♂): 67.4 (66.7–67.9) mm, n = 3

GLS (♀ ♀): 64.6 (62.9–65.7) mm, n = 5

GWS (♂ ♂): 36.8 (35.6–38.0) mm, n = 3

GWS (♀ ♀): 32.6 (32.3–33.0) mm, n = 5

Throughout the range (Watson & Dippenaar 1987) and museum specimens (BMNH)

Skull measurements: N Namibia (Taylor & Goldman 1993)

The type specimen of *H. gracilis flavescens* (♀) had HB = 330 mm and T = 335 mm. Five ♂ ♂ radio-collared by Rathbun & Cowley (2008) ranged in weight from 550 to 907 g; a single ♀ weighed 850 g.

Herpestes ichneumon EGYPTIAN MONGOOSE (ICHNEUMON)

Fr. Mangouste d' Egypte; Ger. Ichneumon

Herpestes ichneumon (Linnaeus, 1758). Syst. Nat., 10th edn, 1: 43. 'In AEliggypto ad ripas Nili, ... in India primario; mansuescit', restricted by Thomas (1911) to 'Egypt'.

The name 'ichneumon' is derived from the Greek word meaning 'tracker', possibly in reference to their ability to dig out and eat the eggs of crocodiles.

Taxonomy Ten subspecies were listed by Coetzee (1977), but most subspecies descriptions are based on limited specimens, and

examination of specimens reveals an extremely high degree of variation between individuals. No subspecies are listed here, pending taxonomic revision. Synonyms: *aegyptiae*, *aegypti*, *angolensis*, *bennettii*, *cafra*, *centralis*, *dorsalis*, *egypti*, *ferruginea*, *funestus*, *grandis*, *grisea*, *lademanni*, *mababiensis*, *madagascarensis*, *major*, *nems*, *numidianus*, *numidicus*, *occidentalis*, *parvidens*, *pharaon*, *sabiensis*, *sangronizi*,

Egyptian Mongoose *Herpestes ichneumon*.

Lateral, palatal and dorsal views of skull of Egyptian Mongoose *Herpestes ichneumon*.

widdringtonii. Chromosome number: $2n = 43$ in ♂♂, $2n = 44$ in ♀♀; nine pairs are metacentric, three submetacentric, three subtelocentric and eight acrocentric (Fredga 1970, 1972).

Description A relatively short-legged mongoose characterized by elongated body with tail slightly shorter than body length, terminating in a black tassel. Head broad and long with muzzle pointed and black rhinarium. Eyes small with pupils horizontally elongated. Ears short and relatively square, set far back in the head. Guard hairs long (up to 80 mm), with alternate light and black bands producing a generally grizzled appearance. Underfur soft and fine, varying in colour, but typically greyish on the forequarters and flanks. Variations in pelage colour are found (Rosevear 1974). Hair on underparts shorter and sparser than on upperparts, particularly on belly. Hair towards base of tail much longer than towards the tip, although the hair on the tassel may be up to 130 mm in length. Five digits on each foot, with all digits long, except the first. Non-retractile, curved claws well developed and of similar length in both fore- and hindfeet (Skinner & Chimimba 2005). Perianal glands present. Sexual dimorphism in weight and body measurements is apparent (♂♂ generally larger than ♀♀), but there is considerable overlap. Normally, ♀♀ have three pairs of nipples although two pairs have been reported (Harrison 1968).

Skull long and narrow, with supraoccipital crest well developed; sagittal crest not well developed. Postorbital bars complete in older animals. Zygomatic arches broad and strongly built. Posterior chambers of the ear bullae are large, compared with the anterior, rising to a high, rounded apex from the skull. The dental formula is $I^{3/3} C^{1/1} P^{4/4} M^{2/2} = 40$. Outer, upper incisors large, those in the lower jaw less so but broad towards their tips. Upper canines

moderate in size, while those in the lower jaw are recurved (Rosevear 1974, Skinner & Chimimba 2005).

Geographic Variation See Taxonomy.

Similar Species

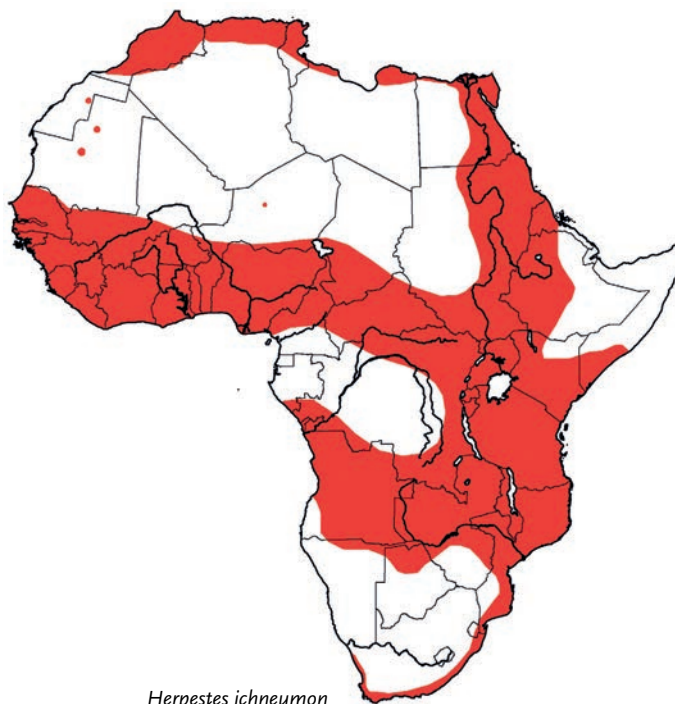

Ichneumia albicauda. Sympatric in much of sub-Saharan Africa, though White-tailed Mongoose is more widely distributed in southern Africa. Longer-legged and the terminal two-thirds of tail usually white (and often black in West Africa).

Atilax paludinosus. Sympatric, except in northern Africa where the Marsh Mongoose is not found and central Africa where the Egyptian Mongoose is absent. Normally darker in colour with shorter tail and longer toes.

Rhynchogale melleri. Sympatric in western part of Africa below the Equator until South Africa (although overlap might be higher). Distinctive crest-like parting on either side of the neck.

Distribution Widely distributed in Africa, with the exception of desert areas and high rainfall forests. Occurs from Senegal and Gambia through most of West Africa, south of the Sahara, to East Africa, then southwards in Angola, Zambia, Malawi and Mozambique. Absent from much of southern Africa, but present in NE Namibia, N Botswana, N and E Zimbabwe and all along the South African coastline (west to about Kleinsee in the Northern Cape; C.T. Stuart pers. comm.). In North Africa they occur in a narrow coastal strip from Morocco to Tunisia, and also from N and E Egypt southwards to Ethiopia (it is unknown whether they still occur in E Libya). Apparently formerly introduced to Madagascar (Haltenorth & Diller 1980), but not recorded recently (F. Hawkins pers. comm.).

Extraliminally, they are present in the Iberian Peninsula (Spain and Portugal), where they were introduced during historical times (Riquelme-Cantal *et al.* 2008), and the Middle East in countries bordering the eastern Mediterranean Sea (Turkey, Lebanon, Jordan)

Herpestes ichneumon

(Delibes 1999a). A century ago the species suffered a retraction of its range in Spain and at present appears to be expanding its range in some areas in Portugal (Borrallho *et al.* 1996).

Habitat Mainly associated with habitats having understorey vegetation in coastal, lacustrine and riparian (streams, rivers, marsh, swamps) locations (Delibes 1982, Ben-Yaacov & Yom-Tov 1983, Palomares & Delibes 1993a, Angelici *et al.* 1999b). In East Africa, this species is commonest in heavily grassed and cultivated areas (Kingdon 1977). In Egypt it is recorded inhabiting desert areas relatively far from the coast (Kasperek 1993), and also from mountainous forest areas up to 1950 m in the Moroccan High Atlas (F. Cuzin pers. comm.); recorded up to 3000 m in the Ethiopian Highlands (Yalden *et al.* 1996). In Morocco, it occurs in forests in higher rainfall areas, and in irrigated and cultivated areas, especially the northern fringe of the Sahara (F. Cuzin pers. comm.). In tropical Africa, the Egyptian Mongoose occurs where there are termitaries, and Kingdon (1977) suggested these could satisfy a need for secure shelter. The presence of other predators may limit the use of optimal habitats, as is the case in Spain where the species is very rare in areas where the Iberian lynx *Lynx pardinus* is abundant (Palomares *et al.* 1996).

Abundance On the African mainland, this species is widespread and locally common. At Vernon Crookes N. R. in KwaZulu-Natal, South Africa, Maddock (1988) estimated a density of 1.2 individuals/km², while Hendrichs (1972) estimated a density of 0.1/km² in East Africa. In Egypt, two family groups of 5–7 individuals each lived in only 900 m² of levees of a fish pond area (Ben-Yaacov & Yom-Tov 1983). In optimal habitats of Spain, where the Egyptian Mongoose has been well studied, this species reaches 2.0 individuals/km² (Palomares & Delibes 1992a).

Adaptations Egyptian Mongooses are entirely terrestrial, but are also good swimmers (Harrison 1968, J. Kingdon pers. comm.). They are well adapted to digging for prey with their strong forelimbs and long, curved claws. Although they have good vision, and apparently have limited colour vision with both cones and rods present in the retina (Dücker 1960), it appears that sense of smell is well developed (Dücker 1965). The dentition is adapted for crushing, with upper and lower second molars occluding closely, and the carnassials having high cusps.

One of the most striking adaptations of this species is its capacity to be largely unaffected by the venom of at least some snakes. It has been proved that the binding site of the nicotinic acetylcholine receptor is resistant to α -neurotoxins (Barchan *et al.* 1992). The secretions of the peri-anal gland contain a mixture of long-chain carboxylic acids and the secretions are specific to each sex (Hefetz *et al.* 1984).

In places where it has been well studied, foraging occurs during the day for 1–2 hours on average after sunrise and an hour or two before sunset (Palomares & Delibes 1992b, Maddock & Perrin 1993, F. Cuzin pers. comm., Skinner & Chimimba 2005). Nocturnal activity is probable in areas where they are subject to disturbance. In Israel they are reported to be crepuscular (Ben-Yaacov & Yom-Tov 1983).

In tropical Africa, Kingdon (1977) reported that this species is commonly mobbed by birds attracted to its antics (which include 'tail-chasing'), a behaviour that seems to derive from the juveniles' 'tracking' or 'following response', which is dependent upon close contact with the mother's (or sibling's) anal glands.

Foraging and Food The Egyptian Mongoose is an opportunistic, omnivorous species that has been reported to consume a great variety of food, including small mammals, birds, amphibians, reptiles, fish, crabs, gastropods, insects, arachnids, carrion, fungi, fruit and other plant material (Rowe-Rowe 1978a, Smithers & Wilson 1979, Stuart 1983). Small mammals have been reported as the main prey in various localities, such as the Western Cape of South Africa (Stuart 1983), where Southern African Vlei Rats *Otomys irroratus* and Four-striped Grass Rats *Rhabdomys pumilio* were particularly favoured; Zimbabwe (Smithers & Wilson 1979), where Angoni Vlei Rats *Otomys angoniensis* and *Mastomys* spp. were common, and the rainforests of SE Nigeria (Angelici 2000). In Israel they are recorded as feeding mainly on poultry and rats (Ben-Yaacov & Yom-Tov 1983), while in some parts of Spain, young European rabbits constitute the main prey (Delibes 1976, Palomares & Delibes 1991).

In spite of the preference for small mammals, the diet can vary between localities and even family groups inhabiting the same area. For instance, in three localities of Doñana (SW Spain) separated by between 3 and 15 km from each other, Egyptian Mongoose mainly consumed lagomorphs in one area, insects, reptiles and small mammals in the second, and birds and small mammals in the third (Palomares 1993a).

Diet varies seasonally according to the availability of prey. In SW Spain, lagomorphs, small mammals and amphibians were consumed more frequently in the wet season, whereas reptiles were more frequent in the diet in the dry season (Palomares 1993a). Limited sample sizes from Zimbabwe revealed little seasonal variation in diet (Skinner & Chimimba 2005).

Foraging is characterized by intense prey searching, walking with the nose close to the ground, inspecting every small hole in the ground, excavating frequently, sniffing around bushes and shrubs, and investigating larger burrows. Individuals may simultaneously enter underground dens to catch rabbits when a family group travels together. When prey items are large enough, these are shared but certain individuals eat before others. Most of their active time is spent foraging (six hours on average; Palomares & Delibes 1992b), with travelling and social interaction occupying minimal time each day (Palomares & Delibes 1993b).

Large prey are caught and killed by a neck bite, but small prey are typically killed by biting the head (Estes 1991). Snakes are attacked from the rear before the victim can retaliate (Kingdon 1977). The Egyptian Mongoose is reported to deal with eggs in the same manner as Slender *Herpestes sanguineus* and Banded *Mungos mungo* Mongooses (Ewer 1973).

Social and Reproductive Behaviour The Egyptian Mongoose is generally solitary, although pairs and family parties of 4–6 are not uncommon. Solitary individuals were seen most frequently (96% of occasions) in one study in South Africa, the remainder comprising groups of two or three individuals (Maddock & Perrin 1993). Packs of up to 14 have been recorded in Namibia (Shortridge 1934), but this is unusual. In Israel, they live in family groups composed of 2–3 ♀♀ with their young and an adult ♂, though ♂♂ spent most of their time alone (Ben-Yaacov & Yom-Tov 1983).

Although no detailed investigations of social behaviour have been undertaken on this species in Africa, the species has been relatively well studied in SW Spain, where mean group size is 1.7 individuals (range 1–5; Palomares & Delibes 1993c), and solitary individuals

Egyptian Mongoose *Herpestes ichneumon*.

are seen on 62% of occasions. Pairs and groups of three individuals, or more, are frequently observed (18% and 21%). Groups of three, or more, individuals are seen all year around except in spring. Pairs were mainly composed of female–young parties (47%), and adults of different sex (41%). The only observation of two adult ♂♂ together was an agonistic encounter, one ♂ chasing the other out his territory. Groups of three or more individuals mainly comprised an adult ♀, adult ♂ and young (58%), although sightings of a ♀ plus young were also frequent (39%). Grouping patterns in Spain seem to be determined by food characteristics (Palomares & Delibes 1993c), although Kingdon (1977) has suggested that the social proclivities of these mongooses in Spain might be encouraged by the fact that they are the only mongoose species occurring.

Members of the same family group share resting sites, which may be located in underground dens or thickets (Palomares & Delibes 1993d). On several occasions, group members met in frequently used dens after spending the day alone.

Average home-range sizes in SW Spain, for each sex–age class, range between 2.8 and 3.5 km² for young and adult ♂♂, respectively (Palomares 1994). Females are territorial in their core areas, whereas ♂♂ are territorial over their entire home-range. Females defend food resources, so heavier ♀♀ (i.e. the socially dominant ones) have smaller home-ranges than smaller ones because they can stay on patches richer in food. However, the main resource for ♂♂ is ♀♀; therefore, heavier ♂♂ can acquire and successfully defend larger territories than smaller ones, including more ♀♀ within their territories. Males have on average four core areas within their home-ranges whereas ♀♀ only have 1.2. Territorial behaviour and relationships with ♀♀ are not the same for all ♂♂ (Palomares 1993b). It has been observed that ♂♂ larger than ♀♀ will adopt a polygamous life-style, sharing a territory with several ♀♀ (up to four), but spending little time with them (4%). When ♂♂ are similar in size to ♀♀, they consort with only one ♀, with whom he spends most of his time (29%).

In SW Spain, temporary latrines are frequently found in open places in the edge of thickets, inside the thickets, or outside underground dens used as resting places and within core areas. This suggests that the latrines are being used as a communication tool. Scattered faeces were also found in the centre of paths within the most used areas and on those leading to resting sites (Palomares 1993c). In Israel latrines are in permanent locations in order to mark home-ranges (Ben-Yaacov & Yom-Tov 1983). Temporary latrines seem to be the rule in Morocco (F. Cuzin pers. comm.). In addition to marking with faeces, scent-marking with the perianal gland on large stones, rock corners

and so forth has been observed in Israel. In Doñana (Spain) scent-marking has been observed on the ground (F. Palomares pers. obs.).

Prior to mating, the ♂ closely follows the ♀ sniffing and licking her vulva, and the pair engages in prolonged social grooming. Mounting attempts at decreasing intervals usually precede mating. Complete copulation may take 6–7 min, but short copulations without ejaculation lasting 0.5–2 min are frequent. During copulation the ♂ embraces the mid-section of the ♀ and thrusts with his hindlegs pressed against her. Postcopulatory behaviour is marked by unrest and defensive threats from the ♀ (Estes 1991).

In Israel, Ben-Yaacov & Yom-Tov (1983) observed cubs suckling from any breeding ♀ of the group, and they would stay with subadults or adults other than the mother. Adults usually bring food to the pups. Cubs first appear outside dens when about six weeks old. Young stay in the family unit until the following breeding season. Several different types of play have been observed: running, fighting, fleeing, hiding, prey stalking and catching, sexual play and experimenting (Rensch & Dürcker 1959).

Five different calls have been recorded in free-ranging individuals in SW Spain, related to alarm, contact, aggression, intimidation and pain (Palomares 1991). The most frequently repeated is the contact call, which is a short duration call emitted repeatedly by every member of the group to maintain contact during foraging; the alarm call is a deep, sharp growl; aggression calls consist of soft and strong growls of barking or spitting, usually during mating and fighting; the intimidating call is a soft, continuous growl, also usually at mating; and the pain call is a sharp sound.

Reproduction and Population Structure Little information is available from Africa, but three captures of young individuals in Zimbabwe and one of a pregnant ♀ in Sierra Leone suggest that births can occur between Oct and Dec (Rosevear 1974, Skinner & Chimimba 2005); births have been recorded in Sep and Feb in Uganda (Kingdon 1977), and between Feb and Oct in Egypt (Harrison 1968). In SW Spain, births mainly occur (78% of cases) in May, Jun and Jul, so, assuming a gestation period of 9–10 weeks, most matings (64%) take place in Mar and Apr. The mean number of cubs was 2.7 for seven litters (Palomares & Delibes 1992a). In Israel, mating occurred in early spring and the average litter-size for captive animals was 3.3 (range 1–4, $n = 10$) (Ben-Yaacov & Yom-Tov 1983). A single litter is the norm, although captive animals breed again if a ♀ loses her cubs (Ben-Yaacov & Yom-Tov 1983). A second litter has only rarely been observed in the wild.

In captivity, Ben-Yaacov & Yom-Tov (1983) found that cubs have closed eyes and ears when born. At 21 days the cubs react to movements and at 25 days begin to call. Cubs appeared to have a sense of smell at 39 days, and their vision seemed to be well developed at 45 days. Cubs try to stand and walk when 21 days old, but only in their fourth week can they walk properly. Jumping has been first observed at 37 days. At 72 days, cubs show complete hunting behaviour, and, at four months, they can hunt by themselves. At 2.5 months young have all deciduous teeth except the molars, which are present three months later; at nine months old the first premolars are replaced (Ben-Yaacov & Yom-Tov 1983). Sexual maturity appears to be achieved in their second year (Dürcker 1960, 1965).

Females are more frequently trapped than ♂♂, with ratios of 1.8 : 1 for both South Africa and Spain (Palomares & Delibes 1992a,

Maddock 1993a). For the same areas, adult individuals have also been more frequently trapped than young, with ratios of 1 : 0.1 and 1.8 : 1, respectively. A similar situation has been found in Israel (Ben-Yaacov & Yom-Tov 1983). In the same area, life expectancy did not exceed 3% after two years. The majority of deaths (69%) were due to human activities, both direct (illegal hunting) and indirect (road kills). A captive ♀ lived to nearly 13 years (Kingdon 1977; and see Weigl 2005).

Predators, Parasites and Diseases In Spain, Egyptian Mongooses are frequently killed by Iberian Lynxes and large eagles in areas where these predators are abundant (Delibes & Palomares 1993, Palomares *et al.* 1996) and, with the exception of Iberian Lynxes, this likely holds true for Africa. One unsuccessful attack by a Golden Eagle *Aquila chrysaetos* has been observed in Morocco (G. Trochard pers. comm.), while bones of this species have been found under the nest of Martial Eagles *Polemaetus bellicosus* (J. Kingdon pers. comm.). It is likely that they are preyed on by various large African predators.

The louse *Felicola (Felicola) inaequalis* frequently has been recorded in specimens trapped in SW Spain (Pérez-Jiménez *et al.* 1990). Cestodes of the genus *Mesocestoides* and *Dipylidium caninum*, and the coccidia *Eimera vulpis* have been reported in samples of dead animals and faeces (Loos-Frank 1990, Rodríguez & Carbonell 1998).

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Egyptian Mongoose is widely distributed on the African continent, occurring in numerous protected areas across their range, and does not appear to be under any significant threat.

Herpestes ochraceus SOMALI SLENDER MONGOOSE

Fr. Mangouste de Somalie; Ger. Somali Manguste

Herpestes ochraceus Gray, 1849. Proc. Zool. Soc. Lond. (for 1848): 138–139. ‘Abyssinia’.

Somali Slender Mongoose *Herpestes ochraceus*.

Taxonomy Monotypic. The Somali Slender Mongoose has been considered a subspecies of the pan-African Slender Mongoose *H. sanguineus* (e.g. Coetsee 1977, Yalden *et al.* 1980, Wozencraft 1993), although it was recognized as distinct by Taylor & Goldman (1993). Authors have assigned specimens to *Calogale*, *Galerella*, *Herpestes*, or *Mungos* (Gray 1849, 1864 [1865], Azzaroli & Simonetta 1966,

Coetsee 1977, Taylor & Goldman 1993). Synonyms: *bocagei*, *fulvidior*, *ochracea*, *perfulvidus*. Chromosome number: not known.

Description A small mongoose of variable colouration, ranging from a pale grizzled grey to a dark brown with some specimens having a distinct reddish colour. As the name suggests, body shape is slender, with long tapered tail about 85% of head and body length. Ears small, rounded. Number of nipples not known.

Geographic Variation None recorded.

Similar Species

Herpestes sanguineus. Sympatric, though probably occurs in moister, higher elevations. Similar in coat colour, though Slender Mongoose has a black tip to a longer tail; skull narrower, longer and not as elevated (and with less inflated auditory bullae and smaller molars; Azzaroli & Simonetta 1966, Yalden *et al.* 1980, Taylor & Goldman 1993).

Helogale spp. Sympatric, but smaller, lacks a black tip to the tail, and social.

Distribution Confined to the north-eastern part of Africa, in Somalia and adjacent parts of Ethiopia and marginally into NE Kenya.

The type locality is Abyssinia (Gray 1849 [1850]) and type specimens in the British Museum (Natural History) are from Wandair (Wardair) (06° 59' N, 45° 20' E) and Mandeira (10° N, 45° 10' E) (Azzaroli & Simonetta 1966, Taylor & Goldman 1993). Sympatric with the Slender mongoose in the more vegetated parts of its range in a manner comparable to that of the overlap of the Kaokoveld Slender mongoose *Herpestes flavescens* and Slender mongoose in south-western Africa.

Habitat Probably found throughout N Somalia, especially in the hilly areas (Drake-Brockman 1910), and through much of S Somalia, extending into adjacent areas of Kenya and Ethiopia (Azzaroli & Simonetta 1966), where it may be sympatric with the Slender mongoose. Occurs to around 600 m altitude (Yalden *et al.* 1996).

Abundance Little information available on this species as few specimens are available in museums. There are 14 specimens in the British Museum and five in the Natural History Museum of the

University of Florence (P. Agnelli pers. comm.). It is assumed that it is relatively common in arid regions.

Adaptations The large auditory bullae are believed to be associated with improved hearing in desert environments where the dry air conducts sound waves poorly (Yalden *et al.* 1980). The colour of the pelage is variable and is probably associated with a humidity gradient, darker forms occurring at higher altitudes, while the grizzled grey forms are from lower elevations. The erythristic colour of some forms is assumed to be a camouflage feature in the reddish rocky area of some of its habitats. It is predominantly diurnal.

Remarks There is a paucity of information on the behaviour and ecology of this species. Solitary, or in pairs or small family groups. Other aspects of its behaviour likely to be similar to the Slender mongoose.

Conservation IUCN Category: Least Concern. CITES: Not listed.

It is not known whether this species occurs in any protected areas; it may, for example, occur in Geedkabeleh G. R. in the north. This is a very poorly known species, and although it is not likely to be threatened it remains in need of further study.

Herpestes pulverulentus CAPE GREY MONGOOSE (SMALL GREY MONGOOSE)

Fr. Mangouste grise du Cap; Ger. Kleinichneumon

Herpestes pulverulentus Wagner, 1839. Gelehrte. Anz. I. K. Bayer. Akad. Wiss. München 9: 426.

'Kap' [Cape of Good Hope, South Africa; exact locality unknown].

Taxonomy The Cape Grey mongoose has been placed in the genus or subgenus *Galerella* (Gray 1864 [1865], Wozencraft 1993, 2005), distinct from *Herpestes* because of smaller size, six upper and five lower cheekteeth (one less premolar on the lower jaw), and two chambers of ear bullae of similar size. Traditionally, six subspecies have been recognized: *ruddi*, *nigratus*, *shortridgei*, *basuticus*, *annulata* and the nominate form (Coetzee 1977, Meester *et al.* 1986, Cavallini 1992), although skull morphological analyses failed to reveal any quantitative differences (Taylor & Goldman

1993). Lundholm (1955a) regarded *nigratus* as a separate species, and described *annulata* as a subspecies of it. Watson & Dippenaar (1987) considered *nigratus* (= *H. flavescens*) as a distinct species with *shortridgei* and *annulata* subspecies of it (and see Crawford-Cabral 1989b, Watson 1990, Taylor & Goldman 1993, Wozencraft 1993, 2005; see also *H. flavescens*). Consequently, three subspecies are recognized here following Cavallini (1992) and Wozencraft (2005). Synonyms: *apiculatus*, *basuticus*, *caffra*, *lasti*, *maritimus*, *ratlamuchi*, *ruddi*, *rufescens*. Chromosome number: 2n = 40 in ♀ ♀ and 2n = 39

Cape Grey Mongoose *Herpestes pulverulentus*.

in ♂♂, less than the Slender Mongoose *H. sanguineus* ($2n = 42$ and 41 , respectively), *H. ichneumon* ($2n = 44$ and 43) and other species of the genus *Herpestes* ($2n = 36$ and 35) (Fredga 1970, 1972, 1977).

Description A small mongoose, typically herpestid in appearance, with short legs and long, bushy tail (ca. 90% of HB). Body and tail grizzled grey (from light grey to dark brown-grey). Ventral surface less grizzled. Muzzle and legs darker, head pointed with ears slightly darker, small, close to the head and partly covered by a band of longer hairs. The rhinarium is small, with a central depression that continues downwards and divides the haired section of the upper lip. Tip of tail sometimes inconspicuously shaded brown (length less than 20 mm). Individual guard hairs black or grey with four to six white to yellowish bands. Five digits on each foot, with the first one reduced. Heel pad not haired and claws not very long. Sexes similar in colour. Males larger than ♀♀ (1.2 times larger in weight). There are three pairs of nipples.

Skull length usually >67 mm (♂♂) and >63 mm (♀♀), with ovoid braincase and short rostrum. The outer incisors are slightly larger than the inner ones. The lower canines are distinctly curved. In the upper jaw, the first molar is small, and the second molar is very small.

Geographic Variation

Herpestes p. pulverulentus: central part of the range, in Western Cape, part of Eastern and Northern Cape and Free State (from the southern and western coast to 32°S in the west and 28°S in the east). Grizzled grey with a similar coloured tail.

H. p. basuticus: higher altitudes, from E Lesotho to W KwaZulu–Natal in South Africa (approx. 27°E to 30°E and 28.5°S to 31°S). More woolly underfur, and a paler appearance.

H. p. ruddi: extreme north-western section of species range (approx. 16.5°E to 22°E and 25.5°S to 32.5°S). More brownish, with darker underfur and yellowish light bands on guard hair.

In all subspecies, character gradients are present in animals from contiguous areas (Lynch 1981).

Similar Species

Herpestes sanguineus. Marginal range overlap in the western part of the Cape Grey Mongoose's range (north of the Orange R., approx. 16.5°E to 18°E and 25.5°S to 28.5°S ; Lynch 1981). Smaller (skull length usually <64 mm in ♂♂, <63 mm in ♀♀), with black (not brown) tail tip (length 60–95; usually more than 75 mm) contrasting with the rest of the tail.

Lateral view of skull of Cape Grey Mongoose *Herpestes pulverulentus*.

H. flavescens. Allopatric, in SW Angola and NW and NC Namibia only.

Intermediate in size between the Slender and the Cape Grey Mongooses, and may have a conspicuous tail tip (Watson 1990, Taylor & Goldman 1993).

Distribution Endemic to southern Africa, ranging throughout the Northern Cape (with one record from near the Botswana border at Hotazel; C. Anderson pers. comm.), Western Cape and Eastern Cape, west to Lesotho and extreme W KwaZulu–Natal (eastern slopes of the Drakensberg). Two specimens were collected in 1937 and 1974 in S Namibia. One ♀ was trapped in 1990 in Wakkerstroom, Mpumalanga, 200 km north of known records in KwaZulu–Natal and Lesotho; this might indicate a range contraction or a very low density in Namibia and an expansion in NE South Africa, as the area has been extensively trapped before (Bronner 1990) and this species is easy to trap.

Habitat This species has a wide habitat tolerance, and is found in forested areas as well as open country. Cape Grey Mongooses are more common in dry than in wet areas (Crawford *et al.* 1983), especially with a warm temperate climate (Lynch 1981), but absent in the driest parts of the region (Kalahari thornveld; rainfall below 200 mm; Lynch 1983). Present from sea level around the Western Cape to 1900 m in

*Herpestes pulverulentus*

KwaZulu–Natal. They occur mainly in Karoo and karroid bushveld, and sclerophyllous bush (as defined in Acocks 1975), but are often associated with refuge areas, such as dense bushes and rocky outcrops, and avoid open fields with short vegetation where they are easily seen because of their dark colour (Cavallini & Nel 1990b). Adapt easily to human settlements, where they search for food scraps.

Abundance Common throughout the range. Densities of up to 10 individuals/km² have been recorded in suitable habitat; also abundant close to human settlements (Cavallini & Nel 1990b, Stuart 1991).

Adaptations Although mainly terrestrial, Cape Grey Mongooses will climb trees, either when hunting or when under stress. They do not use dens, at least not in summer. In areas with little cover, they rest in holes in the ground, in termitaria or under rocks. The claws of the front feet are not well developed, and they are poor diggers and do not dig their own burrows, rather relying on holes dug by other species (which they adjust to their own requirements) or on natural shelters. Cape Grey Mongooses do not leave scats in faecal piles like other mongooses, but scatter them singly or in clusters in well-used areas, especially around sleeping sites (which are changed from day to day; Cavallini & Nel 1990b). Captive animals exhibit anal gland marking (Stuart 1981).

The species is predominantly diurnal and activity is related to sunset and sunrise; activity is reduced in bad weather and at high temperatures (Cavallini & Nel 1990b). As with other small carnivores, it tends to move along existing tracks and paths and is often observed crossing roads. Unlike the Slender Mongoose, which raises its tail while running, the Cape Grey Mongoose keeps it close to the ground. It shows a certain resistance to the venom of the Forest Cobra *Naja melanoleuca* (over 21 mg venom per kg body weight; Hinton & Dunn 1967).

P⁴ is adapted to cutting in occlusion with the M₁ and P₄. A large protocone on the front inner edge of P⁴ and the back of M₁ are adapted to crushing.

Foraging and Food An eclectic predator, preying on anything from termites and grasshoppers to snakes and rodents. Nevertheless, its staple food is generally small mammals or insects (Stuart 1981, 1991, Cavallini & Nel 1990a, Avenant & Nel 1997, Stuart & Stuart 1998b). Cavallini & Nel (1990a) analysed 234 scats from West Coast N. P. in the Western Cape and found that murids (90.4%) predominated. In another study from the same area, Avenant & Nel (1997) found the same predominance, with insects (4.9%) forming a secondary food resource. *Otomys* spp. and Four-striped Grass Rat *Rhabdomys pumilio* appear to be favoured murid prey (Stuart 1981, 1991, Cavallini & Nel 1990a, Avenant & Nel 1992, 1997). Other studies from elsewhere in South Africa (Du Toit 1980, Lynch 1983, MacDonald & Nel 1986, Stuart & Stuart 1998b) echo these insectivorous and carnivorous dietary tendencies. It has been recorded feeding on larger mammal prey such as Scrub Hare *Lepus saxatilis* and Cape Porcupine *Hystrix africaeaustralis* (Cavallini 1992, Stuart & Stuart 1998b), and has even been known to attack Cape Grysbok *Raphicerus melanotis* lambs by tearing at the nose and mouth, eventually killing them (Langley 1986). However, because it will scavenge (Stuart 1981, Stuart & Stuart 1998b) and take urban refuse (Cavallini & Nel 1990a), it is uncertain to what extent this

occurrence of large prey in their diet is the result of active predation or scavenging.

Usually it moves from bush to bush, inspecting potential foraging sites like holes and rodent nests. It seems to rely mainly on sight and smell for locating prey. It scratches the soil in search of invertebrates, but is not an avid digger as other mongooses. Insects caught on the ground are held down with the front feet and then taken directly in the mouth. Larger prey are stalked, the killing bite delivered to the head. Small mammals are chewed in the side of the mouth, and insects are thoroughly masticated. Larger and tougher prey is held with the front feet firmly on the ground and then torn apart. Like other mongooses, it can break eggs by throwing them against a vertical surface (Ewer 1973). While foraging, individuals usually move 50–100 m every 15 min, with much individual variation (Cavallini & Nel 1990b), moving more than 4 km during the course of a day's foraging (Cavallini & Nel 1995). It has been observed to associate with small raptors (e.g. African Marsh Harrier *Circus ranivorus*) during foraging (Lombard 1989).

Social and Reproductive Behaviour Normally seen singly, sometimes in pairs and rarely in trios (more often in summer and early autumn, after parturition; e.g. Crawford *et al.* 1983). Of 163 sightings made by Stuart (1991), 151 were of single animals, seven were of pairs and five were of groups of three; Stuart (1981) recorded groups of up to five. Groups typically consist of one or two adults and juveniles. The lack of observations of ♀♀ moving with young may be due to the fact that the young are weaned in the breeding holes and eventually leave these only at a stage when they are capable of looking after themselves (Skinner & Chimimba 2005).

Males may show some sociality, with stable dyads comprising a large and a small individual. This behaviour has been observed also in the closely related Slender Mongoose. Males do not seem to maintain exclusive territories. In West Coast N. P., Cavallini & Nel (1990b) gave the home-range size of three ♂♂ as 55–92 ha; a ♀ had the smallest range (30.6 ha) while another ♀, a juvenile, ranged more widely (359 ha), possibly dispersing. Home-ranges overlapped widely, both within and between sexes. Similarly, Stuart (1991) gave the mean home-range size of four animals as between 5 and 36 ha in extent and stated that there appeared to be considerable overlap in home-ranges.

Reproduction and Population Structure Cape Grey Mongooses are seasonal breeders. Lactating ♀♀ have been found in Aug and in Nov–Feb, and the breeding season is probably at the end of winter (Aug–Dec; Stuart 1981, Lynch 1983). Reproductive output is low (1–3 young per litter). Rock crevices, farm outbuildings, fodder stores and woodpiles are used for rearing young (C. Stuart & T. Stuart pers. comm.). A captive mongoose lived for more than 11 years (Weigl 2005).

Predators, Parasites and Diseases Because of their small size, Cape Grey Mongooses have a number of potential predators, including large raptors and various carnivores. Martial Eagles *Polemaetus bellicosus* prey on them frequently (7.4% of items collected at nests; Boshoff & Palmer 1980), and Leopards *Panthera pardus* and Caracals *Caracal caracal* kill and eat them; they have even been recorded in the scats of Marsh Mongooses *Atilax paludinosus* (Stuart & Stuart 1998b, 2003a). Several parasites have been found on individuals of this species, including *Echidnophaga gallinacea*, *Ctenocephalides connatus*,

C. felis, *Procaviopsylla angolensis* and *Ixodes pilosus* (Cavallini 1992), while Horak *et al.* (2000) recorded the ixodid tick *Haemaphysalis zumpti* from an animal in the NW Northern Cape, as well as *Amblyomma marmoreum*, *H. zumpti* and an unidentified *Ixodes* sp. from two animals in the Eastern Cape. Cape Grey Mongooses are vectors of rabies, although they are not considered major carriers (Meredith 1982).

Conservation IUCN Category: Least Concern. CITES: Not listed.

No major threats are known, since the species is relatively adaptable, with a very catholic diet, and occurs in a number of protected areas in its range, including West Coast, Tsitsikamma and Mountain Zebra National Parks.

Paolo Cavallini

Herpestes sanguineus SLENDER MONGOOSE

Fr. Mangouste rouge; Ger. Rotichneumon

Herpestes sanguineus (Rüppell, 1835). Neue Wirbelt. Fauna Abyssin. Gehörig. Säugeth. 1: 27. 'Kordofan' [Sudan].

Slender Mongoose *Herpestes sanguineus*.

Taxonomy Included in subgenus *Galerella*. The taxonomy of the Slender Mongoose has been complicated by the description of numerous forms, many of which represent little more than colour morphs. Coetsee (1977) assigned the described taxa to two different sections: the *sanguineus* section, drab brown to yellowish-grey in general colour usually with a black tail tip (31 subspecies), and the *ratlamuchi* section, being reddish in colour and usually with a dark, but not black, tail tip (11 subspecies). Within these sections, Meester *et al.* (1986) listed 18 subspecies for southern Africa alone: 14 in *sanguineus* and four in *ratlamuchi*. In their revision, Watson & Dippenaar (1987) argued for the separation of the forms *nigratus* (here placed in *flavescens*; see species profile) and *swalius*, and considered the form *swinnyi* as *incertae sedis*. In a subsequent study, Watson (1990) could find no evidence to justify the recognition of any subspecies in *H. sanguineus* from southern Africa, and proposed that all subspecies be regarded as synonyms of *H.*

s. cauii, except for *swalius*, which he considered a monotypic species, occurring sympatrically with *H. sanguineus* in C and S Namibia. However, Taylor & Goldman (1993) presented evidence to regard *G. swalius* as conspecific with *sanguineus*, noting that the characters used by Watson (1990) to separate *swalius* (postorbital bar incomplete, coat colour and head and tail measurements) are poor diagnostic features. Azzaroli & Simonetta (1966) also considered *ochraceus* a distinct species, as did Taylor & Goldman (1993) and Wozencraft (2005), and this is followed here. Given the apparent large degree of individual variation within the species, and the unreliability of the features generally used to diagnose subspecies, none are recognized here pending a complete revision of subspecific boundaries. The situation is best summed up by Hinton & Dunn (1967: 112) who remark: 'From a brief examination of the material in the British Museum (Natural History), it would appear that most of the subspecies now recognized are simply seasonal

Lateral view of skull of Slender Mongoose *Herpestes sanguineus*.

or other types of colour variations: the large number of subspecies that have been described testifies to the industry but not to the discretion of taxonomists'.

Synonyms: *auratus*, *badius*, *bradfieldi*, *caldatus*, *canus*, *cauui*, *dasilvai*, *dentifer*, *elegans*, *erongensis*, *fuscus*, *galbus*, *galinieri*, *gracilis*, *grantii*, *ibaeae*, *ignites*, *ignitoides*, *iodoprymnus*, *kalaharicus*, *kaokoensis*, *khanensis*, *lancasteri*, *lefebvreii*, *marae*, *melanura*, *mossambica*, *mustela*, *mutgigella*, *mutscheltschela*, *ngamiensis*, *nigricaudatus*, *ochromelas*, *okavangensis*, *orestes*, *ornatus*, *parvipes*, *phoenicurus*, *proteus*, *punctulatus*, *rendilis*, *ruficauda*, *saharae*, *swalius*, *swinnii*, *ugandae*, *upingtoni*, *venatica*, *zombie*. Chromosome number: $2n = 42$ in ♀♀, $2n = 41$ in ♂♂ (Fredga 1970, 1972, 1977).

Description A small, slender mongoose with elongated sinuous body, short limbs and long tail. Face pointed, and rhinarium small and usually pinkish-brown to light brown in colour; a slit divides the hair on the upper lip. Eyes oval in shape surrounded by bright orange iris. Ears typically herpestid in shape, closely adpressed to side of head. Considerable variation in pelage colour is evident across the range of the species, with some individuals nearly black (melanistic) and others quite red (erythristic); pelage colour seems to correlate with substrate colour and dryness of the environment. Most common colour is grizzled brown or brownish-grey. Length and texture of coat varies. Upperparts of body generally grizzled caused by annulations of buffish-white rings alternating with dark brown to blackish rings. Dark rings are broader than pale rings. Individual hairs have six rings alternating light and dark, the base being pale and the tip dark. Hairs on head more finely grizzled than those on tail. Individual hairs vary greatly in length, those on upper parts reaching as much as 40 mm in length, but shorter on head. Ventral coat more variable, either grizzled or uniform buff, and fur thinner, shorter and softer than dorsal fur due to higher proportion of underfur. Both hind- and forefeet have five toes. First digits are much reduced and situated proximal to plantar pads and generally do not appear in the spoor; sole of hindfoot is nearly naked. A narrow web connects the digits of each foot. Claws sharp and curved, with those on forefeet up to 7 mm in length (measured across the curve). Tail long and slender, approximately equal to HB length; invariably terminates in dark to black tuft (70–130 mm in length). Anal sac beneath tail houses the anus and a pair of anal glands, one on each side of the anus. Anal sac is 20–30 mm in diameter. Males are approximately 9% larger than ♀♀ (Taylor 1971a). Females have two pairs of abdominal nipples, although specimens with three pairs have been reported (Roberts 1951).

Braincase oval, broadest at about level of ear openings and narrowing in front to the postorbital constriction. In adult specimens postorbital bars are complete, enclosing back of eye sockets. Rostrum short and broad. Flange-like supraoccipital crest well developed in adult skulls, but sagittal crest barely noticeable. Coronoid process of lower jaw high, providing ample leverage for temporalis muscles. Canines are sharp, with the upper nearly straight, the lower recurved. Lower incisors smaller than upper

incisors. First upper premolars are small and peg-like and sometimes absent (in a sample of 131 skulls, they were absent in 8%) (Rosevear 1974, Skinner & Chimimba 2005; and see Martinoli *et al.* 2006).

Geographic Variation As noted under Taxonomy, this is a highly variable species with regards to coat colouration, and while there may be some general differences in size (e.g. in West African specimens, southern specimens were generally slightly larger than the northern; Taylor & Goldman 1993), polychromatism is common, even within groups, and the characters generally used to distinguish subspecies appear unreliable.

Similar Species

Herpestes ochraceus. Somalia and Ethiopia. Distinguished by a light sandy coat colour (with black tail tip absent) and a shortened and wider cranium with distinctive inflated auditory bullae.

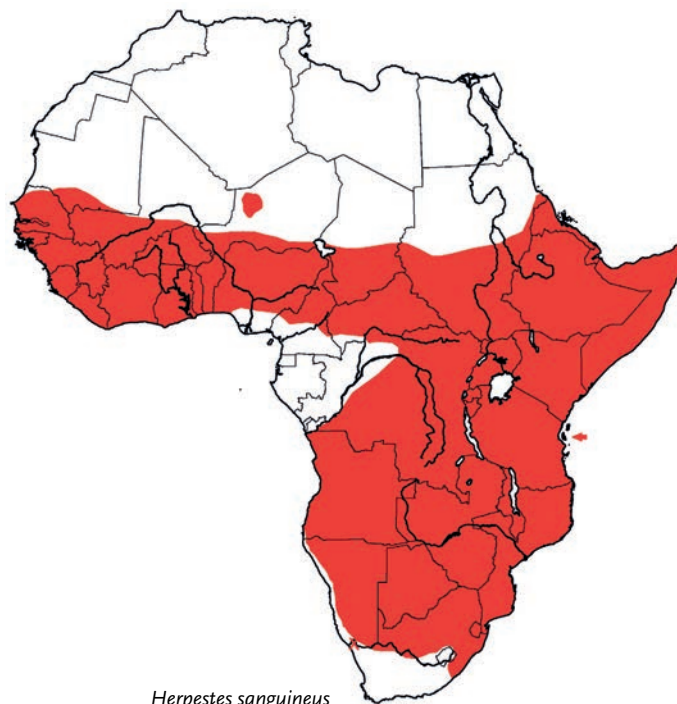

H. flavescens. Apparently sympatric in N Namibia. Generally larger, and usually melanistic or erythristic.

H. pulverulentus. Confined to southern Africa. Slightly larger, generally grey or blackish and lacking a black tail tip (though sometimes with tail tip brown).

H. ichneumon. Sympatric across much of range, but also found across North Africa. Larger, with longer coat and shaggy appearance; generally greyer and with characteristic black-tipped tail.

Helogale parvula. Smaller, has a short tapered tail without a black tip. A colonial diurnal species (while all the *Herpestes* species are primarily solitary and diurnal).

Distribution Endemic to Africa. One of the most widely distributed of the African mongoose species, ranging south of the Sahara from Senegal in the west to the Red Sea coast in Sudan in the east and south to the Northern Cape, north of the Orange R., in South Africa (Taylor 1975, Skinner & Chimimba 2005). Their most southerly distribution limit is probably the far eastern part of the Eastern

Herpestes sanguineus

Cape in South Africa, and they are common throughout most of E KwaZulu–Natal (Rowe-Rowe 1992a). Stuart (1981) mentions a museum record of this species from Mountain Zebra N. P., but this specimen is not mentioned in the studies of Watson & Dippenaar (1987) and Watson (1990). Also occurs on Zanzibar (Pakenham 1984, Stuart & Stuart 1998c, Goldman & Winther-Hansen 2003).

Habitat Occurs in a wide variety of habitats, ranging to altitudes of 2700 m in the Ethiopian Highlands (Yalden *et al.* 1996), but is absent from true deserts (such as the Namib Desert), although Slender Mongooses do occur in the pro-Namib (Coetzee 1969) and in sub-desertic parts of the Sahara such as Aïr, Niger (J. Newby, in Busby *et al.* 2006). They occur on forest fringes, and may penetrate into forests along roads and are sometimes found around villages. Their absence from much of South Africa, south of the Orange R., may well be due to competitive exclusion with the Cape Grey Mongooses *H. pulverulentus*.

Abundance Slender Mongooses are diurnal and are among the most common mongooses in Africa. In the Serengeti N. P., Tanzania, population densities between 1975 and 1990 ranged from three to six individuals/km² (Waser *et al.* 1995).

Adaptations A generalist carnivore, the dentition of the Slender Mongoose is adapted for crushing, but also for slicing. The carnassial shear is well developed. The fourth upper premolar, the carnassial, is large, its length more than 30% that of the total length of the toothrow; the three premolars in the lower jaw are also sharp and high-cusped. All upper premolars have high sharp cusps. The first lower molar is large, and the outer hind cusp enlarged with a sharp cutting edge; the upper first molar is elongated (Rosevear 1974, Skinner & Chimimba 2005).

Although largely terrestrial, Slender Mongooses are more arboreal than most other mongoose species (facilitated by their short, curved claws), and, while not accomplished climbers, they have been recorded running up and down wire netting, stone-walls, trees and branches (Taylor 1970a, T. Struhsaker pers. comm.). Taylor (1970a) investigated the mobility of the limb bones in three animals, and found that the species exhibited a greater degree of flexibility than in Egyptian Mongoose *H. ichneumon*, which was correlated with the high agility of the Slender Mongoose.

Dens are used for shelter and for births. Although capable of digging their own burrows, Slender Mongooses usually make use of pre-existing burrows for their dens. Dens may be either holes in the ground, usually modified Aardvark *Orycteropus afer* burrows, termitaria, rock piles or crevices, under tree roots or at the base of trees, or in hollow logs. Bronner (1992) described four burrows characterized by single entrances connected to single large chambers (398 ± 212 mm long × 327 ± 172 mm wide × 135 ± 54 mm high) via short passages; there was no nesting material present.

Slender Mongooses are predominantly diurnal. Maddock & Perrin (1993) found animals to be active between 08:00h and 18:00h, moving from their resting-sites late in the morning; there was a slight peak in activity about one hour before sunset and activity ceased shortly after sunset. Likewise, camera-trapping studies on Zanzibar found them to be active during the day (Goldman & Winther-Hansen 2003). The Slender Mongoose has a moderate metabolic rate of 0.76 cm³/g/h, comparable with the Small Indian Mongoose *Herpestes javanicus* (Kamau *et al.* 1979).

Foraging and Food Slender Mongooses are generalist carnivores, their diet predominated by small vertebrates and invertebrates. In a sample of 60 stomachs from Botswana and Zimbabwe, insects had the highest percentage occurrence (73%), represented mainly by grasshoppers, followed by termites, beetles and ants. Lizards had the next highest percentage occurrence (27%), with a wide range of species recorded, including, for example, the Southern Tree Agama *Acanthocercus atricollis* and the Variable Skink *Trachylepis varia*; murids, next highest in percentage occurrence (25%), included species of the genera *Mastomys*, *Rhabdomys* and the Large Creek Rat *Pelomys fallax* (Smithers 1971, Smithers & Wilson 1979). Ansell (1965) recorded the remains of a squirrel from one stomach. Other prey items recorded in stomachs include snakes (they are reported to take even large, poisonous snakes such as cobras and mambas; Rood & Waser 1978, Skinner & Chimimba 2005) and wild fruits, such as berries of the raisin bush (*Grewia* spp.) and wild figs (*Ficus* spp.). Feathers are occasionally found in both the stomachs and faeces of Slender Mongooses. These are among the few mongooses known to readily climb trees, and have been suggested to actively hunt birds (Bates 1905, Hinton & Dunn 1967).

Seasonal changes in diet appear evident, with insects having a higher percentage occurrence (68%) in stomachs sampled in the warm, wet months from Oct to Apr compared with the dry cold months from May to Sep (30%), corresponding to the increased abundance of insects at the onset of the rains. On the other hand, murids and reptiles had a higher percentage occurrence during the drier months, when insects were less abundant (Taylor 1969, Skinner & Chimimba 2005).

Slender Mongooses will pounce on or chase after small vertebrates, or flush insects, such as grasshoppers, from hiding and catch them in mid-air. They have been observed to move swiftly and silently when hunting, sniffing and searching visually without pausing to scrape and scratch at crevices (Ewer 1973). A captive animal would toy with its prey before delivering a single killing bite to the head/neck region (Jacobsen 1982). Small rodents appear to be consumed in their entirety, including the skin, as evidenced by the presence of heads, tails, feet and intestines in stomach contents and solid masses of hair in faeces (Rautenbach 1982), although Jacobsen (1982) noted that a captive animal would leave the skin, tail and feet. Captive Slender Mongooses show a predilection for eggs, which they handle in the same manner as Banded Mongooses *Mungos mungo*, hurling them between their back legs against a wall or other hard object in order to break them open (Jacobsen 1982, Skinner & Chimimba 2005).

A Slender Mongoose was seen feeding on the carcass of a Cape Porcupine *Hystrix africaeaustralis*; the mongoose stuck its head deep into the exposed flesh of the porcupine's neck and, after biting off a chunk of flesh, backed out and stood erect, chewing the flesh while surveying the surrounds (Bates 1990). Other authors have also recorded utilization of carrion, as in the case of Rautenbach (1982), who recorded *Cyclorrhapha* maggots in stomachs. Vaughan (1976) observed two ♂♂ and a ♀ visiting a Giraffe *Giraffa camelopardalis* kill in order to feed on fly larvae that they dug up from beneath the carcass. Slender Mongooses are known to be poultry thieves (Roberts 1951).

Social and Reproductive Behaviour Slender Mongooses are primarily solitary. In Serengeti N. P. ♂♂ hold single-male territories of approximately 50 ha in size, which usually encompass the territories of several ♀♀; female territories are approximately

Slender Mongoose *Herpestes sanguineus*.

25 ha (Rood & Waser 1978). Female territories do not overlap, and it is likely that the same applies to ♂♂, although two adult ♂♂ have been seen foraging in the same area (though this may have been a transitory association). In such cases, one animal typically proves to be heavier than the other, perhaps suggesting that dominant ♂♂ tolerate subordinates in their territory. Males also sometimes form loose, non-aggressive associations with as many as four individuals using the same home-range, which may overlap the ranges of up to six ♀♀. These coalitions exclude other ♂♂ from access to ♀♀ within a common territory, although no single individual monopolizes matings with ♀♀ within the territory. Such associations are stable in composition, with ♂♂ often closely related, and may persist for up to seven years (Waser *et al.* 1994b; see also Rood 1989). Territories may be larger in other areas; Maddock (1988) and Taylor (1970a) recorded territories up to 100 ha in size.

Slender Mongooses are often seen travelling along roads or pathways, tail low with only the dark tip raised, nose to the ground, and back arched. When pursued, the tail flips up into a vertical position. When disturbed, they may stand motionless. Both ♂♂ and ♀♀ make use of latrines for urination and defecation. Males mark with the anal gland during the mating season. Baker (1981) studied the agonistic behaviour of Slender Mongooses in captivity. Threat displays between a dominant and subordinate individual included snapping and spitting, with subordinates usually responding to the postures of dominants by turning their lowered head away and retracting their lips to show the pink gums, or by approaching in a submissive posture.

Jacobsen (1982) observed sexual behaviour in a captive pair. The ♂ followed the ♀ closely while she was in oestrus (which may last more than a week), and attempted to mount her whenever she stood still. Initial copulations were brief (30 sec), but later copulations lasted longer (150 sec). In one mating instance, the ♂ grabbed the ♀ by her ear and attempted to pull her along, before proceeding to mate with her while clasping her midriff with his forelegs. Young are born in dens, which are not used for more than 3–4 days at a time, the pups being moved from den to den. Mothers are very protective of their young, and, in captivity, ♂♂ also displayed protective tendencies, often carrying their young (Jacobsen 1982).

Five different vocalizations have been recorded in captive Slender Mongooses, including a loud, sharp 'spit', a growl, a snarl and a 'buzz', which are used in agonistic encounters; growling and spitting are produced when threatening a conspecific or warding off attackers, and snarling when two animals approach each other in attack. The fifth vocalization, a 'huh-nwe' call, is used as a distress call (Baker 1982).

Inter-specific interactions include playful interactions with hyraxes, antelopes and monkeys (Estes 1991), and foraging associations between Slender Mongooses and Pale Chanting-goshawks *Melierax canorus* have been documented (Paxton 1988, Lombard 1989, Borello & Borello 1990; and see Macdonald 1990). Social mongooses, such as Dwarf Mongooses *Helogale parvula* and Banded Mongooses *Mungos mungo*, will go on the offensive if a Slender Mongoose approaches too closely (Rood & Waser 1978).

Reproduction and Population Structure Slender Mongooses are seasonal breeders, and births appear to correspond with the wet season. In southern Africa, this corresponds to the warmer

months from Oct to Mar (Ansell 1963, Smithers 1971, Rowe-Rowe 1978a, Stuart 1981, Rautenbach 1982), while in East Africa this corresponds to either the short rains (Oct and Nov) or long rains (Feb–Apr) (Taylor 1969). Rood & Waser (1978) recorded a ♀ in Serengeti N. P. giving birth in Mar and again in Jul. In Liberia, in West Africa, Coe (1975) recorded a lactating ♀ in early Sep.

Gestation is probably in the order of 60–70 days and litter-size has been recorded as 2–4 (Taylor 1969, 1975). In Serengeti N. P. 35 young were observed in 39 female years, suggesting a mean of 0.9 young per ♀ per year (Waser *et al.* 1995). Pups grow rapidly, attaining two-thirds of their adult body weight in about 50 days. Eyes open fully at three weeks, pups begin eating solid food at four weeks and are weaned at 7–9 weeks (Jacobsen 1982). At the age of one year, Slender Mongooses are close to adult weight. Females routinely reproduce as yearlings (Waser *et al.* 1995).

In Serengeti, juveniles dispersed within their first six months, and ♂♂ appeared to disperse earlier and further; ♂♂ were only 25% as likely as ♀♀ to be captured with their mothers, suggesting earlier emigration (Waser *et al.* 1995).

Waser *et al.* (1995) suggested a juvenile survival rate of 0.63. Once established as adults, ♂♂ and ♀♀ had high survival rates: 0.82 for ♂♂ and 0.79 for ♀♀. Maximum observed longevity in the wild was eight years for both sexes (Waser *et al.* 1995). A captive animal lived to 12.6 years (Weigl 2005).

Predators, Parasites and Diseases The main predators include raptors, such as the African Hawk-eagle *Hieraaetus spilogaster*, Tawny Eagle *Aquila rapax* and Martial Eagle *Polemaetus bellicosus* (see, for example, Robinson & Stuart 1975, Steyn 1980) and mongooses are exceptionally alert to aerial predators. Larger carnivores, such as Lions *Panthera leo*, Leopards *P. pardus* and African Wild Dogs *Lycaon pictus* may also take individuals.

Relative to other herpestids, there is a wide body of information available on ecto- and endo-parasites. Taylor (1975; and see references therein), in reviewing the literature available at the time, recorded the helminth *Rictularis myonacis*, nematodes of the genera *Riticularia*, *Filaroides* and *Travassospirura*, and the cestodes *Mathevotaenia herpestis* and *M. ichneumonitis*. Pierce (1972) recorded the protozoan parasite *Babesia* sp., and Iori & Lanfranchi (1996) documented the Slender Mongoose as a new host for *Oxinema* sp. Haeselbarth *et al.* (1966) mention the following arthropod parasites: *Echinophaga bradyta*, *E. gallinacea*, *Pulex irritans*, *Ctenocephalides felis*, *Synosternus burtoni* and *Listropsylla agrippinae*. Horak *et al.* (2000) recovered five species of ixodid ticks from an animal in Kruger N. P. and another animal from Mpumalanga in South Africa: *Haemaphysalis spinulosa*, *H. zumpti*, *Ixodes* sp., *Rhipicephalus appendiculatus* and *R. zambeziensis*; *H. leachi* has been recorded from a specimen from Congo (Bequaert 1930). Hoogstraal *et al.* (1992) recorded a new species, *H. subterra*. Herrin & Tipton (1976) mention the tick *Laelaps liberiensis* from a specimen from Liberia.

In East Africa, the Slender Mongoose is said to be very prone to rabies (Maberly 1960). They may also have antibodies for various rickettsias, including *Dermacentroxenus akari*, which causes a tick-borne disease known as rickettsialpox (Heisch *et al.* 1962).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Cunningham & Zondi (1991) listed this species among those used in traditional medicine in KwaZulu–Natal. Slender Mongooses have also been recorded in bushmeat markets, as in villages in the Classified Forest of Diecké (Colyn *et al.* 2004), although Cansdale (1946) noted that because of its strong odour it was the only carnivorous mammal not eaten. Otherwise, Slender Mongooses are common and widespread, and present in numerous protected areas across their range.

Measurements

Herpestes sanguineus

TL (♂♂): 595 (560–652) mm, n = 25
 TL (♀♀): 555 (506–600) mm, n = 19
 T (♂♂): 278 (240–299) mm, n = 25
 T (♀♀): 261 (233–272) mm, n = 19
 HF c.u. (♂♂): 65 (60–69) mm, n = 25
 HF c.u. (♀♀): 58 (52–60) mm, n = 18
 E (♂♂): 25 (21–28) mm, n = 25
 E (♀♀): 24 (22–25) mm, n = 18
 WT (♂♂): 637 (523–789) g, n = 24
 WT (♀♀): 459 (373–565) g, n = 15
 Zimbabwe (Smithers & Wilson 1979)

TL (♂♂): 555 (410–630) mm, n = 37
 TL (♀♀): 524 (425–590) mm, n = 37
 T (♂♂): 268 (194–310) mm, n = 35
 T (♀♀): 263 (212–290) mm, n = 38
 HF c.u. (♂♂): 59 (45–70) mm, n = 34
 HF c.u. (♀♀): 54 (44–60) mm, n = 37
 E (♂♂): 23 (14–28) mm, n = 35
 E (♀♀): 22 (15–26) mm, n = 35
 WT (♂♂): 531 (363–650) g, n = 14
 WT (♀♀): 402 (277–498) g, n = 11
 South Africa (Rautenbach 1982)

Skull measurements:

GLS (♂♂): 65.0 (60.0–70.4) mm, n = 52
 GLS (♀♀): 63.0 (58.5–68.0) mm, n = 30
 GWS (♂♂): 33.3 (30.0–37.6) mm, n = 52
 GWS (♀♀): 31.1 (28.3–34.4) mm, n = 30
 Kenya (Taylor & Goldman 1993)

GENUS *Bdeogale*

Bushy-tailed Mongooses (Dog Mongooses)

Bdeogale Peters, 1850 Spenerische Z., 25 June 1850 (unpaginated).

Jackson's Mongoose *Bdeogale jacksoni*.

Jackson's Mongoose *Bdeogale jacksoni* myology.

The genus contains four species: the Bushy-tailed Mongoose *Bdeogale crassicauda*, the Sokoke Bushy-tailed Mongoose *B. omnivora*, Jackson's Mongoose *B. jacksoni* and the Black-legged Mongoose *B. nigripes*.

Mongooses in the genus *Bdeogale* occur in eastern and central Africa. The Bushy-tailed Mongoose occurs in eastern Africa, from E Zimbabwe to Kenya (and including Zanzibar). The Sokoke Bushy-tailed Mongoose, found in the coastal forests of Kenya and NTanzania,

is considered by some authors (e.g. Wozencraft 1993, 2005) to be a subspecies of the Bushy-tailed Mongoose with a distinctively yellowish-orange underfur. Jackson's Mongoose occurs in upland forests in C Kenya, ETanzania and E Uganda and has been included by some authors (e.g. Kingdon 1977) as a subspecies of the Black-legged Mongoose *Bdeogale nigripes*, which is found primarily in the forested regions of N Angola, parts of DR Congo and north-west to Nigeria.

Representatives of this genus are characterized by having a generally dark brown to blackish pelage with distinctly dark legs and feet and four toes on both fore- and hindfeet. The tail is bushy rather than tapered and relatively uniform in colour without any distinctive coloured tip. Head is generally short and rounded and ears rounded. In the skull, the orbits are not closed posteriorly, and the anterior portion

of the bulla is not inflated. Molariform teeth are broad and adapted for crushing rather than shearing; hypocone present. Dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$. Species are primarily insectivorous, but will eat fruits, small vertebrates and carrion. Members are solitary, and primarily nocturnal (though may forage during the day). They are adapted for a walking-trotting form of locomotion.

The genera *Bdeogale* and *Galeriscus* have been considered as separate genera by some earlier authors, the latter genus having been created by Thomas (1894b) to include *jacksoni*; several authors included also *nigripes* (e.g. see Rosevear 1974). Coetzee (1977) used *Galeriscus* as a subgenus for *nigripes* and *jacksoni*. *Bdeogale* shares many dental features with *Ichneumia* (Pocock 1919), and molecular data suggest a close relationship with *Ichneumia*, *Rhynchogale* and *Cynictis* (Perez *et al.* 2006, Patou *et al.* 2009).

Bdeogale crassicauda BUSHY-TAILED MONGOOSE

Fr. Mangouste à queue touffue; Ger Buschschwanzichneumon

Bdeogale crassicauda Peters, 1852. Monatsber. K. Preuss. Akad. Wiss. Berlin 1852: 81.

Africa orient., Tette, Boror, 17–18 Lat. Austr. (pg. 82). Restricted by Moreau *et al.* (1946: 410) to 'Tette' [Mozambique].

Bushy-tailed Mongoose *Bdeogale crassicauda*.

Taxonomy As many as five subspecies of the Bushy-tailed Mongoose have been described (Coetzee 1977, Taylor 1987), but they are poorly defined and are based more on distribution than major structural differences (Taylor 1987; and see Geographic Variation). The closely related Sokoke Bushy-tailed Mongoose *B. omnivora* is treated as a subspecies of the Bushy-tailed Mongoose by some authors (Taylor 1987, Wozencraft 1993, 2005, Engel & Van Rompaey 1995). The four subspecies listed here are provisional, and require critical revision.

Synonyms: *nigrescens*, *puisa*, *tenuis*. Chromosome number: not known, but likely $2n = 36$ as in other *Bdeogale* (Wurster & Benirschke 1968).

Description A medium-sized mongoose with uniform brownish coat, darker limbs and feet and bushy tail about 60% of head and body length. Head rather rounded for a mongoose, giving the appearance of a short muzzle, and the rhinarium divides the hairy portions of the upper lip. Ears rounded. The eye has a horizontal pupil with greyish-brown iris. Underfur dense and greyish-buff in southern forms, grading to yellowish-brown in northern races. Guard hairs about 5 mm long on the forehead, increasing in length towards the rump where they reach about 45 mm; banded with two or three whitish

annulations although the degree and extent of banding is variable (Sale & Taylor 1970, Skinner & Chimimba 2005). Limbs are covered in uniform short black hair. Tail length is less than 300 mm, bushy towards the distal third (Peters 1852) with guard hairs up to 55 mm long. Four digits on both fore- and hindfeet. The relatively short claws are robust. The forefoot has a single symmetrical ovoid pad while the hindfoot pad has two, a larger ovoid distal pad and a distinct smaller proximal lobe. Longest claw length 11 mm (Peters 1852). There is no appreciable difference in size between ♂♂ and ♀♀. The vulva is only a short distance below or in front of the anal sac. The baculum is about 15 mm long. Two pairs of abdominal nipples.

Skull broadest at level of the glenoid articulation, postorbital bars never complete and supraoccipital crest well developed. Sagittal crest high at back of braincase, tapering anteriorly and disappearing at level of the postorbital constriction. Zygomatic arches robust, suggesting well-developed masseters, and the high coronoid process of the mandible indicates a large area for insertion of temporalis muscle (and strong jaw action).

Upper incisors long, well separated, and forming a curved row; lower incisors lie tightly together. Upper canines nearly straight with sharp cutting edges in front and behind though in some specimens they are markedly worn. First premolars small and peg-like, second premolars like members of the genus *Herpestes*, while posterior premolars and molars are broadly rectangular in shape.

Geographic Variation

B. c. crassicauda: Mozambique, E Zimbabwe, and north through Malawi.

B. c. puisa: NE Mozambique and E Tanzania.

B. c. tenuis: Zanzibar.

B. c. nigrescens: inland at Lukenya near Nairobi in Kenya. This subspecies appears darker than the other subspecies partly due to the darker underfur; tail with dense covering of dark hairs giving a 'bottle-brush' appearance (Sale & Taylor 1970).

Lateral and palatal views of skull of Bushy-tailed Mongoose *Bdeogale crassicauda*.

Populations from the south, *B. c. crassicauda* and *B. c. puisa*, may be slightly larger, though the range in body and cranial measurements for other mongooses in East Africa suggest that this is possibly due to the small sample of published measurements (Peters 1852, Sale & Taylor 1970, Skinner & Chimimba 2005). Sale & Talyor (1970) detail the coat characteristics of the four subspecies.

Similar Species

Bdeogale omnivora. Coastal forests from N Tanzania to coastal S Kenya. Slightly smaller, and generally more yellowish due to the distinct orange underfur and brown rather than black portions of guard hairs (Sale & Taylor 1970).

B. jacksoni. Highland regions of Kenya, SE Uganda, and the Udzungwa Mtns in Tanzania. Head and body length greater than 500 mm (Kingdon 1977).

Paracynictis selousi. Sympatric in Zimbabwe and Mozambique. Larger; greyish, with white end to the tail; P4, M1 and M2 are noticeably thicker and rounded.

Rhynchogale melleri. Woodland habitat from N Tanzania south to NE South Africa. Individuals may have partially white tails, but pelage overall more brown; distinct crest-like parting on either side of neck; no central vertical slit on front of rhinarium.

Distribution Endemic to Africa, the Bushy-tailed Mongoose ranges from the Lukenya foothills of SE Kenya southwards through Tanzania, Malawi and SE Zambia to N and E Zimbabwe (extending about as far west as L. Kariba; see Ansell 1978) and C Mozambique, their most southerly limit of distribution at around 20° 10' S (Taylor 1986, 1987). Also present on Zanzibar (Pakenham 1984, Stuart & Stuart 1998c, Goldman & Winther-Hansen 2003). Camera-trapping surveys have resulted in many new distribution records, particularly in Tanzania including records from Ngorongoro Conservation Area, and from Biharamulo-Burigi-Kimisi G. R. and Mahale Mountain N. P. in the west (Pettorelli *et al.* 2010) and from Udzungwa N. P. (F. Rovero pers. comm.). These records provide evidence that the species is more widely distributed and more common than previously thought, and complement what has been considered an outlying record from Mweru Wantipa in the north of Zambia (Ansell

Bdeogale crassicauda

1978). The species has also apparently been recorded from DR Congo, where Ansell (1974) reported on two specimens (originally identified as Meller's Mongoose *Rhynchogale melleri*) in the Musée Royal de l'Afrique Centrale, Tervuren, from Kansenia (10° 19' S, 26° 02' E) and from Katentania (10° 19' S, 25° 55' E).

The Bushy-tailed Mongoose has been reported from coastal sites in Yemen (Nader & Al-Safadi 1991) where it may have been introduced from traders carrying animals from eastern Africa or Zanzibar; however, Simmons (1995) states that this record requires confirmation using cranial features, inferring that the juvenile female specimen in question could represent the White-tailed Mongoose *Ichneumia albicauda*.

Habitat The Bushy-tailed Mongoose is found in a variety of habitats through its range. It is found in *Acacia* woodlands in Mozambique, on rocky outcrops in NE Zimbabwe and Kenya, in *Brachystegia* woodland in parts of Zimbabwe and Malawi and in riverine woodlands. This species was photographed in most habitats within Udzungwa Mountains N. P., including montane and bamboo forest up to 1850 m (De Luca & Mpunga 2005) and in coral-rag thicket and ground-water forest in Zanzibar (Goldman & Winther-Hansen 2003). There do not appear to be obvious explanations as to its habitat preferences and consequent distribution as it appears to occur in disjunct populations in a variety of habitats.

Abundance In spite of extensive collections of mongooses through eastern Africa during the past 150 years, there are relatively few specimens of this species in museum collections, and it has generally been reported as uncommon (Ansell 1978, Smithers & Wilson 1979, Ansell & Dowsett 1988). Bushy-tailed Mongooses are very rarely observed in the wild: K. Howell (pers. comm.) has not seen this species in ten years of fieldwork, and D. Moyer (pers. comm.) has only seen it twice. John Sale collected two animals in Feb 1965, and Sale & Taylor (1970) collected seven animals in Nov and Dec 1967 at Lukenya, 37 km south-east of Nairobi (from

whence they described the subspecies *nigrescens*), suggesting that the species is relatively easy to catch when present. Indeed, the advent of camera-trapping has shown this species to be more common than supposed. Pettorelli *et al.* (2010) photographed the species in 31 different locations and five different study areas in Tanzania during 11 surveys. A photo-trapping exercise in the Udzungwa Mts took 79 photographs of this species in 674 trap-nights; at 8.5 trap-nights per photo this was by far the most frequently recorded carnivore (by contrast, 126 trap-nights per photo for Leopard *Panthera pardus*; De Luca & Mpunga 2005). This species was also the most common animal camera-trapped in other parts of the Eastern Arc Mts, including the Ulugurus and Ngurus (F. Rovero pers. comm.), and among the most frequently captured during a live-trapping survey in Arusha N. P. (Martinoli *et al.* 2006). J. Kingdon (pers. comm.) also reports the species was relatively common in densely wooded areas along Tanzanian river courses, in many pockets throughout the coastal littoral and around hilly and lower montane areas immediately inland from the coast.

Adaptations The Bushy-tailed Mongoose appears to be modified towards a cursorial form of locomotion. The proportions of the limb bones are indicative of an animal's normal gait, and longer distal elements (metapodials and epipodials) are indicative of cursorial habitats. It lacks first digits, and metacarpals II, III and IV are almost equal in length indicating a digitigrade foot (Taylor 1971a, 1974, 1976, 1988). Teeth are adapted for an insectivorous to omnivorous diet, the molariform teeth being broad and rounded.

Foraging and Food Bushy-tailed Mongooses are omnivorous, and insects, reptiles, amphibians, mice, millipedes, spiders, scorpions, snails and herbage have been found in their stomachs (Smithers & Wilson 1979). It is probable that they are largely opportunistic and eat insects when they are abundant during the wet seasons and eat vertebrate prey during the dry seasons together with any carrion or other food that may be available (Taylor 1986). Information from an examination of microwear of their teeth indicates a 'puncture-crushing' type of mastication (Taylor & Hannam 1987), which is supported by the generally robust nature of the molariform teeth. Teeth of several individuals collected and examined in museum collections were very worn, indicating that a reasonable amount of sand and dirt particles are ingested with the food, causing significant wear. Captive animals were offered a wide selection of fruit, live mice and snakes but were generally inept at catching vertebrates, though eventually they used a neck bite and shaking to kill prey items. These were then held between the forefeet while the mongoose tore pieces off to ingest (Sale & Taylor 1970). Bushy-tailed Mongooses are considered to be nocturnal (as evidenced by camera-trapping surveys), but they may be active during the day (and this is partly borne out by their occurrence in the caches of bones beneath two Crowned Eagle *Stephanoaetus coronatus* nests; J. Kingdon pers. comm.).

Social and Reproductive Behaviour Bushy-tailed Mongooses are primarily solitary, although one would expect to encounter ♀♀ with young for a few weeks or months after birth. Ansell & Dowsett (1988, 1991) mention four seen together at around 16:00h on the Nyika Plateau in Malawi, probably a ♀ and her three young. One of

the most distinctive features of this species is its apparent docility (Sale & Taylor 1970, Kingdon 1977). When animals were live-trapped, they did not behave aggressively, neither barking nor trying to bite. In large cages, where one was observed and filmed for several days, the animal was curious, investigated the author and did not try to hide.

Reproduction and Population Structure Little is known but ♀♀ caught in Zimbabwe in Aug, Sep, Oct and Dec showed no signs of breeding (Skinner & Chimimba 2005). It is probable that the breeding season coincides with the wet season, which varies from two seasons in Kenya to one in Zimbabwe. This presumably affects the reproductive capabilities of the species across its range.

Predators, Parasites and Diseases A Spotted Hyaena *Crocuta crocuta* has been photographed carrying this species in its jaws. Caches of bones collected in 1989 from beneath two Crowned Eagle nests in Matumbi revealed that this mongoose was their third most frequent prey (after monkeys and Natal Red Duikers *Cephalophus natalensis*) (J. Kingdon pers. comm.).

Guinea-worms of the genus *Dracunculus* have been recovered from a captive animal, which had been caught near the confluence of the Lupande and Luangwa rivers, 13°0'S, 31°49'E, in Zambia. The female worm measured 97 cm and was found loosely coiled against the muscles of the inside right hindleg (C. Ogden in litt.).

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Bushy-tailed Mongoose has a relatively wide distribution in a variety of habitats, and although it is not commonly seen, recent camera- and live-trapping work in the Udzungwa Mts and elsewhere in Tanzania suggests that they are not rare. They are present in several protected areas across their range, including Selous N. P., Arusha N. P., Mahale Mountain N. P. and Udzungwa Mountains N. P. (Tanzania), and there is no reason to believe that they are currently threatened.

Key References De Luca & Mpunga 2005; Skinner & Chimimba 2005; Taylor 1986, 1987.**Mark E. Taylor*****Bdeogale jacksoni* JACKSON'S MONGOOSE**

Fr. Mangouste de Jackson; Ger. Jackson Ichneumon

Bdeogale jacksoni (Thomas, 1894). Ann. Mag. Nat. Hist., ser. 6, 13: 522. Mianzini, Masailand, 8000 feet.Restricted by Moreau *et al.* (1946) to 'a few miles E.S.E. of Naivasha, 9000 feet', Kenya.Jackson's Mongoose *Bdeogale jacksoni*.

Taxonomy Monotypic. Originally described as *Galeriscus Jacksoni* (with a capital J) by Thomas (1894b), who created a new genus because of a supposed similarity with the South American Grison (*Galictis* sp.), a mustelid. Named after the collector of the type specimen F. J. Jackson. Although Matschie (1895) and Pocock (1916b) made *Galeriscus* synonymous with *Bdeogale*, Thomas (1928b) recognized his mistake but retained the genus *Galeriscus* for *G. jacksoni* as did Allen (1939), Sanderson (1940), Schouteden (1945), and Rosevear (1974) for *G. nigripes*. Perret & Aellen (1956) and Coetzee (1977) used *Galeriscus* as a subgeneric name for the species *nigripes* and *jacksoni* on the strength of the larger body size and larger last lower molar. Jackson's Mongoose was often regarded as a montane isolate of the Black-legged Mongoose *Bdeogale nigripes* and considered a subspecies of Black-legged Mongoose by Hayman (in Sanderson 1940) and Kingdon (1977), and a subspecies of the Bushy-tailed Mongoose *Bdeogale crassicauda* by J. A. Allen (1914). Recognized as a valid species by Hollister (1918), G. M. Allen (1939), Coetzee (1977), Wozencraft (1993, 2005) and Kingdon (1997). Synonyms none. Chromosome number: not known, but likely $2n = 36$ as in other *Bdeogale* (Wurster & Benirschke 1968).

Description A large, silvery-grey, rather long-legged mongoose with bushy tail. Muzzle blunt. Rhinarium with median groove running down the upper lip. Muzzle and chin brownish-white. Eyes surrounded by a few brown hairs. Ears round, broad and well haired, but less prominent than in other species of *Bdeogale*. Hairs of ears

outside grizzled grey, inside yellowish-white. Cheeks, throat and sides of neck yellowish. Crown grizzled grey. Dorsal pelage long, dense, glossy, grizzled black and white. Dorsal hairs more than 20 mm with basal part white, middle third dark, terminal third white. Underfur dense and woolly. Ventral pelage light grey. Legs distal to elbow and knee blackish-brown. Hind- and forefeet with four digits, hallux and pollex missing. Metacarpal and metatarsal pads naked. Claws thick and strong. Tail ca. 57% (range 53–60; n = 7) of head and body length, bushy with hairs longer than on back. Young but breeding animals may be well below average adult size, probably due to a slow and prolonged adult growth (Kingdon 1997).

Jackson's Mongoose is smaller than the Black-legged Mongoose, but has relatively large teeth (length M_2 : *B. nigripes*: 7.3 mm [range 6.6–8.1, n = 19]; *B. jacksoni*: 7.0 mm [range 6.2–7.5, n = 9]; *B. crassicauda*: 5.35 mm [range 4.8–6.0, n = 29]). The length of both upper and lower last molars of the Black-legged Mongoose and Jackson's

Lateral view of skull of Jackson's Mongoose *Bdeogale jacksoni*.

Mongoose is smaller than that of the Bushy-tailed Mongoose. Whereas there is some overlapping in the case of M^2 , there is none with M_2 .

Geographic Variation None recorded.

Similar Species

Bdeogale crassicauda. Sympatric in Tanzania. Smaller; lacks the yellowish colouring on the cheeks, throat and sides of neck.

B. nigripes. Allopatric, occurring in the central African rainforests. Larger, shorter haired, and silvery-grey in colour.

B. omnivora. Restricted to the coastal forests of Kenya and Tanzania; it is not clear whether or not the two species may be sympatric. Smaller, with distinctive yellow to orange underfur and limbs dark brown to black.

Ichneumia albicauda. Woodland and savanna habitats in sub-Saharan Africa from Senegal eastwards to the Horn of Africa, and southwards to SE South Africa. Larger (up to 6 kg); five digits on each foot.

Distribution Endemic to Africa, and known only from C and S Kenya, including Mt Elgon, SE Uganda (Kingdon 1997) and Matundu Forest in the Udzungwa Mts (900 km to the south) in SC Tanzania (De Luca & Mpunga 2005, De Luca & Rovero 2006). A mongoose corresponding to the description of Jackson's Mongoose was reported at the edge of bamboo forest at 1700 m in Kihulula, Mwanihana forest, which is at an altitude significantly higher than Matundu. If this record is confirmed, it would be in habitat more similar to the montane forest and bamboo reported for the Kenyan records of the Aberdares and Mt Kenya (De Luca & Rovero 2006). It is possible that this species occurs in and around other massifs within the Eastern Arc Mts, including the Uluguru, Nguru and Usambara mountains. Museum specimens are few and originate from Kijabe Station and Murang'a, Aberdare Range; Elgeyo Forest; Mt Kenya; between Murang'a and Nyeri; Naivasha region; and Yala (Lukosa) R.

Habitat Montane forests and bamboo zones up to 3300 m in Kenya, lowland forest mosaics immediately south of Mt Elgon, in Kenya and Uganda (Kingdon 1997), and lowland semi-deciduous forest (about 300–400 m) at the base of the Udzungwa Mts (De Luca & Mpunga 2005, De Luca & Rovero 2006). The presence of remains of rodents of the genera *Dasymys* and *Otomys* in stomachs suggests that they hunt frequently in the thick herbaceous growth around swamps (Kingdon 1977).

Abundance Rare, with a limited distribution range. The Tanzanian population seems to be highly localized: camera-trapping studies conducted over three years in 76 sites throughout the Udzungwa Mts recorded Jackson's Mongoose in only five sites, all within Matundu Forest (De Luca & Rovero 2006).

Adaptations Mainly nocturnal and crepuscular. The animal was photographed 25 times in the Udzungwa Mountains N. P. between 19:00h and 06:00h; 73% of the photographs were taken between 19:00h and 00:00h (De Luca & Rovero 2006). The small amount of ants in subadults' diet (see Foraging and Food) could suggest that coping with well-defended columns of army ants (*Anona* sp.) depends on maturity and learning, which implies that adaptation to this diet could be relatively recent. However, the shorter, hairier ears contrast with larger, barer ears in the Bushy-tailed Mongoose, and the dense, woolly coat suggests improved protection against the bites of army ants. These features could imply species-specific adaptation against the defensive attacks of one of their preferred foods. The very light colouring and white tail of this species make it unusually conspicuous. Vulnerability to attack by Verreaux's Eagle-owl *Bubo lacteus* could be mitigated by this species' preference for very dense vegetation. The adaptive value of such conspicuousness is not known. When the animal is surprised or harassed, scent is released from the anal glands and the tail is fluffed out. A captive ♀ made no noises other than a soft growl and a snort (Kingdon 1977).

Foraging and Food Omnivorous. In the Aberdare Mts, Kenya, analysis of some 40 scats revealed that 40% of the adult diet consisted of insects, principally workers of army ants but also beetles, caterpillars, weevils, millipedes, snails, lizards, birds' eggs and carrion. More than 50% of the diet comprised rodents (genera *Otomys*, *Dasymys* and *Praomys*), and about 80% of the juveniles' diet is rodents (*Otomys*, *Lophuromys*, *Mus*, *Praomys*) complemented with beetles, lizards, birds and a few ants (Kingdon 1977). A captive specimen ignored a live bird but took a dead one, crushing bone and tissue slowly with its molars while sometimes steadying the carcass with a paw. Feeding was nearly always conducted while standing (Kingdon 1977).

Social and Reproductive Behaviour Not infrequently seen in pairs, occasionally in groups of four. Latrines possibly used by both adult and younger animals (Kingdon 1977).

Reproduction and Population Structure No information available.

Predators, Parasites and Diseases No information available.

Jackson's Mongoose *Bdeogale jacksoni*.

Conservation IUCN Category: Near Threatened. CITES: Not listed.

Given its apparent dependence on forest habitat, the main threat to this species is likely to be ongoing forest loss. In Kenya, Jackson's Mongoose is confirmed in Aberdare N. P. and Mt Kenya N. P., and is also likely to occur in Mt Elgon N. P. on the border with Uganda. In Tanzania, all confirmed localities lie within protected areas, including the Udzungwa Mountains N. P. and Matunda F. R., although it may well occur in other smaller forest reserves in other parts of the Eastern Arc Mts. De Luca & Rovero (2006) recommend full protection of adjacent forests (Matundu F. R. outside Udzungwa Mountains N. P.; and Iyondo and Udzungwa Scarp Forest Reserves), and that other East African ground-water-dependent forests (including those near Matundu and Nambiga Forest Reserves) be surveyed for the presence of Jackson's Mongoose. Similarly, surveys of other mountain forests in the Kenyan highlands should also be undertaken.

Bdeogale nigripes BLACK-LEGGED MONGOOSE

Fr. Mangouste à pattes noires; Ger. Schwarzfussichneumon

Bdeogale nigripes Pucheran, 1855. Rev. Mag. Zool. 7 (2): 111. 'Gubon' [= Gabon].

Lateral view of skull of Black-legged Mongoose *Bdeogale nigripes*.

Taxonomy Monotypic. Thomas (1894b) created the genus *Galeriscus* to describe a newly discovered mongoose from East Africa *G. jacksoni*, which he mistook for a mustelid. Although subsequently recognized as a mongoose, several authors (Allen 1939, Sanderson 1940, Schouteden 1945, Rosevear 1974) retained genus *Galeriscus* for both *nigripes* and *jacksoni*; the genus *Bdeogale* was accepted by J. A. Allen (1924), Kingdon (1977) and Wozencraft (1993, 2005). There is some question as to the position of *jacksoni*, which has been considered by Hayman (in Sanderson [1940]) and Kingdon (1977) to be a subspecies of *B. nigripes* (see also *Bdeogale jacksoni* species profile).

Examination of endocranial casts shows that the Black-legged Mongoose is unusual among herpestids in lacking a well-developed posterior ectosylvian sulcus and in having a better developed posterior suprasylvian sulcus and less expanded temporal lobe. One out of three examined museum specimens has what appears to be an expanded coronal gyrus with a dimple in it, but its functional significance is somewhat of an enigma. Radinsky (1975a) thought that perhaps more than one species might be included in *B. nigripes*. Synonyms none. Chromosome number: $2n = 36$ (Wurster & Benirschke 1968).

Description A large, short-haired, silvery-grey, rather long-legged mongoose. Muzzle blunt with large rhinarium and a median groove continuing in a narrow, naked strip parting the upper lip. Forehead and muzzle short-haired and lighter coloured than body. Ears short, wide, shallow and hairy on both sides. Pelage greyish-

Black-legged Mongoose *Bdeogale nigripes*.

white but sometimes brownish-red. Dorsal pelage and hair on flanks short and close-lying, with guard hairs 20 mm or less in length. Underfur dense, fine and short with yellow to brown hairs 10–12 mm long. Hairs annulated with white and brown rings and white tip. Colour of throat and belly varies from greyish-white to dark brown. Legs and feet distinctly darker in colour, from light brown to mostly brownish-black. Hind- and forefeet with four slightly webbed digits; hallux and pollex missing. Soles hairy up to the pads. Tail (ca. 63% of HB) white to yellowish, moderately bushy and slightly tapering. Young appear white and long-haired, becoming gradually darker and shorter-haired with age. There are two pairs inguinal nipples (F.A. Ulmer pers. comm.).

Geographic Variation Hayman (in Sanderson 1940) found no appreciable differences between specimens from Nigeria, Cameroon and DR Congo, but Rosevear (1974) felt that on the basis of size, some aspects of colouration and pelage length, the population of E DR Congo merits differentiation. Skull measurements show that specimens from DR Congo are slightly smaller.

Similar Species

Bdeogale jacksoni. Allopatric, occurring in C and S Kenya, SE Uganda and SC Tanzania. Smaller; dorsal pelage longer.

Ichneumia albicauda. Woodland and savanna habitats in sub-Saharan Africa from Senegal eastwards to the Horn of Africa, and southwards to SE South Africa. Larger (up to 6 kg); five digits on each foot.

Distribution Found only in the central African rainforests from the Cross R. in SE Nigeria westward to Cameroon and Central African Republic and southward to Equatorial Guinea, Gabon, Congo and DR Congo, north of the Congo R. eastwards to the western Rift Valley in DR Congo. The species has been reported from Angola (e.g. Hill & Carter 1941). Bocage (1865, 1882, 1889) cites specimens from the district of Duque de Bragança, Caconda and Humbe, Seabra (1908) from an unknown locality, and Themido (1928) from Cassôco-Benguela. Unfortunately, the specimens could not be examined (all were destroyed in a fire), and because skins of Black-legged Mongooses can be confused with those of Selous's Mongoose *Paracynictis selousi*, the species is rejected from Angola by Crawford-Cabral (1989a).

Habitat Dense ground-scrub in deep, tall, deciduous forest (Sanderson 1940) to more than 1000 m. Not usually found in disturbed forest.

Abundance Most authors consider Black-legged Mongooses to be rare or very rare (Bates 1905, Jeannin 1936, Eisentraut 1973). Widespread and more common in the east and south of its range, in Congo and Gabon (Malbrant & MacLachy 1949). In the Ituri Forest, DR Congo, Bambuti pygmies hunting with dogs captured 28 individuals in 53 hunts, representing ca. 25% of all carnivores (Hart & Timm 1978).

Adaptations Largely terrestrial, but a specimen was seen moving around with great agility in a tree 15 m above ground, stalking a

young Potto *Perodicticus potto* at night (Charles-Dominique 1977). A hunted specimen took refuge in a hollow tree trunk on the ground (Durrell 1953). Nocturnal according to pygmies of NE DR Congo, although according to some it is also active by day. Ba'aka pygmies report that this species sleeps in holes between the roots of big trees and in dens of Brush-tailed Porcupines *Atherurus africanus* after killing them (Carpaneto & Germi 1989).

The large molar teeth may be related to the insectivorous diet (Kingdon 1977) but the large, straight, dagger-like upper canines point to the ability to tackle larger prey. Bequaert (1922) thought it likely that the Black-legged Mongoose forages on dead ants since it has no adaptations to devour them without being bitten or stung, but according to Kingdon (1977) it is likely that the peculiar fur, the short woolly ears and the well-plushed muzzle and feet protect all parts of the animal against soldier ants and termites. The light, conspicuous colouring may be related to an offensive smell. When surprised or threatened, scent is released from the anal glands and the tail is fluffed out.

Foraging and Food Omnivorous. In Dzanga-Sangha, Central African Republic, 86% of 21 scats contained arthropods (mostly ants, termites, beetles and orthopterans), 48% held mammalian prey (mostly shrews, but also small rodents, squirrels, porcupines and a Long-nosed Mongoose *Xenogale naso*), 14% herpetofauna (snakes, lizards and anurans) and 5% fruit (Ray & Sunquist 2001). According to the pygmies of NE DR Congo, rodents (primarily Brush-tailed Porcupines), insects, ants, termites, snakes, mushrooms, fruits (bananas, oil palm fruit) and carrion are favoured prey items (Carpaneto & Germi 1989). Termites are an important food item (Verschuren 1972), and termites and driver ants (*Dorylus* and *Myrmecaria* sp.) were found in the stomachs of three of nine specimens examined by Bequaert (1922). Sanderson (1972) mentions a wild specimen stalking a caged squirrel. Kingdon (1997) also cites frogs, snails and crabs as dietary items.

Captive specimens seized a guinea-pig by various parts along its back and by the leg using their forepaws in an attempt to hold it. They bit it almost everywhere while directing their biting to the head several times, then seized it by the throat, and delivered the killing bite while holding it down with the forelegs (Eisenberg & Leyhausen 1972). A cornered wild specimen growled, bared its teeth, barked and defended its prey like a dog (Sanderson 1972).

Social and Reproductive Behaviour Solitary, but often seen in pairs. Latrines may be used (Kingdon 1977, but in reference to Jackson's Mongoose *B. jacksoni*). Nothing else is known of their social behaviour.

Reproduction and Population Structure According to Mbuti pygmies there are usually 1–2 young (Carpaneto & Germi 1989). The capture of three juveniles, born between the beginning of Nov and the beginning of Jan, suggests that the mating time in West Africa is the early dry season, with births from Nov to Jan (Rosevear 1974). A suckling ♀ and one young were collected early Dec in Ituri Forest in DR Congo (F. A. Ulmer pers. comm.). The longevity record for a captive specimen is 15 years and 5 months (Jones 1982).

Predators, Parasites and Diseases Nothing is known about predators. According to the Mbuti pygmies, the species is not eaten because of the bad smell of its skin (Carpaneto & Germi 1989);

nevertheless, Black-legged Mongooses make up 1% of the carnivore bushmeat in NE DR Congo (Colyn *et al.* 1987). Nematode parasites (e.g. *Toxocara* sp.) have been recorded (Warren 1972).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Numbers probably declining as a result of forest fragmentation and forest loss from logging, mining and slash-and-burn farming, and to a lesser degree from bushmeat hunting, but the species currently is not thought to be threatened.

Bdeogale omnivora SOKOKE BUSHY-TAILED MONGOOSE

Fr. Mangouste de Sokoke; Ger. Sokokeichneumon (Swahili Kitu ya Sokoke)

Bdeogale omnivora Heller, 1913. Smithsonian Misc. Coll. 61: 12–13. Mazeras, Kenya 03° 58' S, 39° 33' E.

Lateral view of skull of Sokoke Bushy-tailed Mongoose *Bdeogale omnivora*.

Taxonomy The Sokoke Bushy-tailed Mongoose was described as a new subspecies of the Bushy-tailed Mongoose *Bdeogale crassicauda* (Heller 1913), being different from *B. c. crassicauda* primarily in coat colour and being slightly smaller. Subspecies status has been maintained by most authors (Sale & Taylor 1970, Wozencraft 1993, 2005, Engel & Van Rompaey 1995), but regarded as a distinct species by Kingdon (1997). Synonyms: none. Chromosome number: not known, but likely $2n = 36$ as in other *Bdeogale* (Wurster & Benirschke 1968).

Description A medium-sized mongoose with distinctive yellow to orange underfur and grizzled dark brown guard hairs with lighter annulations. Limbs dark chocolate brown to black. Head shortish with rounded ears. Tail bushy and short. Four digits on both fore- and hindfeet, claws short and stout.

Geographic Variation None recorded.

Similar Species

Bdeogale crassicauda. Unlike Sokoke Bushy-tailed Mongoose, not restricted to the coastal forests of Kenya and N Tanzania, although the precise boundary between the two species requires further investigation. Similar size, but overall darker brown.

B. jacksoni. Currently known only from C and S Kenya, SE Uganda and from the Udzungwa Mts in SC Tanzania; it is not clear whether the two species may be sympatric. Larger (2–3 kg), with blackish legs and light grey to almost whitish body and tail; teeth less rounded.

Distribution Endemic to Africa, and restricted to the coastal forests of Kenya and Tanzania (Engel & Van Rompaey 1995, Engel 1996). In Kenya, the majority of confirmed records are from Gedi, south of Malindi in Kenya, where Taylor (1986) mentions trapping several specimens. Other specimens have been collected in Diani Beach, Shimba Hills N. R., Tiwi, Kwale, Mazeras (the type locality, from which three specimens were recorded in 1911), and Arabuko-Sokoke Forest (Engel & Van Rompaey 1995, Engel 1996); reports of this species from coastal parts of N Kenya have been reported, including museum specimens from the Kipini area and from Milmani in the Boni Forest, close to the Somali border (Engel & Van Rompaey 1995). In Tanzania, they are recorded from Magorota (05° 02' S, 39° 06' E) in the East Usambaras, about 10–15 km from Sigi (Allen & Loveridge 1942) and from Magamba in the West Usambaras (Allen & Loveridge 1927). The latter authors also wrote that the same species had been observed in the Uluguru Mts, though this remains unsubstantiated. There is a recent possible record of this species from the Amani N. R. in the East Usambara Mts (Göller 2005), but this requires confirmation. Indeed, these records from the West and East Usambara Mts are within a few kilometres of the range of the Bushy-tailed Mongoose and it could well have been mistaken for the latter species.

Habitat Confined to forested habitats in a narrow belt on the coast and in mountainous or hilly areas close to the coast (the record from Magamba was taken at 1700 m). An animal was observed in the

Sokoke Bushy-tailed Mongoose *Bdeogale omnivora*.

Shimba Hills along a rough road between a large, open grassland area (with bush and very small islands of forest) and a plantation of pine (*Pinus caribaea*) (Engel & Van Rompaey 1995).

Abundance This mongoose is only locally common and occasionally seen by villagers. Nowhere are members of this genus common, and Taylor (1986) compared this mongoose with other small carnivores and was not able to suggest extrinsic causes of its rarity. The suggestion that habitat destruction is a causal factor cannot be assumed as this species has appeared rare to collectors since it was first described a century ago, and habitat destruction in much of its habitat is a relatively recent phenomenon.

Adaptations The molariform teeth are rounded without a distinct carnassial shear and are adapted for crushing, which results in microscopic pitting of the teeth (Taylor & Hannam 1987). Several specimens examined had very worn teeth, which could be explained by ingesting dirt with insect food.

Foraging and Food The Sokoke Bushy-tailed Mongoose has been observed foraging on insects (either queen termites or male driver ants, *Dorylus* sp.) on a road after rainfall after sunset (Engel & Van Rompaey 1995). The individual would rush a few metres to catch crawling, wingless insects on the road surface and did this for at least 20 min. Beetles and a mouse were recovered from the stomach of the type specimen (Heller 1913), and beetles from specimens caught by Allen & Loveridge (1927).

Social and Reproductive Behaviour Nocturnal and solitary. No other information is available, but likely similar to the Bushy-tailed Mongoose.

Reproduction and Population Structure A female Sokoke Bushy-tailed Mongoose nursing a quarter-grown young was caught in mid-Dec on the Kenya coast. The type specimen,

collected around the same time, had a large foetus (Hollister 1918, Kingdon 1977) that would suggest that breeding occurred during the monsoon periods of Nov/Dec and Apr/May when insect food is usually abundant.

Predators, Parasites and Diseases No information is available. This species is reportedly the type host for the chewing lice *Felicola bedfordi* (Hopkins 1949). Individuals may sometimes be injured or killed by vehicles while foraging after insects on roads at night. A ♂ caught at Gedi had a broken ulna, and showed signs of a broken radius that had since mended (Taylor 1971b).

Conservation IUCN Category: Endangered B1ab(iii). CITES: Not listed.

The population in the Arabuko-Sokoke Forest is under threat from illegal logging and the Shimba Hills population is potentially under threat from afforestation with non-native pine species together with management for the Sable Antelope *Hippotragus niger* (Schreiber *et al.* 1989, Engel & Van Rompaey 1995). There is a need to improve the protection and management of these protected areas. In addition, further survey work is required to confirm the records of this species from the Usambara Mts in Tanzania.

Measurements

Bdeogale omnivora

HB (♀ ♀): 420 mm

T (♀ ♀): 245 mm

HF c.u. (♀ ♀): 81 mm

E (♀ ♀): 34 mm

GLS (♀ ♀): 84.6 mm

GWS (♀ ♀): 45.4 mm

Type specimen (Heller 1913)

The topotype (adult ♀), as provided by Hollister (1918/1924), had measurements: HB = 400 mm; T = 250 mm; HF = 80 mm; E = 37 mm; GLS = 84.5 mm; GWS = 44.6 mm.

GENUS *Rhynchogale*

Meller's Mongoose

Rhynchogale Thomas, 1894. Proc. Zool. Soc. Lond. 139.

A monotypic genus with an apparently patchy distribution in suitable woodland habitats. The single species, *Rhynchogale melleri*, was originally placed in the genus *Rhinogale* by Gray (Proc. Zool. Soc. Lond. 1865: 573). Pocock (1919) believed this genus to be closely allied with *Ichneumia* and *Bdeogale* on the basis of dental features, and this relationship (together with *Cynictis*) has been borne out by molecular studies (Perez *et al.* 2006, Patou *et al.* 2009).

Chris Stuart & Tilde Stuart

Skull of Meller's Mongoose *Rhynchogale melleri* showing positions of brain, frontal sinuses and rhinarium.

Rhynchogale melleri MELLER'S MONGOOSE

Fr. Mangouste de Meller; Ger. Meller-Manguste

Rhynchogale melleri (Gray, 1865). Proc. Zool. Soc. Lond. 1864: 575 [1865]. 'from a ravine on the outskirts of the Otto Estate, near Mbweni, about 2½ miles [4 km] west of Kilosa, Tanganyika Territory'. The exact locality is unknown; Zomba, Malawi has been suggested – and contested (see Roberts 1951, Ansell 1978).

Taxonomy Coetsee (1977) listed three subspecies, *R. m. caniceps*, *R. m. langi* and *R. m. melleri*, cautioning that *caniceps* and *langi* might not be valid. Ansell (1965, 1978) also expressed doubt as to the validity of *caniceps*. Meester *et al.* (1986) considered *caniceps* synonymous with the nominate form, retaining only *melleri* and *langi*. Differentiation is based on minor aspects of pelage colour, especially on that of the tail, which may be black, brown, white, or variables of these within any one population. Synonyms: *caniceps*, *langi*. Chromosome number: not known.

Description A medium-sized mongoose with tail slightly less than 50% of total length. Head quite short, but muzzle appears somewhat swollen. No central vertical slit on the front of the rhinarium. This mongoose has a distinctive crest-like parting on either side of the neck that is diagnostic, but difficult to see from a distance. Has an overall brownish appearance from a distance, but when close at hand it is coarsely grizzled. Hairs of the coarse guard coat have broad buffy, brown to dark brown annulations that are white to off-white at their bases. Fine underfur greyish at base, browning towards tip.

Meller's Mongoose *Rhynchogale melleri*.

Length of guard hairs on forehead may reach 10 mm, 45 mm on rump, with longest hairs towards tail tip. Lower limbs are darker than upper parts of the body. Pelage of the underparts somewhat paler than upper body. Confusingly, Meller's Mongoose may have predominantly white, brown or black tail hairs, within any one population. In the case of those with black tails the individual hairs are white to brownish-white at the base but black towards the tip. Those with predominantly white tails have hairs with white bases, then broad black annulations, with white tips. In this form the hairs at the tail tip are completely white. Ansell (1960a) recorded that many Zambian specimens have variable tail colouration. Five digits on each foot. Claws on the front feet are short (about 8 mm), curved and sharp, whereas those of the hindfeet are heavier, less curved but similar in length. Anal glands open into a circular pouch. There are two pairs of abdominal nipples.

Skull lightly built, elongated and highest at the level of the mid-point of the zygomatic arches, which are thick and weak; skull slopes gradually back to supraoccipital crest and sharply forward to nasals. The eye sockets are positioned such that the eyes point more forward than in other members of the family. Front chamber of ear bullae much smaller than hind. Rostrum short and broad (Skinner & Chimimba 2005). Dental formula $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$; although Haltenorth & Diller (1980) give a range of 4–5 upper premolars for a total of 40–42 teeth, Skinner & Chimimba (2005) give the total as 40 and this has been confirmed from museum specimens (H. Van Rompaey pers. comm.). The first upper premolars are tiny, the fourth upper premolars broad and molariform, and the fourth lower premolars broad with high cusps. The first and second molars are broad-faced and flat; both first and second molars have three cusps on the front, although those on the first are high (Skinner & Chimimba 2005).

Geographic Variation

R. m. melleri: C Mozambique, C Zimbabwe and extending into Malawi, Zambia, SE Congo and C Tanzania.

R. m. langi: NE South Africa, Swaziland and S Mozambique.

Rhynchogale melleri

Similar Species

Ichneumia albicauda. Broadly sympatric. Larger, and usually a predominantly white tail and overall grizzled grey appearance (however, black-tailed specimens are known throughout the range); upper lip is divided by internarial groove from nose to mouth.

Bdeogale crassicauda. E Zimbabwe and C Mozambique to Tanzania. Similar in size, but has a relatively shorter tail, appears black at a distance but at close-quarters usually more grizzled; tail and legs very dark to black, with four digits on each foot.

Atilax paludinosus. Riparian habitats from Senegal east to north-east Africa and south to South Africa. Larger (up to 5 kg); overall dark brown to blackish, shaggy pelage.

Paracynictis selousi. Savanna grassland and woodland from Angola to Malawi south to NE KwaZulu–Natal. Smaller; generally pale speckled grey to tawny-grey; feet and legs dark brown to black,

Lateral, palatal and dorsal views of skull of Meller's Mongoose *Rhynchogale melleri*.

contrasting with rest of pelage; partially white tail; fine philtrum between nostrils, dividing haired portion of upper lip.

Herpestes ichneumon. Sympatric in western part of Africa below the equator until South Africa (although overlap might be greater). Lacks distinctive crest-like parting on either side of the neck.

Distribution Endemic to Africa. Meller's Mongoose is often described and depicted as having a disjunct distribution (e.g. Skinner & Chimimba 2005), although several recent distribution records of this species provide some evidence that their range is indeed more continuous than has been supposed. For example, Stuart & Stuart (1998a) photographed a road casualty close to the eastern sector of L. Kariba in N Zimbabwe, which lies between the nearest known locality records for this mongoose in Zambia and the Zimbabwean Midlands. Ansell (1978) remarked that although there were no records from NE Zambia, it probably ranges throughout this part into Tanzania. Other recent records include those from Udzungwa Mountains N. P. in the Mwanihana montane bamboo forest (De Luca & Mpunga 2005), a record from Niassa G. R. in Mozambique (C. Begg & K. Begg pers. comm.) and a possible record from Chobe N. P. in Botswana (Purchase *et al.* 2007), which if substantiated would be the first record for this country. The range of this species, therefore, would appear to be relatively continuous in suitable woodland habitat from C Tanzania south through Malawi, Zambia (probably as far west as the Zambezi R.), Zimbabwe and Mozambique (where they almost certainly occur more widely despite the paucity of records). The species reaches its southernmost limit in the extreme south of Mozambique, extending into NE Swaziland (from which there is only a single confirmed record in 1937; see Monadjem 1998) and parts of NE South Africa (Mpumalanga and Limpopo Province; Skinner & Chimimba 2005). They have not yet been

recorded from N KwaZulu–Natal (Rowe-Rowe 1992a), but may well occur.

Habitat A savanna mongoose that is mainly associated with open woodland and grassland with termitaria. In Zimbabwe and Malawi they are associated with *Brachystegia* woodland (Skinner & Chimimba 2005), where they show a preference for more open grassland and seasonally wet areas. This is similar to the situation over parts of their Zambian range where they occur in open, short-grassed dambos fringed by miombo woodland (C. Stuart & T. Stuart pers. obs.). It is within these areas that their main termite food is located; indeed, in Niassa G. R., two animals were seen in mature miombo woodland with numerous small termitaria (C. Begg & K. Begg pers. comm.). In a recent camera-trapping survey, the species was recorded in montane bamboo forest at 1850 m (De Luca & Mpunga 2005).

Abundance Apparently uncommon to rare across its range but it may be easily overlooked. During some 800 km of spotlight counts through miombo woodland in Niassa G. R., N Mozambique, their density was 0.3 ind/100 km travelled (C. Begg & K. Begg pers. comm.).

Adaptations The skull has a swelling (of variable size) above the orbit caused by enlarged empty sinuses. Kingdon (1977) has speculated that this could allow this mongoose to give vent to a loud nasal bark. Unfortunately, the call of Meller's Mongoose *Ichneumia albicauda* is unknown, but as the White-tailed Mongoose has a similar skull modification and is known to give a loud barking call it is probable that this is the case. Loud, harsh calls could serve to intimidate potential predators, as well as facilitate contact between widely spaced individuals.

The coronoid of the lower jaw is only of medium height, which suggests that the masseter and temporalis muscles are not well developed and that the jaw action is not very powerful. The molars are broad, somewhat flattened, and highly suited to grinding their mainly termite prey. The densely furred and swollen upper lip and set-back nostrils are possible adaptations to feeding on termites.

Foraging and Food Nothing is known of the foraging behaviour of this terrestrial mongoose, but the nature of their front claws and of their principal prey indicates that they are scratchers rather than active diggers. According to Skinner & Chimimba (2005), termites, and particularly *Macrotermes* spp. and *Hodotermes* spp., are by far the most important prey. Of the 23 stomach contents collected in Zimbabwe, ten contained only termites and one 80% termites and in the remainder termites made up varying percentages. Other invertebrates (grasshoppers, beetles) had only a limited presence and small vertebrates, including a Peters' Thread Snake *Leptotyphlops scutifrons* and a frog, only single occurrences. A single stomach from Zambia (Ansell 1965) was made up only of termites and two centipedes. The same author trapped a specimen using only pumpkin seeds as bait, and Thomas (1894a), quoting a collector, stated that wild fruits are always found in their stomachs.

Social and Reproductive Behaviour A nocturnal mongoose that apparently only starts foraging well after sunset. Most sightings are of single animals, suggesting that they are primarily solitary

Meller's Mongoose *Rhynchogale melleri*.

(Skinner & Chimimba 2005). Ansell (1965) reported finding two old ♂♂ dead together, which suggests a possible territorial conflict had taken place; both specimens were old, with heavily worn teeth and had lost their molars in both jaws. Apart from this meagre information, nothing further is known about these aspects of their biology.

Reproduction and Population Structure The only information available comes from Zimbabwe and Zambia. In the former, a ♀ was collected with three foetuses in Nov, and a ♀ with two young taken from an Aardvark *Orycteropus afer* burrow in Jan (Skinner & Chimimba 2005). A litter of two newborn young was collected in a small cave in hills in Zambia in December (Ansell 1960a) and Wilson (1968) recorded another litter of two from the same general area. In both litters from Zambia, each comprised a male and female youngster. This limited information suggests that young are born during the summer wet season.

Predators, Parasites and Diseases There is no information available on these aspects of their biology, but they may be susceptible to predation by some larger carnivores.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Probably not under any particular threat over much of its range as its favoured habitat is extensive, and in some parts with very low human populations. However, in the Tanzanian and Zambian part of the range there has been considerable expansion of the human

population and their dogs. The latter could represent a significant local threat.

GENUS *Cynictis*

Yellow Mongoose

Cynictis Ogilby, 1833. Proc. Zool. Soc. Lond. 1833: 48.

Monotypic genus with a single species, the Yellow Mongoose *Cynictis penicillata*, endemic to southern Africa, where it has successfully colonized semi-arid and largely open habitats (Karoo, fynbos, grassland and arid Kalahari savannas) in the western parts of the sub-continent.

An allozyme phylogeny of some African mongoose species placed *Cynictis* basal to a 'social' lineage (with *Suricata* and *Helogale*), derived from a *Galerella*-like ancestor (Taylor *et al.* 1991). This is consistent with the social organization of *Cynictis*, which has been described as somewhat intermediate between the solitary and social species. On the other hand, a close relationship with *Ichneumia* was previously suggested on morphological grounds, including ear and plantar pad characteristics (Pocock 1919) and has been suggested by recent evidence from cytochrome *b* DNA sequences (Veron *et al.* 2004).

Using molecular data from six nuclear genes, Flynn *et al.* (2005) recovered a strong relationship between *Cynictis* and *Paracynictis* (the latter has been included in *Cynictis*; e.g. McKenna & Bell 1997), but *Ichneumia* was not included in this analysis. Recent molecular studies (Perez *et al.* 2006, Patou *et al.* 2009) group *Cynictis* along with *Bdeogale*, *Rhynchogale* and *Ichneumia*, based on molecular, chromosomal and morphological evidence (*Paracynictis* was not included in these analyses).

Fossil *Cynictis* is known from the late Pliocene of South Africa. Petter (1987) records the possible presence of this genus in the early Pliocene of Tanzania, but this record is in error (L. Werdelin pers. comm.).

Peter J. Taylor

Cynictis penicillata YELLOW MONGOOSE

Fr. Mangouste fauve; Ger. Fuchsmanguste

Cynictis penicillata (G. Cuvier, 1829). Le Règne animal, 2nd edn, 158. 'du Cap', designated as Uitenhage, Eastern Cape [South Africa] (Roberts 1951).

Yellow Mongoose *Cynictis penicillata*.

Taxonomy As many as 12 subspecies have been recognized in the past (Roberts 1951, Ellerman *et al.* 1953), distinguished mainly on the basis of colour, size and length of the tail, all features that are highly variable geographically (see below). Lundholm (1955b) considered all to be part of a cline, and did not recognize subspecies. Three subspecies were defined on morphometric and colorimetric grounds (Taylor *et al.* 1990b, Taylor & Meester 1993b), although data from allozymes (Taylor *et al.* 1990a) and mitochondrial DNA (mtDNA restriction fragment, and mtDNA control region sequences; Jansen van Vuuren & Robinson 1997) revealed little or no geographic partitioning, and no correlation with recognized subspecies, suggesting very recent range expansion, subspeciation and morphometric differentiation (Taylor 1990, Jansen van Vuuren & Robinson 1997). Synonyms: *bechuanae*, *brachyura*, *bradfieldi*, *cinderella*, *coombsii*, *intensa*, *kalaharica*, *karasensis*, *lepturus*, *levaillantii*, *natalensis*, *ogilbyii*, *pallidior*, *steadmanni*, *typicus*. The karyotype is constant throughout the geographic range ($2n = 36$; $NF = 72$) although supernumerary micro-chromosomes have been found in certain populations (Fredga 1972, Taylor 1990, 1993).

Description Tawny to greyish-yellow-coloured mongoose, with relatively large ears (seldom less than 9% of head and body length), projecting above the line of the head (unlike in other mongooses), and long, bushy tail, giving a somewhat fox-like appearance. Upper lip lacks a philtrum (Pocock 1916a). Size similar to Meerkat *Suricata suricatta*, but smaller than most other African mongoose species. Body size and pelage colour highly variable geographically. Southern specimens are larger-sized, with dorsal pelage dark tawny (reddish-brown) to paler yellowish-brown, slightly paler on flanks, paler buffy-cream ventrally and on the legs, chin and throat. Anterior

margin of the ears pallid, with tuft of pale hairs anterior to, and partially covering, the ear opening. Tail colour similar to dorsal pelage basally, becoming heavily pencilled with black over most of its length, but ending in a pure- to dirty-white tail-tip (of variable length, <20 mm to >60 mm). Longer body (>20 mm, mid-dorsal) and tail (>30 mm, mid-tail) hairs. Individual hairs blackish-brown basally, with alternating orange to yellow phaeomelanin and black eumelanin bands, usually two of each, although the terminal band may be dark brown rather than black. The more basal of the two phaeomelanin bands, which is typically longer, may be a richer orange than the shorter, more terminal, yellower band, giving a slightly grizzled, greyish-yellow wash to the deeper orange background colour in some specimens. Subterminal black bands are wide on the tail hairs, but otherwise subequal or narrower than the brown bands. Pelage colour varies seasonally in southern (but not conspicuously so in northern) specimens, resulting in a summer pelage with shorter hairs and a brighter, redder colouration than in winter. A transitional colour, appearing in Nov and Dec, is paler yellow in colour and patchy in appearance due to uneven moult of the winter pelage (Taylor *et al.* 1990b).

Northern specimens are distinctly smaller, with dorsal pelage grizzled, greyish-yellow colour (due to numerous black-tipped guard hairs), becoming paler on flanks, and pure creamy-white ventrally and on the legs, chin and throat. Tail similar in colour to dorsal pelage basally, becoming pencilled with brown over the distal two-thirds of the tail, without a white tip. Shorter body (<15 mm) and tail (<25 mm) hairs, compared with southern specimens. Individual hairs brown basally, with alternating pale buffy and black bands, ending in a terminal black band. Black bands tend to be wider than pale buffy bands, giving grizzled appearance (Taylor *et al.* 1990b). Five digits on forefeet, four on hindfeet; all digits on forefoot, except the first, armed with claws up to 10 mm on Digits 2, 3 and 4. Sole of hindfoot more hairy, forefoot palm naked to wrist. Anal glands open on either side of the anus. Cheek glands are present and used for marking of objects (Earlé 1981, Wenhold & Rasa 1994). There is no sexual dimorphism in size or pelage colour. Three pairs of nipples.

Skull pear-shaped with postorbital bar complete in adults. Rostrum short and broad, zygomatic arches weak, and the supraoccipital crest little more than a slight ridge. Anterior ectotympanic chamber of bulla subequal in size to posterior entotympanic (anterior typically reduced in other mongooses); septum between the chambers angled (vertical in other mongoose genera). Dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$; upper and lower P1 sometimes absent, especially the latter.

Geographic Variation

C. p. penicillata: Western Cape, Eastern Cape, Northern Cape (south of Orange R.), Free State, KwaZulu–Natal, North West and Limpopo Provinces, north to the Soutpansberg Mts. Largest of subspecies, head and body length >300 mm, condylobasal skull length >64 mm; dorsal pelage richer and redder overall, from tawny to yellowish-red, with conspicuous white tail tip.

C. p. bradfieldi: Northern Cape (north of Orange R.), S Botswana and S, C and NW Namibia. Intermediate-sized, head and body length 267–370 mm, condylobasal skull length 59–66 mm; colour intermediate, orange to yellowish in hue, pallid and moderately faded, with white tail tip present but not conspicuous.

C. p. coombsii: Limpopo Province, north of Soutpansberg Mts, C and N Botswana, intergrading with *C. p. bradfieldi* in NE and E Namibia and S Botswana. Smallest in size, head and body length <300 mm, condylobasal skull length <61 mm; pelage colour grizzled greyish-yellow and faded, without white tail tip.

A fourth subspecies, *C. p. natalensis*, was proposed by Taylor (1990), but later withdrawn by Taylor & Meester (1993b).

Similar Species

Suricata suricatta. Sympatric across much of the range and often co-exist. Tail not bushy, with a dark tip; ears smaller; dark circles around eyes; mottled upperparts, sometimes forming transverse bars; individuals often adopt a characteristic upright observation stance.

Paracynictis selousi. Only sympatric in parts of N Namibia and Botswana. Larger (as much as twice the body weight of Yellow Mongoose), with general appearance pale speckled grey to tawny-grey and tail white towards the tip. Nocturnal and solitary.

Distribution Virtually endemic to southern Africa, with limited records from extreme SW Angola close to the Namibia border (Crawford-Cabral 1989a). Within this range, Yellow Mongooses occupy the drier western parts, being widespread in Namibia, Botswana and much of C and W South Africa. They are absent from the Namib Desert and Caprivi Strip in Namibia, the Okavango Swamps in Botswana, Zimbabwe (except for an extreme western record) and the easterly regions of southern Africa (including much of KwaZulu–Natal, Swaziland, Kruger N. P., W Lesotho and Mozambique) (Rowe-Rowe 1992a, Monadjem 1998, Skinner & Chimimba 2005).

Habitat Predominantly open grassland, scrub and arid savannas (e.g. *Combretum*/*Terminalia* in the Kalahari) in the drier, semi-arid, western parts of southern Africa, largely corresponding to the South-West Arid Biotic Zone. Absent from deserts and from forested, mountainous and mesic savanna areas in the southern and eastern parts of southern Africa. Owing to their use of burrows, rocky and hard soils are avoided. The availability of water is not an essential habitat requirement.

Abundance Population densities vary geographically, with the highest densities reported for the central plateau grassland region of South Africa (particularly the Free State, North West Province and Gauteng). Since the Yellow Mongoose is the primary vector of viverrid-type rabies in South Africa, high population densities of this species are strongly correlated with areas of high incidence of viverrid-type rabies cases (Snyman 1940, Zumpt 1976). A population density of 6.0–7.1 individuals/100 ha was estimated in West Coast N. P. of South Africa (Cavallini 1993b, Cavallini & Nel 1995) and 4–14 individuals/km² in the Kalahari (Le Roux *et al.* 2008a), whereas a much higher density of 133–200 individuals/100 ha was reported by Earlé (1981) for a study population at the Vaal Dam on the central plateau, which was centred on a large garbage dump that served as a good feeding source. In the Kalahari, numbers of Yellow Mongoose have been found to increase with increasing shrub cover (especially where shrub cover varies between 10 and 15%), but then decrease at higher shrub densities (>17.5%). The amount of

shrub cover presents a trade-off between the abundance of suitable shrubs for reproductive burrows (protection) at small scales and the proportion of shrub cover at large spatial scales (which reduces prey availability and perhaps detection of terrestrial predators) (Blaum *et al.* 2007a, b).

Adaptations The absence of a sagittal crest, and the poor development of the zygomatic arch, both suggest relatively weak masseter and temporalis muscles, indicating a diet of softer food. The dentition is not well adapted for slicing (only the fourth premolar has a sharp outer edge), but molars are suitable for the crushing of insects and similar food (Skinner & Chimimba 2005).

Yellow Mongooses occupy open country where their predominantly insect prey may be more abundant (Cavallini & Nel 1995). Being mostly diurnal (some nocturnal activity has been recorded), their tawny to greyish yellow-coloured dorsal pelage offers an effective camouflage against diurnal predators in open habitats. Their use of burrows also offers protection against predators; in the southern Kalahari, Yellow Mongooses build their burrows preferably under the cover of large and solitary *Acacia* shrubs (shrub diameter 6–9 m) to reduce predation by raptors (Blaum *et al.* 2007a). Burrows also offer a significant thermoregulatory advantage by buffering extremes in ambient temperature. For example, in the Free State, at maximum summer ground temperatures of 39°C, burrow temperature was 14°C cooler, while at a winter minimum of –3.6°C, the burrow temperature was 14°C warmer (Lynch 1980).

Burrows may be simple, with one or two entrances, or much more complex, having up to 60 entrances and comprising linked underground tunnels at two or three levels up to 1.5 m in depth. Nest chambers are excavated at intervals along the tunnels. Yellow Mongooses may construct their own burrows, or even modify existing burrows, and sometimes they share those excavated by Meerkats and Ground Squirrels *Xerus inaurus* with which they may cohabit. Lynch (1980) proposed that the close association between

Lateral and palatal views of skull of Yellow Mongoose *Cynictis penicillata*.

Yellow Mongooses and Meerkats may benefit the former species via improved predator detection. Do Linh San & Somers (2006) described an apparent case of cooperative vigilance between a Yellow Mongoose and three Meerkats while the animals were travelling in open terrain from one termite mound to another. The authors proposed that this interaction was probably favoured by a high degree of inter-specific tolerance emerging through the shared use of burrows and the higher predation risks associated with living in small groups. After leaving their dens in the morning, Yellow Mongooses may sunbathe for periods exceeding an hour, which also has a thermoregulatory function. They have not been observed climbing trees, and may be considered exclusively terrestrial.

The anal glands secrete a milky fluid with a sour, cheesy smell, comprising some 22 volatile compounds (Apps *et al.* 1989a).

Foraging and Food Yellow Mongooses are predominantly insectivorous, preferring Isoptera (termites: *Hodotermes*, *Trinervitermes*, *Microhodotermes*), Coleoptera (beetle larvae and adults) and Orthoptera (locusts and grasshoppers); however, they are highly opportunistic feeders and, depending on availability, will readily hunt rodents, birds, reptiles, amphibians and arachnids (scorpions, spiders) (Zumt 1968, Smithers 1971, Herzig-Straschil 1977, Du Toit 1980, Lynch 1980, Earlé 1981, Stuart 1981, Avenant & Nel 1992, 1997, Cavallini & Nel 1995, Kok & Louw 2000). Detailed reviews of dietary variation in the species, based on many of the dietary studies cited above, are provided by Taylor & Meester (1993b) and Nel & Kok (1999). The latter study analysed diet from populations in the Free State and Northern Cape from 1984 to 1997, and compared these findings with all previous dietary studies. They suggested that termites (Isoptera) were predominant in wetter than average rainfall years (e.g. Lynch 1980) while Coleoptera (beetles) predominated in drier than average years (Nel & Kok 1999).

Diet varies both geographically and seasonally. Contrary to all other studies, in which insects predominate in the diet, in a study of the prey remains in 95 stomachs collected from the central parts of South Africa, Zumt (1968) found rodents to have a higher occurrence than insects. In Botswana, insects occurred more

frequently (92%) than murids (15%), scorpions (13%) and reptiles (11%) ($n = 54$ stomachs; Smithers 1971). In a study in South Africa, invertebrates (mostly termites and locusts) occurred slightly more frequently (87%) than vertebrates (including mammals, birds and amphibians; 28%) ($n = 76$ stomachs; Herzig-Strachil 1977). Rodents were present in 40% of 332 scats analysed at a coastal site in the Western Cape, compared with insects (mostly Isoptera), which occurred in 90% of scats. Five species of rodents were recorded, in order of importance: Four-striped Grass Mouse *Rhabdomys pumilio*, Bush Karoo Rat *Otomys unisulcatus*, Tiny Pygmy Mouse *Mus minutoides*, Pygmy Hairy-footed Gerbil *Gerbillurus paeba* and Cape Gerbil *Gerbilliscus afra* (Avenant & Nel 1992). The occurrence of rodents in the diet of Yellow Mongooses at this site varied considerably during the year, corresponding with fluctuating population densities of rodents. At a site in the Karoo (South Africa), rodents were present in only 3% of a sample of 86 scats, compared with insects (mostly Coleoptera and Orthoptera), which were present in 100% of scats (Avenant & Nel 1992). Isoptera were present in 74% of stomachs ($n = 156$) in a study in the Free State, where other important prey items, in order of importance, were Orthoptera, Coleoptera and Lepidoptera, with vertebrates and other invertebrate groups occurring at much lower percentages (Lynch 1980).

Yellow Mongooses are also known to feed occasionally on fruits, for example, in winter when other food items may be unavailable (Du Toit 1980), and on carrion. Stuart (1981) recorded them feeding on a decomposing Common Duiker *Sylvicapra grimmia*, and they have been recorded feeding on the remains of a Southern African Springhare *Pedetes capensis* (Wenhold 1990). They have been observed feeding on the aloe-type plant *Chlortolirium angolense*, but this may have been for the water content (Zumpt 1968). They have been known to feed on hen's eggs and free-ranging hens, but anecdotal reports by farmers of them preying on newborn lambs are almost certainly false. Snyman (1940) maintained that Yellow Mongooses play an important role in controlling insect numbers, and reported discernible local increases in insect populations following mass eradications of Yellow Mongooses during rabies vector control programmes.

Yellow Mongooses usually forage individually, but also sometimes in pairs or small groups, typically during the early morning and late afternoon. On the west coast of South Africa, a radio-tracking study indicated that 37% of their time was spent foraging (Cavallini 1993a). Timing of activity was correlated with sunset and sunrise times, minimum and maximum temperature, windspeed and meteorological conditions (mist, rain, cloudiness), all variables that in turn are correlated with activity of their main diet of termites (Isoptera). In the Western Cape they have been observed feeding throughout the day, except during the hottest days of the summer (Z. Balmforth pers. comm.).

Social and Reproductive Behaviour Yellow Mongooses have been described as facultatively social. They spend nights in communal dens and even cooperate in raising their young. Based on five studies reviewed by Taylor (1993), mean group size varies from 2 to 13 individuals living together. Since they are mainly solitary away from the burrow, and social at the burrow, their social system appears to be intermediate between that of solitary and social species of mongooses, leading Wenhold (1990) to suggest that this species has a social system representative of a 'missing link' in the evolution of sociality in the

herpestids. Larger group sizes appear to be a feature of areas of high population density, forcing family groups to live together, and young to remain in their natal colony and help raise young.

Although Yellow Mongooses mainly forage alone (unlike social mongooses such as the Meerkat where cooperative foraging is obligatory), they also commonly forage in pairs and small groups, and have been observed following one another whilst foraging (Cavallini 1993b, J. A. J. Nel pers. comm., Z. Balmforth pers. comm.). In contrast to Meerkats, the presence of conspecifics during foraging increases individual vigilance and reduces their foraging time and success. Instead, Yellow Mongooses avoid predator detection by remaining close to safe refuges and making use of inconspicuous vigilance behaviours (avoiding the sentinel behaviour of Meerkats), which do not interfere with foraging (Le Roux *et al.* 2009b). This reinforces the suggestions of Nel & Kok (1999) – who compared low foraging group size of Yellow Mongoose with the high foraging group sizes of Bat-eared Fox *Otocyon megalotis* and Meerkat – that competition may not be a major constraint of group size in foraging Yellow Mongooses.

Groups typically comprise a dominant ♂, with separate hierarchies for the subordinate ♀♀ and ♂♂. Juveniles are the lowest ranking. To assess dominance status, two individuals approach one another and sniff each other's facial glands. The dominant individual rises higher on its feet while biting the subordinate's neck. The subordinate lies on its side and may emit a high-pitched scream. A dominant individual marks a subordinate by straddling it from above and using the anal glands in a standing position. In a colony studied by Earlé (1981), the dominant ♂ marked colony members daily; however, in the study of Wenhold (1990), the dominant ♂ was not involved in dominance interactions, but high-ranking subordinates deferred to the dominant ♂♂, and in turn dominated lower ranking members.

In a radio-tracking study in a coastal area of the Western Cape, ♂♂ moved an average of just over 3 km per day, with ♂♂ and ♀♀ moving, on average, similar distances per hour (292 m/h and 228 m/h, respectively). Home-ranges of ♂♂ (minimum convex polygon method: 102 ha) are larger than for ♀♀ (10–49 ha) (Cavallini 1993b). Overlap among ♂♂ was substantial and individual home-ranges overlapped those of several ♀♀, while the ranges of female groups in different burrows showed almost no overlap (Cavallini 1993b, Cavallini & Nel 1995). There was no evidence for group territories. However, it appears that social structure may vary geographically, again possibly in response to population density, since, in other studies, both ♂♂ and ♀♀ were shown to patrol, mark (with middens) and defend group territories (Earlé 1981, Le Roux *et al.* 2008a, Z. Balmforth pers. comm.). Le Roux *et al.* (2008a) recorded a mean territory size of 76 ha for dominant ♂♂ ($n = 6$) and a home-range size of 20 ha for a dominant ♀. Yellow Mongooses are partly nomadic, and they may rotate the use of several burrow systems on different nights, within a much larger territory (Wenhold 1990).

Defecation takes place on middens close to burrows (or along a group territory in the case of Earlé's study), and the faeces have a distinct odour possibly due to anal gland secretions. The anal glands function in scent-marking of home-ranges and allo-marking between colony members. The dominant pair and juvenile ♀♀ concentrate their markings mainly around the burrow. Objects may also be marked by means of the cheek gland, often preceded by wiping the entire side of the body on the ground or side-swiping (Earlé 1981, Wenhold & Rasa

1994). All members of the group help mark, although Wenhold & Rasa (1994) noted that most marking was done by younger, subordinate individuals, which they suggested was a means of advertising for potential mates. In other studies, dominant ♂♂ were the main territory defenders and demarcators (Earlé 1981). Comparing a low-density population in the Kalahari with that of Wenhold & Rasa (1994), a high-density population on farmland displaying natal philopatry, Le Roux *et al.* (2008a) recorded marked differences in terms of individual contributions to territorial marking: subordinate group members in the low-density population performed almost no territorial marking or defence, but were the primary scent-markers and territory defenders in the high-density population (presumably because larger groups in high-density populations interact with neighbours more frequently, causing more conflict but also opportunities for mating and sexual advertisement between neighbours).

Fights between dominant ♂♂ of adjacent colonies occur frequently and may be violent (Wenhold & Rasa 1994), with dominant ♂♂ often bearing scars on their faces. However, in a low-density population in the Kalahari, aggression between neighbours appeared to be low with encounters of brief duration and seldom drawing blood; territory expansion into neighbouring territories was never observed (Le Roux *et al.* 2008a).

When ♀♀ are in oestrus, ♂♂ purr, 'caw' and scream while following the ♀♀ around and attempting to mount. Oestrous ♀♀ will allow copulation over a two-day period, after which ♂♂ are vocally rebuffed accompanied by bites to the head and neck. Earlé (1981) recorded young-adult ♀♀ mating with dominant and other ♂♂. Two observed copulations lasted 37 and 45 min. During copulation, the ♂ kept up his purring, while the ♀ bit or licked the male's ears and neck. Young are born in nesting chambers in the burrows. The Yellow Mongoose adopts a unique system of infant care, whereby adult 'helpers' (some of the previous year's young that do not disperse but remain in the natal group) provision young at their dens for the first four weeks, carrying back large prey items (rodents, bats, reptiles and large arachnids) (Rasa *et al.* 1992). However, in a low-density population in the Kalahari, Yellow Mongooses lived in small family groups and showed no cooperative breeding; young dispersed by nine months of age (establishing territories 2.5 km from their natal territories; Le Roux *et al.* 2008a) and became parents immediately if they found a mate (Vidya *et al.* 2009). The young first accompany adults on foraging expeditions at about eight weeks of age. By contrast, the young of other social mongooses (*Helogale* and *Mungos*) must accompany the adults to forage and hence suffer greater predation from avian predators (Rasa *et al.* 1992).

Yellow mongooses have a repertoire of at least nine distinct vocalizations that are used in multiple contexts (Le Roux *et al.* 2009a). A tenth reported vocalization, a purring sound that accompanies mating (Earlé 1981, Wenhold 1990), adds to the repertoire. Compared with solitary mongooses, the Yellow Mongoose has a large proportion of 'friendly' vocalizations (five) that enhance group cohesion, but its vocal repertoire is smaller and less context-specific than those of obligate social species, such as the Dwarf Mongoose *Helogale parvula* and Meerkat (Le Roux *et al.* 2009a). Social context has been shown to affect both communicative and flight behaviour of Yellow Mongooses: alarm vocalizations were used almost exclusively when individuals were in a group rather than solitary, while the visual alarm signal, a raised tail, was predominantly used by solitary

individuals when predators were outside attack range (Le Roux *et al.* 2008b).

Reproduction and Population Structure Between one and five young, most commonly two, are born during up to two distinct birth seasons (Wenhold 1990, Rasa *et al.* 1992, Taylor & Meester 1993a, Z. Balmforth pers. comm.). In contrast to earlier reports of monoestry and an extended breeding season, based on anatomical observations of pregnant ♀♀ (Zumpt 1969, 1976, Lynch 1980), later studies based on long-term behavioural observations of breeding ♀♀ have demonstrated the existence of dioestry (Wenhold 1991, Rasa *et al.* 1992). Based on observations of four colonies from geographically widespread localities, ♀♀ first came into oestrus in early Aug, followed by a gestation period lasting 60–62 days, with births occurring in early to mid-Oct. In South Africa, a second oestrus occurs rapidly postpartum in mid-Oct (while ♀♀ were still suckling their young), with births occurring in mid- to late Dec (Rasa *et al.* 1992). In contrast, unpublished observations from the Western Cape (Z. Balmforth pers. comm.) suggest that most second breeding attempts fail, with one birth reported in late Jan, suggesting a two-month postpartum oestrus. In Namibia (Etosha N. P.) and Botswana (Kgalagadi Transfrontier Park) a second oestrus occurred up to two months after birth, in mid-Dec, and births followed in mid-Feb (Rasa *et al.* 1992).

The production of up to two small, but closely spaced, litters annually, and the provisioning of young at their dens by helpers, may be part of an evolutionary strategy to maximize reproductive output whilst ensuring greater survival of young through guarding of dens by helpers (group size is relatively small, so only a few helpers are available per litter). Unlike the situation in the Dwarf Mongoose, there is no reproductive suppression in a colony so that more than one ♀ can breed simultaneously, another factor that may explain small litter-size. Lactation lasts 6–8 weeks, and young are nutritionally independent at 16–18 weeks of age (Rasa *et al.* 1992).

In one study, 41 litters were found to comprise a single sex only. At birth, the male : female sex ratio was 1.6 : 1 whereas in adults this changed to 1.2 : 1 (Zumpt 1976). Yellow Mongooses live up to 15 years in captivity (Jones 1982, Weigl 2005).

Predators, Parasites and Diseases Large snakes (such as Cape Cobra *Naja nivea*) and water monitor lizards *Varanus* spp. prey on young or immature Yellow Mongooses and Black-backed Jackals *Canis mesomelas* may take adults and young. Large raptors such as Tawny Eagles *Aquila rapax*, Martial Eagles *Polemaetus bellicosus* and Wahlberg's Eagles *Aquila wahlbergi* are important avian predators.

Many species of parasites have been recorded, including at least eight species of fleas (among them the plague vector, *Xenopsylla perei*), ten species of ticks (most commonly *Haemaphysalis zumpti*), seven species of mites, two species of lice, nine species of helminths and a nematode parasite, *Tenuostrongylus cynictis* (Hinton & Dunn 1967, Lynch 1980, Horak *et al.* 1999, 2000). After examining 80 Yellow Mongooses, Horak *et al.* (1999) found one species of biting louse *Felicola cynictis* to be the most prevalent ectoparasite. Penzhorn & Chaparro (1994) found a very high prevalence (77%) of infection by the haemo-protozoan *Babesia cynictis* in 97 animals from the Pretoria, Ermelo and Potchefstroom areas of South Africa.

The Yellow Mongoose is the primary maintenance host for the viverrid strain of rabies endemic to the interior plateau of South

Africa, where Yellow Mongoose population densities are highest. The role of the Yellow Mongoose as a maintenance host is promoted by its diurnal and colonial, burrow-living habits. Viverrid rabies was first confirmed in 1928, and, by 1940, the Yellow Mongoose was implicated in 21 human deaths, the deaths of five head of cattle and 80 outbreaks of rabies. By 1992, some 2119 confirmed cases of rabies infections in Yellow Mongooses had been documented (Snyman 1940, Swanepoel *et al.* 1993). The incidence of viverrid rabies increased each decade, peaking in the 1970s. Between the 1930s and 1970s, wholesale eradication of Yellow Mongooses was applied to control the disease, but this is now applied selectively in areas with a high risk of possible infection by humans. A seasonal peak in the incidence of rabies coincides with the peak birth period of Yellow Mongooses (Zumpt 1969, 1976). Chaparro & Esterhuysen (1993) demonstrated that viral maintenance in the Yellow Mongoose was not due to a carrier state, as experimentally infected animals showed high mortality, and serum antibodies to the rabies virus were present only in the terminal stages of the disease. Apart from specific outbreaks, the level of rabies infection in nature may be very low. In one sample of 97 animals from a rabies-endemic area, no rabies virus or antibody was detected in any specimens (Chaparro & Esterhuysen 1993).

Conservation IUCN Category: Least Concern. CITES: Not listed.

The Yellow Mongoose occurs in numerous protected areas across its range in southern Africa, including Etosha N. P. (Namibia) and Kgalagadi Transfrontier Park (Botswana/South Africa), and does not appear to be under any significant threat at present.

GENUS *Paracynictis*

Selous's Mongoose

Paracynictis Pocock, 1916. Ann. Mag. Nat. Hist., ser. 8, 17: 177.

Paracynictis is a monotypic genus of south-central Africa, occupying a range of savanna habitats. *Paracynictis* was originally assigned to the genus *Cynictis*, because of its similarities to the Yellow Mongoose *Cynictis penicillata*, a species with which it is probably closely related (and was included in *Cynictis* by McKenna & Bell 1997) (see Flynn

et al. 2005). Molecular data (Patou *et al.* 2009) cluster Yellow Mongoose and Selous's Mongoose as sister species.

Chris Stuart & Tilde Stuart

Paracynictis selousi SELOUS'S MONGOOSE

Fr. Mangouste de Selous; Ger. Trugmanguste

Paracynictis selousi (De Winton, 1896). Ann. Mag. Nat. Hist., ser. 6, 18: 469. 'found on a grassy heap under a tree, EssexVale, Matabeleland ... near Bulawayo' [Zimbabwe].

Taxonomy Coetsee (1977) listed four subspecies: *P. s. bechuanae* from E Botswana; *P. s. ngamiensis* from N Botswana, N Namibia, Angola, Zambia and Malawi; *P. s. selousi* from Zimbabwe, western border of the Vila Pery District, Mozambique, and NE South Africa; and *P. s. sengaani* from N KwaZulu–Natal and S Mozambique. Coetsee (1977) cautioned that this listing was provisional, noting that subspecies were separated on the basis of slight differences in pelage and that they were likely no more than stages in clinal colour variation. Rautenbach (1982) suggested that *P. s. sengaani* is a geographical isolate, and Meester *et al.* (1986) considered *bechuanae* and *ngamiensis* as synonyms of the

nominate race, retaining only *P. s. selousi* and *P. s. sengaani*. Ansell & Dowsett (1988) similarly regarded Malawian specimens as *P. s. selousi*. Synonyms: *bechuanae*, *ngamiensis*, *sengaani*.

Chromosome number: not known.

Description A medium-sized mongoose, with a partially white tail. General appearance pale speckled grey to tawny-grey. At close quarters coat distinctly grizzled, with white annulations on guard hairs. Guard hairs on head about 15 mm long, to 40 mm on rump and up to 100 mm towards tail tip. Underparts slightly paler than

Selous's Mongoose *Paracynictis selousi*.

upperparts but similar in colour. Underfur is thick, woolly and hairs are dark at bases, with buff or buff-grey tips. Rhinarium small for size of head, fine philtrum between nostrils, dividing haired portion of upper lip. Ears rounded and partially covered in front by longer hair. Feet and legs dark brown to black, contrasting with rest of pelage. Four digits on each foot, with stout claws. Light coloured, well-haired tail white towards tip and constitutes about 40% of the total body length. A specimen taken by Hill (1941) in Angola had two pairs abdominal nipples, although the author pointed out that three pairs, one pair pectoral, has been reported as the norm. There is no sexual dimorphism.

Skull elongated, braincase ovoid, narrowing slightly to the interorbital constriction. The rostrum is short and broad, the supraoccipital crest well developed. The width of the zygomatic arches is about half the total length of the skull. Ear bullae large relative to size of skull. Dental formula is $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$. Upper canines short, rounded and slightly recurved, the lower distinctly recurved. Both upper and lower outer incisors are slightly larger than the remainder; the first upper and lower premolars are not always present. The fourth upper premolar teeth have two well-developed cusps on their outer edges and a low cusp on their inner sides. The first molar in the lower jaw has three high cusps towards the front of the teeth (Skinner & Chimimba 2005).

Geographic Variation

P. s. selousi: C and S Angola, S Zambia, much of C and S Malawi, almost throughout Zimbabwe except the north-east, with a marginal occurrence in NE Namibia and in Botswana, north from L. Ngami and in a narrow belt in the extreme east and south-east. Also present in extreme NE and E South Africa.

P. s. sengaani: NE KwaZulu–Natal (South Africa) and S Mozambique.

Similar Species

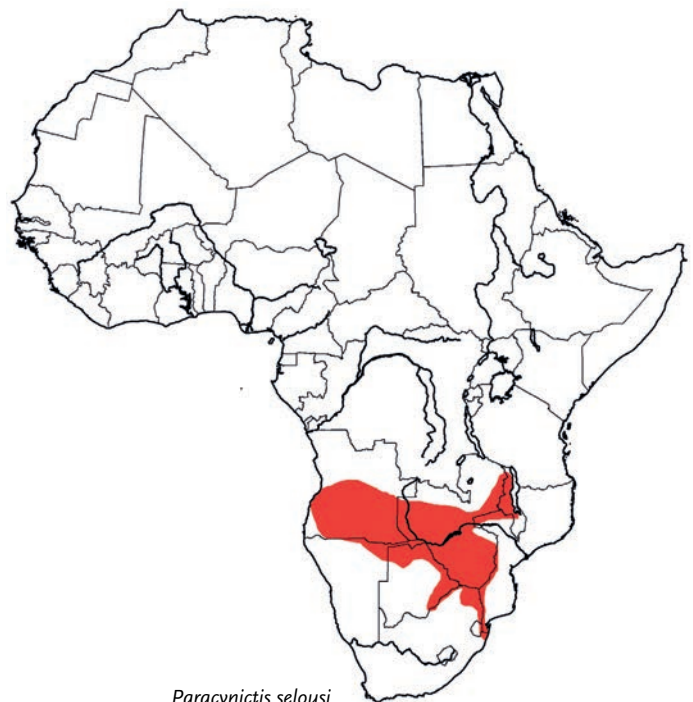

Ichneumia albicauda. Woodland and savanna habitats in sub-Saharan Africa from Senegal eastwards to the Horn of Africa, and southwards to SE South Africa. Much larger (up to 6 kg); limbs longer and more extensively dark to black in colour; rump higher than shoulders and head held low when walking.

Rhynchogale melleri. Woodland habitat from N Tanzania south to NE South Africa. Individuals may have partially white tails, but pelage overall more brown; distinct crest-like parting on either side of neck.

Cynictis penicillata. Only sympatric in parts of N Namibia and Botswana. Pelage reddish-yellow to greyish-yellow, usually but not always with white hairs at extreme tip of the tail; smaller (to 900 g); strictly diurnal.

Bdeogale crassicauda. Sympatric in Zimbabwe and Mozambique. Slightly smaller; uniform brownish coat, limbs and feet not contrasting strongly with the coat.

Distribution Endemic to Africa, ranging from Angola in the west to Malawi in the east, with its most southward extension in NE KwaZulu–Natal. In Angola the species occurs in the central and southern parts, but is absent from the arid coastal part (Crawford-Cabral 1989a). It has a marginal occurrence in Namibia, being limited to the extreme north-east centred on the Caprivi Strip (Skinner & Chimimba 2005). In Zambia, it occurs throughout the south-western parts, including the middle Zambezi Valley, with a possible record from the Mwinilunga District in the north-east (not mapped); its range extends through the Central and Eastern Provinces to Malawi (Ansell 1978). Ansell (1978) cautioned that it was not clear whether there was a break in distribution between the central and eastern provinces of Zambia. In Malawi, Ansell & Dowsett (1988) give the northernmost records as 'eight miles east of Mzimba and the Perekezi Forest' and point out that the species is unlikely to occur east of the Shire R. There are as yet no records from the Tete district of Mozambique (Smithers & Lobão Tello 1976), but they probably do occur. In Zimbabwe, they occur throughout much of the country, except the north-east (Smithers & Wilson 1979); they have been recorded from the western border of the Manica province in Mozambique (Smithers & Lobão Tello 1976). In Botswana they occur mainly in the north-west, apparently as far south as L. Ngami, east to the Zimbabwe border. In South Africa, they are present in the

Paracynictis selousi

Lateral and palatal views of skull of Selous's Mongoose *Paracynictis selousi*.

north-eastern parts (Limpopo Province and Mpumalanga) south to NE KwaZulu–Natal (Skinner & Chimimba 2005). They are not yet recorded from Swaziland (Monadjem 1998), but may well occur.

Habitat A mongoose of savanna grassland and woodland that is absent from forest and arid areas. Known distribution range falls within the 400–1000 mm rainfall zone. Most authors (Shortridge 1934, Ansell 1960a) found them to be associated with areas dominated by sandy substrates. In areas of harder substrates they may occupy more open grassed areas, such as flood-plains and cultivated land (Smithers 1971). Not dependent on the availability of water.

Abundance Appears to be uncommon throughout its range. However, many areas within its known range are zoologically poorly explored and in parts it may be more abundant than currently recorded.

Adaptations The large ear bullae indicate that sense of hearing is well developed and an aid to locating its largely subterranean prey. The carnassial shear has little slicing ability and appears better adapted to a diet of insects and other soft food. Selous's Mongooses carry heavy and stout claws on the front feet, which enable them to excavate their own burrows, as well as dig for prey.

Foraging and Food Selous's Mongoose may be predominantly insectivorous, eating a wide range of species, although in a sample of 51 stomachs from Zimbabwe and Botswana insects from the orders Orthoptera, Isoptera and Coleoptera were the dominant prey items (Smithers 1971, Smithers & Wilson 1979). Other invertebrate groups, especially solifugids and scorpions, were also of importance. A wide range of small vertebrates has also been recorded, including murids, lizards, snakes, amphibians and birds. Earlier authors, such as Shortridge (1934), listed small vertebrates as being more important than insects in this mongoose's diet. In no case is much detail presented but this may indicate regional and seasonal differences in their food. Smithers (1971) found that during a drought period in Botswana stomach contents were dominated by invertebrate remains, but when the rains came and rodent populations increased these became the favoured food.

Selous's Mongoose is a nocturnal, solitary forager that appears to move about only well after sunset. When foraging animals, frequently

stop to investigate possible food sources, and readily dig and scratch for subterranean prey. They move at a rapid walk with nose close to the ground and they are believed to have an acute sense of smell.

Social and Reproductive Behaviour Mainly solitary, but pairs have been recorded and it is presumed that larger young accompany their mothers during foraging (Smithers 1971). In sandy substrates Selous's Mongooses excavate their own burrows, which may be extensive with two, or more, entrances (Skinner & Chimimba 2005, C. T. Stuart pers. obs.). In areas of harder substrate they make use of burrows excavated by other species. Nothing is known of reproductive behaviour.

Reproduction and Population Structure The few records of reproduction, mainly from Botswana and Zimbabwe, indicate that litters of from two to four young are born during the warm, wet summer months, from Aug to Mar. Smithers (1971) recorded two gravid ♀♀ from Botswana, one (Feb) with three and the other (Sep) with four foetuses. A ♀ with three foetuses was collected in W Zimbabwe in Aug (Smithers & Wilson 1979). Shortridge (1934) took a pregnant ♀ in Namibia in Oct, and Hill (1941) recorded that the nipples in an adult ♀, taken in early Dec in Angola, were active. Young animals have been recorded in Dec, Jan and Feb.

Predators, Parasites and Diseases The only record of predation on this species is by Martial Eagles *Polemaetus bellicosus* in Zimbabwe (Steyn 1980). There is limited information available on diseases and parasites, although a preliminary survey found that this species does not play a role in the epidemiology of rabies in Zambia (Sawchuk & Rottcher 1978). Fuhrmann (1943) recorded the cestode *Pseudandrya monardi* from Angola.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although it occurs at low to fairly low densities right across its range, it remains widespread and the nature of its habitat is such that it faces no known threats.

Measurements

Paracynictis selousi

HB (♂♂): 397 (445–455) mm, n = 22

HB (♀♀): 419 (328–443) mm, n = 25

Chris Stuart & Tilde Stuart

GENUS *Ichneumia*

White-tailed Mongoose

Ichneumia I. Geoffroy Saint-Hilaire, 1837. Ann. Sci. Nat. Zool. (Paris), 8 (2): 251.

The genus is monotypic, including only one species, the White-tailed Mongoose *Ichneumia albicauda*, which ranges throughout most suitable habitats in sub-Saharan Africa, and also in Yemen and other coastal regions of Arabia. Molecular data reveal a close relationship

between *Ichneumia*, *Cynictis*, *Rhynchochale* and *Bdeogale* (Patou *et al.* 2009).

Mark E. Taylor

Ichneumia albicauda WHITE-TAILED MONGOOSE

Fr. Mangouste à queue blanche; Ger. Weißschwanzichneumon

Ichneumia albicauda (G. Cuvier, 1829). Le Règne animal, 2nd edn, 1: 158. 'l'Afrique australe et le Senegal' [southern Africa and Senegal].

White-tailed Mongoose *Ichneumia albicauda*.

White-tailed Mongoose *Ichneumia albicauda* melanistic form.

White-tailed Mongoose *Ichneumia albicauda* myology.

Taxonomy Taylor (1972) and Coetzee (1977) recognized six subspecies in Africa. Subspecies have been distinguished on the basis of variations in pelage colour, and since variations in colour and size are probably determined by environmental determinants such as moisture and elevation, there have been doubts as to their validity. Phylogenetic analysis based on partial sequences of the mitochondrial control region lends some support to several of these subspecies (*I. a. grandis*, *I. a. dialeucos* and the nominate subspecies), but has indicated the need for much broader sampling before proposing a new subspecific classification of the species based on molecular data (Dehghani *et al.* 2008). Synonyms: *abuwudan*, *albescens*, *almodovari*, *dialeucos*, *ferox*, *grandis*, *haagneri*, *ibeana*, *leucurus*, *loandae*, *loempo*, *nigricauda*. Chromosome number: $2n = 36$. The autosomes are composed of 14 pairs of meta- or submetacentric and three pairs of acrocentric elements. The X chromosome is a medium-sized metacentric and the Y is a very small submetacentric (Wurster & Benirschke 1968).

Description A large distinctive mongoose, usually grey, with black limbs and grey tail with distal third of tail usually white. Ears rounded and lightly furred, barely protruding above head profile. Upper lip divided by internarial groove from nose to mouth. Head

and body grizzled grey due to banding of guard hairs, with guard hairs longer (up to 90 mm) on nape and back with longer black tips. Undercoat thick, and underfur buffy. Individuals from high rainfall parts of the range often very dark to melanistic, while in arid areas the general colour is light grey. Tail tapers, is usually grey in proximal half and becomes progressively whiter distally. Black-tailed specimens are known throughout the range of the species (e.g. Botswana, Smithers 1971; N Mozambique, C. Begg & K. Begg pers. comm.; East Africa, Kingdon 1977; Ethiopia, Duckworth 1995), and are even more common than the white-tailed variant in West Africa (Rosevear 1974, Grubb *et al.* 1998). Legs are long, with hindquarters higher than their forequarters, and limbs dark brown to black from mid-leg to feet. Feet pentadactyl, the first digit small and set well back from the plantar pads, and palms naked to wrist (but soles hairy from behind first toe to wrist); hindfeet heavier and broader than front feet. Interdigital pads well developed. Claws robust and curved, reaching up to 13 mm over the curve. Anal glands appear to be used for marking territory. No noticeable sexual dimorphism, although

Lateral and palatal views of skull of White-tailed Mongoose
Ichneumia albicauda.

♂♂ slightly heavier than ♀♀ (Smithers & Wilson 1979, Waser & Waser 1985). Three pairs abdominal nipples (Skinner & Chimimba 2005); however, some authors report two pairs (Roberts 1951).

Skull heavy with somewhat inflated nasal region and inflated posterior chamber of tympanic bullae, well-developed supraoccipital crest, robust zygomatic arches and postorbital bar complete in adults. The White-tailed Mongoose retains a more primitive generalized carnivore dentition, with a dental formula of $I^{3/3}, C^{1/1}, P^{4/4}, M^{2/2} = 40$. Upper canines slightly curved and pointed. Taylor (1992) provides additional details on the skull and dentition.

Geographic Variation

- I. a. albicauda*: relatively dry woodlands from Somalia through Uganda and C Sudan to Senegal.
- I. a. loempo*: West African forest fringes.
- I. a. grandis*: southern Africa south of the Cunene–Zambezi, large parts of Zambia, Malawi and N Mozambique.
- I. a. loandae*: Angola and adjacent NW Zambia and S DR Congo.
- I. a. ibeana*: C and S Kenya, Tanzania, Uganda and NE DR Congo.
- I. a. dialeucos*: N Kenya and S Ethiopia and Somalia.

Similar Species

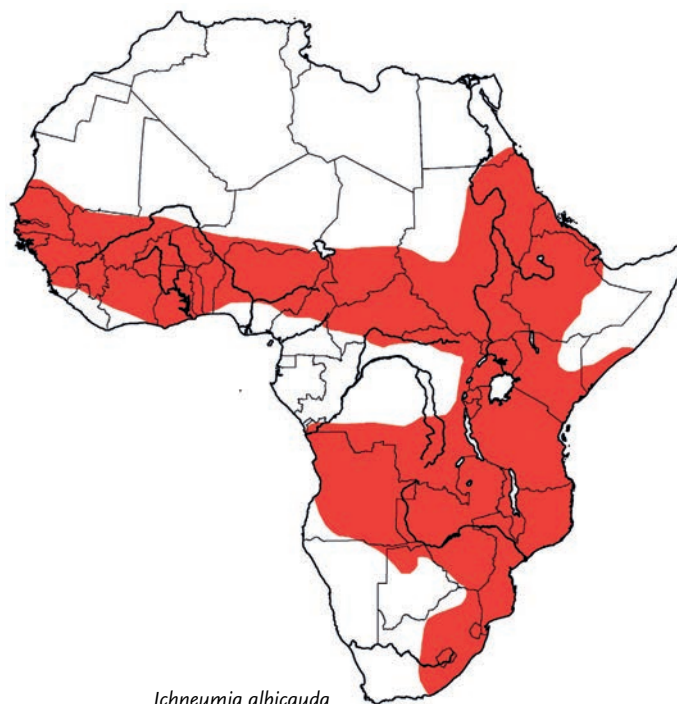

- Herpestes ichneumon*. Widely distributed from Senegal to East Africa, southwards to NE Namibia and E South Africa. Slender tapering tail and a tufted darker tip; more uniformly grizzled grey.
- Atilax paludinosus*. Riparian habitats from Senegal east to north-east Africa and south to South Africa. Uniform brown with a rather shaggy and rich brown coat; relatively short tail; distinctive feet in which the interdigital web is much reduced allowing the digits to be splayed out when walking on soft substrates.
- Rhynchogale melleri*. Woodland habitat from N Tanzania south to NE South Africa. Smaller, and with shorter, whitish tail; dark muddy-grey or buffy-brown; distinctive crest-like parting on either side of the neck; no split in the rhinarium.
- Bdeogale jacksoni* and *B. nigripes*. Larger, generally light-coloured with dark tetradactyl (four digits) limbs; occurring in forested areas rather than savannas.

Paracynictis selousi. Savanna grassland and woodland from Angola to Malawi south to NE KwaZulu–Natal. Smaller; generally pale speckled grey to tawny-grey; feet and legs dark brown to black, contrasting with rest of pelage; partially white tail.

Distribution Occurs in woodland and savanna habitats in sub-Saharan Africa from Senegal and Gambia in the west, eastwards to S Somalia, Ethiopia, Eritrea and Djibouti, and then southwards to SE South Africa. While it occurs throughout the Sahelian region it is absent in the more arid regions. There are as yet no confirmed records from Egypt (Osborn & Helmy 1980, Hoath 2003), though they may well occur in the south-east. They also are absent from the moist equatorial forest regions, but extend through Malawi, Zambia, Zimbabwe and N Botswana to NE Namibia and Angola. They penetrate forested regions along roads and agricultural areas and also penetrate the eastern extension of the low scrub (karroid) vegetation between the Free State and the Northern Cape of South Africa (C. Stuart pers. comm.).

Extralimital to the continent, this species is present in suitable habitats along much of the coast of Saudi Arabia to Oman in the east (Harrison & Bates 1991, Gallagher 1992, Stuart & Stuart 1998d). This population is estimated to have colonized the Arabian Peninsula ~32,500 years ago, making it a relatively long-term resident of Arabia (Fernandes 2011). They are also recorded from Farasan Kabir I. in the Red Sea, where they may have been introduced (Simmons 1995, Masseti 2010).

Habitat Occurs in grasslands, savanna and woodland areas. Absent from moist forested areas, high altitudes above the treeline, desert and semi-desert. Common in farmland and other human-modified habitats in Ethiopia (to about 3500 m) and likely elsewhere in East Africa (Admasu *et al.* 2004b). White-tailed Mongooses are highly flexible in their habits and thus adaptable to human land use, with individuals often found around towns and villages where they feed opportunistically on garbage. In Oman they have been found associated with gardens and

Ichneumia albicauda

plantations (Harrison & Bates 1991). The species requires suitable denning locations to rest in during the day, so the absence of suitable cover may restrict its distribution in short to long grasslands.

Abundance The species is common in parts of its range and densities as high as 4.3 ind/km² were reported from Serengeti N. P., Tanzania (Waser 1980). In some areas density may be limited by the availability of dens for resting up during the day. The most detailed studies have been conducted in Serengeti N. P. where population densities were found to be higher in the west and lower in the east, in parallel with the higher rainfall in the west and associated greater amounts of insect food. High densities have been reported in protected urban areas such as ravines and parks and around livestock operations, where the presence of dung and associated insects provides an ample supply of food.

Adaptations The teeth are broad and heavy, particularly the last premolars and first two molars. They are well adapted to crushing insect prey (though they still have a carnassial shear, unlike *Bdeogale* that has crushing molars), and their diet of insects and small vertebrates results in pitting and grooving of the surface enamel (Taylor & Hannam 1987).

White-tailed Mongooses are the most cursorial of the mongooses, with long metapodials and digitigrade fore- and hindfeet (Taylor 1988). Although accomplished diggers, with stout, curved claws, they are not as long as those of the Banded Mongoose *Mungos mungo* and they do not appear to dig their own burrows, using disused Aardvark *Orycteropus afer* or springhare *Pedetes* spp. holes to rest in during the day. They also use holes in termitaria, which previously have been opened up by Aardvark or other species. In Serengeti N. P., Waser & Waser (1985) found that most occupied dens were inactive termite *Odontotermes* mounds; they appeared to enlarge the ventilation shafts to gain entry to underground chambers. No dens were dug from scratch and several dens were so shallow that the mongoose was visible from outside. Other dens are located in hollows at the bases of trees such as *Acacia* and *Balanites* spp. In farmland adjacent to Bale Mountains N. P. in Ethiopia, diurnal resting sites were found amongst rocks and in disused buildings (Admasu *et al.* 2004b). It is unknown whether they use bedding material.

White-tailed Mongooses are predominantly nocturnal and generally emerge from dens shortly after dusk and may be active through into the early hours of the morning; some diurnal activity is reported in a few areas (Waser 1980, Stuart 1981, Sillero-Zubiri & Marino 1997).

Foraging and Food White-tailed Mongooses are primarily insectivorous, eating medium to large insects (especially termites, beetles, grasshoppers, crickets and beetle larvae) that emerge or are active at night. In a sample of 65 stomachs from Zimbabwe, insects had the largest percentage occurrence at 86%, followed by amphibians (31%), murids (18%) and reptiles (15%) (Smithers 1971). In Kenya, S. Takata (pers. comm.) found their diet to be approximately 55% arthropod, 25% mammal and 20% birds. Insects seem to be a major part of their diet during the wet seasons with a shift to more vertebrate prey during the dry seasons (M. Taylor pers. obs.). They rarely eat fruits and vegetable matter, although these are eaten where available; Pitman (1954) reported them feeding on avocado pears in Uganda.

White-tailed Mongooses usually forage singly (but see Social and Reproductive Behaviour), quartering an area and grabbing insects,

usually larger than 5 mm (Waser 1980). Prey is located mainly by scent. They may forage in a zig-zag fashion, thereby quartering an area more effectively for emerging insects. They may catch several insects a minute and forage for 6–8 hours a night, travelling approximately 4–5 km and usually traversing their entire home-range (Waser 1981, Waser & Waser 1985). They continue foraging during light rain and brief thunderstorms. They occasionally dig for beetles, alates and other insects and will jump or pounce on small vertebrate prey (amphibians, reptiles, mice and other small mammals), although they rarely catch prey on the wing. They are opportunistic and may be attracted to insects below street lights, to dung insects associated with cattle enclosures, and to garbage and refuse associated with human habitations. White-tailed Mongooses often hunt insects on roads at night and this sometimes results in them being hit by vehicles and numerous animals sustain fractures to their pelvis or hindquarters as a result of this hunting activity (Taylor 1972).

The species has been recorded eating carrion: Rowe-Rowe (1978a) states that 17 animals were accidentally killed by coyote-getters, baited with carrion, in KwaZulu-Natal (South Africa). Numerous authors have reported White-tailed Mongooses killing and preying on poisonous snakes. As with other mongooses, they also eat eggs, breaking them by hurling them between their back legs against rocks. Kingdon (1977) reported an account by Pitman (1954) of White-tailed Mongooses using their tail as a lure to attract chickens at night, but while this may occur in some circumstances, their major diet of insects would suggest that this is an unusual use of the white-tipped tail. They may coexist with Bat-eared Foxes *Otocyon megalotis* and Aardwolves *Proteles cristatus*, two other insectivorous nocturnal carnivores, but there is no indication that they actually compete for food resources (Waser 1980).

Social and Reproductive Behaviour White-tailed Mongooses are predominantly solitary. In Serengeti N. P., 87% of about 390 sightings were of solitary animals (Waser 1980), and 79% of 110 sightings in Bale Mountains N. P. were of solitary animals (Admasu *et al.* 2004b), similar to observations obtained in the Ethiopian Rift Valley (88%; Duckworth 1995). Groups usually comprise ♀♀ with large young, but all group sightings in Bale comprised an adult ♀ with an adult ♂ (Admasu *et al.* 2004b). Individuals may be seen foraging together in areas where insects are emerging or there is a concentrated food source (Kingdon [1977] reports up to nine seen foraging together), but the animals are not social in the way in which Dwarf Mongooses *Helogale parvula* or Banded Mongooses are. There may be no advantages conferred on sociality for a mongoose of this size, as well as the fact that most habitats do not provide suitable denning places for groups of individuals and probably the dispersed nature of the food source it exploits.

The species appears to be territorial, though territories of ♂♂ may overlap and ♀♀ often overlap; the ranges of three adjacent radio-tagged adult ♂♂ in Bale were mutually exclusive, and overlapped to a maximum of 3% (Admasu *et al.* 2004b). Once animals have been removed from an area, it usually takes some weeks before new individuals arrive and establish territories. The home-ranges of ♂♂ overlap those of ♀♀, and may include parts of 2–3 females' ranges while the home-range of a ♀ sometimes lay within the ranges of two or more ♂♂. In Bale, ranges of adult ♀♀ overlapped 81% with one ♂ and 25% with a second ♂ (Admasu *et al.* 2004b).

Agonistic encounters between ♂♂ have not been described and it appears that scent-marking of territories and display behaviour may be sufficient to space individuals through suitable habitat, the size of each home-range being dependent upon available food resources and den availability. However, at high densities, home-ranges of ♀♀ may be shared, perhaps by grown daughters (P. Waser pers. comm.). If the food available is largely emerging insects, there are few advantages to be gained by any individual excluding other individuals from the area (Waser 1981); therefore, there is no need for territoriality. The advantages that small social mongooses gain from being social is probably more to do with warning, protection from potential predators, and increased reproductive success, than being able to forage more efficiently, as these species are all considerably smaller than White-tailed Mongooses and are diurnal rather than nocturnal.

Range sizes appear to vary in different habitats: in Serengeti N. P., Waser & Waser (1985) gave the mean home-range size for ♂♂ as 0.97 km² (range 0.8–1.23; n = 4) and for ♀♀ as 0.64 km² (range 0.39–1.18; n = 9), while in Omo N. P., Ethiopia, a single individual tracked over a few weeks at an artificial food source occupied a home-range of approximately 0.03 km² (Ikeda *et al.* 1982). Range size in Bale over a 14-month period averaged 3.17 km² for three adult ♂♂ and 2.63 km² for one ♀; the large range size was probably due to less abundant food in Bale than in Serengeti, where dung beetles are very common due to the availability of faeces produced by large herds of grazing ungulates (Admasu *et al.* 2004b). Taylor (1972) reports a home-range of 8 km² for a Kenyan animal. The

home-ranges of seven ♀♀ included an average of three den sites, though not all were necessarily in use. Mongooses used the same den for 5–15 days before moving to a new den (Waser 1980), but may return after a period when food supplies have built up again.

Social grooming has rarely been observed, though individuals that come into contact may sniff each other's noses or genitals before proceeding on their way. Aggressive interactions were only observed with outsiders (Waser & Waser 1985). Defecation occurs in the vicinity of the den but often also at a large latrine site. Urination by both sexes involves a characteristic tail-arch that makes the behaviour readily recognizable. White-tailed Mongooses have conspicuous anal scent pouches and mark with a squat or anal drag. All adults as well as independent juveniles engage in this behaviour (Waser & Waser 1985). White-tailed Mongooses are largely silent, though they may make chattering noises and when cornered and defensive they utter a very loud and startling bark screech (M. Taylor, pers. obs.).

During oestrus, a ♂ and ♀ pair up for several hours. Waser & Waser (1985) reported that copulation occurred in bouts of 15–20 mounts, spread over half an hour, with individual mounts lasting 5–40 sec, and being terminated by the ♀ breaking away. In four of six observed copulations, the ♂ and ♀ remained together following copulation, but in one instance the ♀ mated with another ♂ within one hour.

Weaned juveniles forage alone for several hours each night from about nine months of age, although they continue to forage within the maternal home-range for at least four months after weaning. Where mongoose density is high, and food abundant, some female offspring do not disperse (Estes 1991).

White-tailed Mongoose *Ichneumia albicauda*.

Reproduction and Population Structure Pregnant or lactating ♀♀ have been taken from Oct to Feb in Zimbabwe (Smithers 1971), and in Nov in Namibia (Shortridge 1934) and KwaZulu–Natal (Rowe-Rowe 1978a). In East Africa, young are born during the long (Mar–Apr) or short rains (Oct–Dec) (Taylor 1972). Rosevear (1974) suggests the dry season as the favoured breeding period in West Africa, with juveniles having been taken in Jan and Feb. Young are probably born in dens, and litter-size is 1–4; four gravid ♀♀ taken in Zimbabwe had three foetuses each (implantation was 2R : 1L), one ♀ had one foetus only (1R). In Serengeti N. P., the mean size of litters sighted at independence (at about 1.5 kg) was 1.4 (Waser & Waser 1985). A single young mongoose born in a trap weighed 81 g and had body measurements (mm): HB = 152, T = 94, HF = 30 and E = 12 (S. Takata pers. comm.). In captivity they are able to live for 10–14 years (Jones 1982, Weigl 2005).

Predators, Parasites and Diseases Occasionally, White-tailed Mongooses may be preyed upon by larger carnivores, but this is unlikely to occur often. In one observation, a Lion *Panthera leo* flushed a White-tailed Mongoose from a shallow den, and the mongoose barked and stood its ground and the Lion backed down (P. Waser pers. comm.). In another incident, a Leopard *Panthera pardus* killed and ate a White-tailed Mongoose in Zambia (C. Stuart pers. comm.), and Waser (1980) mentions that African Wild Dogs *Lycaon pictus* flushed an animal from a thicket, ran it down and killed it. Kingdon (1977) mentions 45 White-tailed Mongooses being killed by a pack of dogs during the course of a year in an Entebbe township, though this is probably a function of unnaturally high levels of mongooses moving into an urban area for food and being caught by dogs.

The cestode *Pseudandrya mkuzii* was collected from the stomach of a White-tailed Mongoose in KwaZulu–Natal (Ortlepp 1963), and the nematode *Arthrocephalus gambiense* from an animal in Somalia (Macchioni 1995). The brown ear tick *Rhipicephalus appendiculatus* and ticks of the *Haemaphysalis leachi* group, as well as immature individuals of *R. hurti* and *R. jeanneli* group and *Ixodes thomasea* were found on the White-tailed Mongoose in Kenya (Punyua & Newson 1985), *H. paraleachi* was recorded from an animal in Sudan (El Kammah *et al.* 1992), *H. parmata* from an animal in Ghana (Ntiama-Baidu *et al.* 2005), and *Amblyomma hebraeum*, *A. marmoreum*, *Haemaphysalis zumpti*, *Hyalomma truncatum*, *Rhipicephalus appendiculatus* and *R. zambeziensis* from animals in Kruger N. P., South Africa (Horak *et al.* 2000). The flea *Ctenocephalides damarensis* was recorded from two animals in South Africa (Horak *et al.* 2004). Ectoparasite loads are heavy, with fleas, mites and lice being common. The sera of *Ichneumia* tested positive for *Rickettsia* antibodies (Heisch *et al.* 1962).

Admasu *et al.* (2004b) note that there is potential for disease transmission between the species and domestic dogs, although none of their animals had antibodies to canine parvovirus, canine distemper or canine adenovirus.

Conservation IUCN Category: Least Concern. CITES: Not listed.

White-tailed Mongooses are common through much of their range, occur around many towns and villages, and feed opportunistically, so there is little reason to believe they are currently threatened. They may be caught incidentally in control programmes principally aimed

at Black-backed Jackal *Canis mesomelas* and Caracal *Caracal caracal* (Rowe-Rowe 1978a, C. Stuart pers. comm.).

Subfamily MUNGOTINAE – Social Mongooses

Mungotinae Gray, 1864. Proc. Zool. Soc. Lond. 1864: 509.

Subfamily Mungotinae includes the mainly smaller social mongooses of the genera *Crossarchus*, *Helogale*, *Dologale*, *Liberiictis*, *Mungos* and *Suricata*.

Serial silhouettes of running Banded Mongoose *Mungos mungo*.

GENUS *Suricata*

Meerkat

Suricata Desmarest, 1804. Tabl. Méth. Hist. Nat. In: Nouv. Dict. Hist. Nat., 24: 15.

The genus is monotypic, and includes only a single species, the Meerkat or Suricate *Suricata suricatta*, which is endemic to the western half of southern Africa, with a marginal intrusion into extreme SW Angola.

David W. Macdonald

Suricata suricatta MEERKAT (SURICATE)

Fr. Suricate; Ger. Scharrtier.

Suricata suricatta (Schreber, 1776). Die Säugethiere, p. 117. Listed as 'Cape of Good Hope' by Meester *et al.* (1986), restricted by Thomas and Schwann (1905: 133) to 'Deelfontein' [South Africa].

Meerkat *Suricata suricatta*.

Taxonomy Polytypic. Three subspecies have been recognized (Coetzee 1977, Meester *et al.* 1986, Van Staaden 1994). Synonyms: *capensis*, *hahni*, *hamiltoni*, *iona*, *lophurus*, *marjoriae*, *namaquensis*, *surakatta*, *tetradactyla*, *typicus*, *viverrina*, *zenik*. Chromosome number: $2n = 36$; there are 34 metacentric, submetacentric and subtelocentric autosomes, a submetacentric X and a telocentric Y (Todd 1966).

Description A long and slender mongoose, with large black eyes, long thin legs and tapering thin tail. Head broad and muzzle short and sharp-pointed. Head pelage greyish-white, with black eye-rings, round black ears and large black nose; a fine dark line extends from above the small eyes towards the tops of the ears. Brows and cheeks white. Dorsal pelage varies considerably across the range, from tan to grey, with brown banding on back, rump and sides. Hair of the guard coat is about 15 mm long, but may reach 30–40 mm on flanks. Individual hairs on upperparts are light-coloured at the base with two dark annulations separated by a light-coloured one, and a silvery-white tip (sometimes dark). Ventral hairs sparse and white (the dark-coloured skin showing through), with greyish-white throat and chin. Tail (ca. 80% of HB) similar in colour to dorsal parts of the body for more than half its length, tapering towards a dark tip with black hairs. Tail thinly haired, with hair at base of the tail long (20 mm), but those on the dark tuft only 12 mm long. Four digits on each foot, each with a swollen digital pad. Claws long and curved, those on the front feet about 15 mm across the curve, those on the hindfeet shorter (about 8 mm). Paired

Lateral and palatal views of skull of Meerkat *Suricata suricatta*.

anal glands, the secretion of which does not differ between ♂♂ and ♀♀ (Decker *et al.* 1992). Females have three pairs abdominal nipples. Sexes are similar in colour and size (Lynch 1980), but dominant animals are heavier than other group members (Clutton-Brock *et al.* 1999a).

Skull lightly built, high and rounded. Eye sockets large, rostrum narrow, supraoccipital crest barely perceptible in some specimens; there is no sagittal crest. Posterior chambers of the ear bullae are ovoid, large and inflated; the anterior chambers are about half the size. Zygomatic arches thin, the coronoid processes of the lower jaw only medium height, which suggests that the temporalis and masseter muscles are less developed than in more carnivorous species. Dental formula $I^{3/3}, C^{1/1}, P^{3/3}, M^{2/2} = 36$. Third upper premolar has a distinct protocone, the fourth premolar and first molar with distinct cusps on their inner extensions; the second premolar is small (Skinner & Chimimba 2005).

Geographic Variation

S. s. suricatta: S Namibia, S Botswana and South Africa.

S. s. iona: SW Angola.

S. s. marjoriae: Namib Desert, including central and NW Namibia.

Similar Species

Cynictis penicillata. Sympatric. Pelage lighter with yellow underfur; tail bushy with white tip; claws shorter; lacks brown banding on back; eyes red.

Mungos mungo. Sympatric. Body larger; tail longer; pelage brownish-grey with alternating dark brown and whitish banding on back; fur is coarser and longer; eyes smaller relative to head.

Distribution Endemic to southern Africa, south of the Cunene and Zambezi Rivers, with a very marginal intrusion into extreme SW

*Suricata suricatta*

Angola in Iona N. P. (see Crawford-Cabral 1971, 1989a). Widespread in arid and semi-arid lands in the western parts of southern Africa, including W and S Namibia, SW Botswana (north to about 21° N and east to about Makgadikgadi Pan) and N and W South Africa, being particularly widespread in the Northern Cape, North West Province and Free State (Skinner & Chimimba 2005). They may occur in the lowlands of Lesotho (Lynch 1994).

Habitat Prefers arid, open country, characterized by short grasses and sparse woody growth. Found in Kalahari *Acacia* bushland, Karoo scrub, Highveld rangelands and fynbos associations, where average annual rainfall is less than about 600 mm, and also in rocky areas associated with dry river beds. Absent from true desert and forested areas, and also from mountainous terrain. Meerkats are usually associated with a hard, often stony or calcareous substrate (Van Staaden 1994, Skinner & Chimimba 2005).

Abundance Densities across the species' distribution are heavily influenced by rainfall and predation pressure, and can fluctuate greatly. In Kgalagadi Transfrontier Park, South Africa (river bed habitat and associated grasslands and *Acacia* bush habitat), densities ranged from 0.95 animals/km² (Apr 1994) to 0.32 animals/km² (May 1995) (Clutton-Brock *et al.* 1999a). This density reduction followed a reduction in rainfall, ca. 10% of long-term average, and virtual cessation of breeding (Clutton-Brock *et al.* 1999a). Total number of Meerkats in study area fell from 100 to 35, six of ten original groups became extinct and mean group size fell from ten to four animals, although mortality was no higher than in any other year (Clutton-Brock *et al.* 1999b). With the resumption of normal rainfall, group size and population size recovered. In Kgalagadi Transfrontier Park, where predators are more abundant and Meerkats more subject to predation, population density was lower compared with those on similar ranchland where predators are reduced (Clutton-Brock *et al.* 1999a).

Adaptations Dentition appears adapted towards an insectivorous diet. Cheekteeth have high cusps, and the carnassial sheer appears poorly developed. The hind part of the first lower molar is relatively flat and together with the second lower molar occludes with the first and second upper molars, to provide a platform for grinding.

Meerkats are well adapted both behaviourally and physiologically to survive the harsh desert environment. They are physiologically adapted to cope with periods of low food supply (necessary during dry winter months and also because feeding may be restricted either by cold winter mornings or hot summer midday) and with the extreme heat of the desert. Meerkat metabolic rate is only 58% of that found in other mammals of a similar size (Müller & Lojewski 1986). A low metabolic rate lowers internal heat production, reduces energy demands during resting (and thus reduces the amount of time required for foraging) and limits evaporative water loss. They also have a high thermal conductance, enabling them to lose heat without concomitant loss of water and a remarkable capacity for heat dissipation through evaporation (Müller & Lojewski 1986). At air temperatures as high as 40° C, Meerkats can resist heating for up to five hours by panting like a dog. Behaviourally, Meerkats avoid both extreme high and low temperatures (Doolan & Macdonald 1996a). As temperatures decrease and day length shortens, Meerkats emerge from the den later, start foraging later and finish activities before sunset. They avoid the problem of rapid heat loss at night (due to their high thermal conductance and extremely high lower critical temperature, 30° C; Müller & Lojewski 1986) by sheltering in burrows (where temperature fluctuations are far less than above ground; Lynch 1980) and huddling in groups for extra warmth. Huddling is particularly important for kits that are vulnerable to cold and as a means of increasing the amount of energy that can be allocated to development (Doolan & Macdonald 1997b). Extreme high midday temperatures in Jan, Feb and Mar are avoided by taking 'siestas', which cease in Apr. Meerkats often sprawl on damp ground or warm rocks to assist with changing body temperature.

Meerkats are accomplished diggers, excavating their own burrows, which usually have many entrances, and forming large warren sites. Entrance holes are about 150 mm in diameter, narrowing to tunnels 75 mm high or more that descend 1.0–1.5 m, end at two or three levels, and are interconnected by chambers 300 mm high and up to 450 mm long (Lynch 1980). They also expel Cape Ground Squirrels *Xerus inauris* and Yellow Mongooses *Cynictis penicillata* from burrows, although they will also share burrows with these two species apparently without competition or agonistic behaviour. They have also been recorded sharing burrows with Southern African Springhares *Pedetes capensis*, *Rhabdomys* sp., African White-tailed Mice *Mystromys albicaudatus*, Highveld Gerbils *Gerbilliscus brantsii*, Rock Hyraxes *Procavia capensis*, Cape Grey Mongooses *Herpestes pulverulentus* and Slender Mongooses *H. sanguineus* (Lynch 1980). Deserted warrens are sometimes found. Digging to maintain bolt-holes and dens is carried out as a group. When burrowing, the ear pinnae fold over the ear opening to prevent the entry of dust and debris into the external auditory meatus.

Meerkats are opportunistic, generalist insectivores, never entirely dependent on a single food category, which allows flexibility to cope with variable abundance of food resources according to habitat and weather. They are highly social, with unique sentinel behaviour when group foraging, thereby increasing predator avoidance in open and exposed habitats. They have a remarkable ability to withstand

snakebites (can tolerate six times the venom that would kill a rabbit), and are immune to scorpion venom, allowing them to use these venomous species as food resources.

Foraging and Food Carnivorous. Meerkats feed mostly on invertebrates, particularly Coleoptera but also Hymenoptera, insect pupae, Orthoptera and scorpions; reptiles (including lizards, geckos, snakes and amphisbaenids) are an important supplement in all months (Meerkats are more reliant on reptiles than are other mongooses) (Zumpt 1968, Smithers 1971, Lynch 1980, Stuart 1981, Doolan & Macdonald 1996a). Termites may also be important (Lynch 1980). Unlike Yellow and Banded Mongooses *Mungos mungo*, Meerkats do not take large active rodents, although during rodent population explosions small murids may be taken. Meerkats will opportunistically feed on birds' eggs.

Doolan & Macdonald (1996a) recorded diet in SW Kalahari, where insects constituted 78.1% of the diet (by frequency of occurrence), of which larvae (33.4%) and adult Coleoptera (27.5%) were most important throughout the year. Snakes and amphisbaenids were a minor prey component, but geckos were more important, especially *Ptenopus garrulus* (53.7%) and *Chondrodactylus angulifer* (13.3%). Two scorpion species were eaten (*Opisthophthalmus* and *Parabuthus* spp.), both of which are tackled according to anatomical differences (although Meerkats are apparently relatively immune to scorpion venom): the large pincers of *Opisthophthalmus* are avoided by eating the rear end first, while the large abdominal sting of *Parabuthus* is avoided by consuming the head first.

Overall, diet varies depending on availability, which is affected by habitat and weather. In the Kalahari, telebrionid beetle larvae are particularly numerous in red sand dunes, Barking Geckos *Nephruroides miltii* and large scarabid beetles in the tangled roots of rhyzozum bushes and Cockchafer Beetles *Melolontha melolontha* in river beds. Beetle larvae are abundant in hot, wet conditions, thus during the dry winter (when general prey abundance is reduced) food is limited to ants and smaller insects. During Jul (winter), much effort is expended in digging deep foraging holes to capture large geckos (Doolan & Macdonald 1996a). On the Makgadikgadi Pans, where Barking Geckos are absent, bullfrogs are an important dietary component (Wilson & O'Riain 2004). Meerkats rarely drink, obtaining their water from succulent prey. However, Tsama Melons *Citrullus lanatus*, succulents, tubers or fruit may be chewed during dry weather (Kingdon 1997).

Meerkats forage by day in tightly cohesive groups; individuals generally within 5 m of one another (often within 1 m), the whole group covering a 20–50 m long axis (up to 100 m in the dry season) (Doolan & Macdonald 1996a). They forage for 5–8 hours per day, meticulously searching through sand (digging up to 20 cm below ground) for prey (Clutton-Brock *et al.* 1999a). Generally, a different area is searched each day – it may be a week or more before a particular route is repeated. Two or three Meerkats may dig together to unearth large geckos. Foraging interference is rare but may occur during the dry season. Food intake decreases in winter. Breeding ♀♀ increase food intake rates when reproductively active (Jan–Apr).

Social and Reproductive Behaviour Meerkats have a sophisticated social organization involving much group cooperation. Groups typically contain ten individuals, although as many as 30 is not

unusual. Groups consist of one to three breeding ♀♀, up to four adult ♂♂, several yearlings and up to a dozen young. In SW Kalahari, groups typically comprised 4.2 adults and 1.9 yearlings (Doolan & Macdonald 1997b). Group size remains relatively constant from year to year although there can be considerable change in individual membership and many individuals may be non-kin (Doolan & Macdonald 1997a).

There is a dominance hierarchy amongst both sexes. Social status increases with age, but ♀♀ can attain dominance (breeding status) by inheritance, by the outcome of aggressive competition (fighting, although challenges by subordinate ♀♀ are rare; Sharp & Clutton-Brock 2011), by immigration into a group without a breeding ♀, or by forming a new group with ♂♂ emigrated from another group (Doolan & Macdonald 1996b, Clutton-Brock *et al.* 1998a). The dominant ♀ is usually the largest and heaviest ♀ in the group (Clutton-Brock *et al.* 1999b, 2001b).

Females are more likely to breed in their natal group than ♂♂ (Clutton-Brock *et al.* 2002). Some individuals of both sexes may remain in the group for all, or much, of their lives although both yearlings and adults of both sexes regularly disperse and join other groups; ♂♂ are more likely to disperse than ♀♀. Both sexes are known to disperse *en masse* (often in groups of kin), although ♂♂ are more likely to disperse as a group (Doolan & Macdonald 1996b). Conversely, dispersing ♀♀ usually travel further than dispersing ♂♂. Old ♂♂ also can be ousted by a gang of ♂♂ taking over the group. Dispersal amongst adults is highest early in the breeding season when within-group hostility is greatest (Doolan & Macdonald 1996b). Subordinate ♀♀ rarely leave the group of their own volition, whereas ♂♂ usually do (Clutton-Brock *et al.* 1998a). However, subordinate ♀♀ can be forcibly expelled from the group by dominant ♀♀ during the latter weeks of the dominant female's own pregnancy, but often return soon after the birth of the pups (Clutton-Brock *et al.* 1998a). Few emigrants successfully establish new groups (Clutton-Brock *et al.* 1999a). Immigrants sometimes have to persist for days to gain acceptance to a group; successful immigrants to established groups are almost exclusively male (Clutton-Brock *et al.* 1999b).

Groups are territorial, inhabiting expansive territories of between 200 and 1000 ha in the S Kalahari. Bolt-holes and dens are important territorial features, with Meerkats seldom being more than 50 m from the nearest safe burrow. Scent-marking is frequent near territory borders, and also used in response to the scent of a neighbouring group; some latrines are found in territorial core regions where they may play a role in mate defence (Jordan *et al.* 2007). Scent-marking is undertaken mainly by the dominant pair in the group, with burrow entrances frequently marked using the anal gland. Territories are actively defended from neighbouring groups, and during skirmishes between troops some individuals may be severely wounded or even killed.

Group members act as sentinels while others forage, using prominent features (e.g. tops of large termite mounds) as look-out posts (see Clutton-Brock *et al.* 1999c for a discussion of the selfishness of this behaviour; it is possible that Meerkats guard when satiated, so, rather than putting themselves at risk are actually safer when guarding as they see the predator first and are often near a bolt-hole). These duties are shared by all group-members but vary with status (e.g. older subordinate ♂♂ spend more time guarding and often from the highest vantage points than other group members).

The entire group is in constant vocal communication during foraging. Complex vocalizations are used to communicate to the group during guarding – they signal that the guard is alert and also when danger is present (calls differ depending on type and severity of threat). A sharp bark from the sentinel sends the colony scattering to their burrows. They can distinguish a Martial Eagle *Polemaetus bellicosus* (that will attack) from a very similar looking Black-breasted Snake-Eagle *Circaetus pectoralis* (not considered a threat). Manser (1999) and Townsend *et al.* (2011) suggest that coordination of vigilance is strongly influenced by vocal communication although does not appear to mediate a strict rotation of guarding duty. Manser & Bell (2004) demonstrated by means of manipulation experiments that Meerkats know in which direction to run when an alarm call is given and must have detailed knowledge of the direction and the distance of specific burrow locations. However, the authors did not conclude that they have a spatial map of their territory, but using place recognition or reorientation of specific landmark features Meerkats were able to escape to the nearest bolt-hole.

Subordinate ♀♀ are reproductively suppressed (Doolan & Macdonald 1997a), the mechanism for which is not fully understood, although hormone excretory patterns during oestrus intervals are possible (Moss *et al.* 2001). This reproductive suppression is aggressively enforced by the dominant ♀ by means of forced emigration and infanticide. Pregnant, dominant ♀♀ frequently kill pups born to subordinate ♀♀, most often those of closely related ♀♀ (Clutton-Brock *et al.* 1998a). However, although dominants monopolize reproduction, subordinates may become pregnant. Pregnant subordinates also kill pups, including those of other subordinates and of the dominant ♀. Litters born to ♀♀ of any rank are less likely to survive their first four days if a subordinate is pregnant. However, dominant ♀♀ are more likely than subordinates to give birth when no other ♀♀ are pregnant, and so lose fewer litters to infanticide than subordinates (Young & Clutton-Brock 2006).

Baseline levels of reproductive hormones are low in subordinate ♀♀. O’Riain *et al.* (2000) suggest that this has more to do with avoidance of incest and lack of unrelated mates than with presence of the dominant ♀, but Young *et al.* (2008) also raise the possibility of subordinate restraint in response to potential dominant interference. Hormone levels are also correlated with age in both sexes, with female levels also affected by body weight and access to unrelated breeding partners. Carlson *et al.* (2004) observed that when these factors are controlled for there are no rank-related differences in the plasma levels of luteinizing hormone among ♀♀ or testosterone among ♂♂. Physiological suppression apparently rapidly reversed as subordinates of both sexes were observed to mate with unrelated roving individuals (O’Riain *et al.* 2000). Griffin *et al.* (2003) identified a strong reproductive skew in favour of dominants, but the extent of skew was variable across sexes and sites suggesting that the skew arises from incest avoidance and reproductive suppression of the subordinates by the dominants. Reproductive suppression in ♂♂ probably operates through behavioural mechanisms (Moss *et al.* 2001), and does not always work. Reproduction suppression amongst ♀♀ may have a more physiological basis and also is not always complete. For example, in SW Kalahari up to three ♀♀ have been recorded as reproductively active simultaneously and each made several breeding attempts within a breeding season. Plural breeding

was common, occurring in 40% of all band years, particularly in larger Meerkat groups and among older individuals (Doolan & Macdonald 1997a), and reproductive suppression likely varies with the relative costs of subordinate breeding to dominants (Clutton-Brock *et al.* 2010). In four groups observed by O’Riain *et al.* (2000), all ♀♀ within each group fell pregnant following immigration of an unrelated ♂, and Young *et al.* (2007), using paternity analyses, estimate that prospecting subordinate ♂♂ sire 20–25% young in the population through extra-group matings.

Social factors tend to determine reproductive success; this contrasts with non-cooperatively breeding social vertebrates in which this is governed by maternal factors (Russell *et al.* 2002). All group members provide food to young and participate in ‘babysitting’ at the den (chasing away predators and huddling with kits to provide warmth) while the mother feeds, and guards the ‘crèche’ when the young are old enough to accompany the group foraging (Doolan & Macdonald 1999, Clutton-Brock *et al.* 2002). Helpers benefit lactating mothers in that increasing the number of helpers reduces a mother’s daily energy expenditure, while every ten helpers (even in the absence of allolactators) allow mothers to decrease their daily energy expenditure during peak lactation by an amount equivalent to the energy cost of one pup (Scantlebury *et al.* 2002). Reduction in the ratio of helpers to pups depresses daily weight gain and growth of pups and daily weight gain of helpers. The effect of helpers on fitness of pups extends beyond weaning: helpers reduce the age at which offspring begin to reproduce as subordinates and increase the probability that they will compete successfully for alpha rank (Russell *et al.* 2007). In turn, helpers may gain direct as well as indirect benefits by feeding pups (Clutton-Brock *et al.* 2001c). The number of helpers within a group is also correlated with the number of litters that ♀♀ deliver each year, probably due to ♀♀ in large groups giving birth earlier with shorter inter-birth intervals (Russell *et al.* 2003). However, Russell *et al.* (2003) found no evidence to suggest that helpers have a direct effect on either litter-sizes at birth or pup weights at weaning, suggesting that the influence of helper numbers up to weaning is indirect through an influence on maternal weight at conception. Female Meerkat helpers contribute more to rearing young than do ♂♂, and also feed female pups more frequently. These sex differences in cooperative behaviour are probably generated by sex differences in philopatry because ♀♀ derive greater direct benefit from raising recruits to their natal group (Brotherton *et al.* 2001).

Doolan & Macdonald (1999) observed allonursing in six of 25 litters that included three incidents of spontaneous lactation when subordinates nursed the young of higher-ranking ♀♀. Clutton-Brock *et al.* (1999b) report allosuckling in around half (8/17) of all breeding attempts in which more than one mature ♀ was present in the group; in this case all allosucklers were subordinate ♀♀ and, in one case, three subordinate ♀♀ suckled one litter. Clutton-Brock *et al.* (2003) observed that dominant breeders contributed less than adult helpers to babysitting and pup feeding, but raised their individual contributions to pup care to a greater extent when helper : pup ratios were low. In contrast to subordinates, dominant breeders did not increase their contributions when they foraged successfully; while subordinates of both sexes assisted in rearing the young when dominants bred, dominant ♀♀ contributed little when subordinates attempted to breed, and male helpers (but not females) reduced their contributions to the care of pups.

Pups are initially incapable of finding their own prey, and use vocalizations in soliciting food from potential feeders. One call type is emitted continuously when following foragers (a repeat call that may be heard up to 20 m away, although pups usually within 2 m of the feeder), another distinct and higher pitched call (heard up to 30 m or more away) emitted when a forager finds prey, possibly to attract attention to them rather than a littermate (Manser & Avey 2000). The two calls differ in length, rate, frequency and amplitude. Using observations and playback experiments, Manser & Avey (2000) demonstrated that pups that called longer and more intensely obtained more prey from feeders, and comparisons of food-deprived and experimentally fed Meerkat pups revealed that hungry pups increased the rate of repeat calls, which adults responded to by increasing their food allocation (Manser *et al.* 2008). Recently, Thornton & McAuliffe (2006) have shown that Meerkats teach pups prey-handling skills by providing them with opportunities to interact with live prey. In response to changing pup begging calls, helpers alter their prey-provisioning methods as the pups grow older, thus accelerating learning without the use of complex cognition. Cessation of begging, and adult provisioning, occurs when juveniles (aged 100–120 days) are no longer able to produce stimulating begging calls (Madden *et al.* 2009).

Individual helpers vary widely in their provisioning, with food items given to pups ranging from 3 to 49% of the total found (average 26%) (Clutton-Brock *et al.* 2001a) and is reduced as pups approach three months (Manser & Avey 2000). The proportion of food given to pups by helpers is higher when more food is acquired by the helper, and is also higher in smaller groups and larger litters. The probability of prey being fed to a pup shows a positive relationship with prey size and a negative relationship with pup distance (Brotherton *et al.* 2001). Females and older individuals contribute more food than either ♂♂ or young individuals, respectively (Clutton-Brock *et al.* 2001a). The authors suggest that kinship is not related to food provisioning. Females are also observed to feed female pups significantly more than male pups, while ♂♂ feed pups of both sexes equally. These sex biases in feeding contributions may result from female group members benefiting more than ♂♂ from higher pup survival, and in particular higher female pup survival, because ♀♀ are the philopatric sex (Brotherton *et al.* 2001). ‘False feeding’ (when helpers carry food to pups and then eat it themselves) may also occur when helpers decide not to deliver food items to pups after assessing the needs of pups relative to their own (Clutton-Brock *et al.* 2005).

Individual contributions to guarding pups at the burrow are also unrelated to kinship, although the amount of time helpers are present at the den ranges from 8 to 42% of the daytime (Clutton-Brock *et al.* 2000). Pups are only rarely left alone at the den and the absence of a babysitter is not affected by group size; a lack of babysitters is compensated for by other helpers contributing more time to babysitting (Clutton-Brock *et al.* 1998b). Females contribute more to babysitting than do ♂♂, with adult ♀♀ contributing the most (amongst ♂♂, yearlings and subadults contribute more than both juveniles and adults), and heavier individuals and those that gained more weight during foraging babysit more than lighter individuals or those that gained less weight (Clutton-Brock *et al.* 2000). Parents rarely contribute to babysitting, yet it seems to incur a substantial energetic cost (Clutton-Brock *et al.* 1998b). Babysitters usually stay at

the burrow for the whole day, feeding little or not at all; consequently, they may suffer substantial weight loss. Over a 24-hour period, an individual babysitter may lose 1–2% of its body weight, while foraging individuals gain about 2%, and frequent babysitters may lose up to 11% of body weight over the entire babysitting period (Clutton-Brock *et al.* 1998b). In ♀♀, at least, weight losses of this magnitude are likely to incur a fitness cost, as breeding is dependent upon weight (Clutton-Brock *et al.* 1998b). Individual differences in foraging success appear to be the principal factor affecting contributions to cooperative behaviour. Contributions to different cooperative activities are positively correlated across individuals, with some helpers consistently contributing more than others to all cooperative activities (English *et al.* 2010).

Reproduction and Population Structure Breeding season in the S Kalahari is from Oct to Jun, generally after heavy rains, but may be extended in wetter years (Doolan & Macdonald 1997b). Most young are born between Jan and Mar, but litters may be born throughout the year (Clutton-Brock *et al.* 1999b). Breeding might not occur when rainfall is low (Clutton-Brock *et al.* 1999b). Generally only the dominant ♂ and ♀ breed, but in particularly productive years subordinates may also breed though at a lower rate than dominants. Females rarely breed before three years old (Doolan & Macdonald 1997b), although animals as young as 14 months old have been recorded breeding (P. Brotherton pers. comm.). Dominant ♀♀ usually produce one to three litters (depending on the amount of rainfall) (average = 1.9) (Doolan & Macdonald 1997b) of 3–7 young per litter at emergence. When subordinates breed they usually produce fewer litters than dominants, and litter-size is in the range 1–8. Mean litter-size at emergence is about four (Doolan & Macdonald 1997b, Clutton-Brock *et al.* 1999b). Daily energy expenditure of lactating mothers increases with litter-size (Scantlebury *et al.* 2002).

Up to four litters per year is possible in dominant ♀♀, but rare when pups from earlier litters survive (Clutton-Brock *et al.* 1999b). About 1.8–1.9 emerging litters are produced per group per year (Doolan & Macdonald 1997b, Clutton-Brock *et al.* 1999b). Gestation is ca. 60–70 days, inter-birth interval (for the same ♀) 82–90 days, with a minimum of 71 days (Doolan & Macdonald 1997b, Clutton-Brock *et al.* 1999b). Young emerge from the den at ca. 19 days, and begin foraging with the group at ca. 26 days (Clutton-Brock *et al.* 1999b). Clutton-Brock *et al.* (1999b) found that pups grow rapidly during their first month: within five days of emergence they averaged 100 g (n = 70), at six weeks 179 g, at three months 394 g (n = 40), and at six months 529 g (n = 28). Pups had a daily growth rate of 4.5 g/day over the first three months. At 12 months, pups had attained roughly 90% of adult body weight.

Population adult sex ratio is ca. 1 : 1, whereas adult/young ratio is ca. 1 : 0.4 (Clutton-Brock *et al.* 1998b). Pup survival between emergence and independence is related to maternal status, pup sex and overnight weight loss as well as group size, daytime temperature and monthly rainfall (Russell *et al.* 2002). Litters may be abandoned during a drought and flooding is a potential risk for litters confined to the den. Between three and five weeks of age the young are particularly vulnerable to hypothermia, and between five and 12 weeks, to predation. Annual mortality rate of adults (>1 year) ranges from 0.32 to 0.68 depending on predator density (Clutton-Brock

et al. 1999a) and from 0.76 to 0.80 for pups (Doolan & Macdonald 1997b, Clutton-Brock *et al.* 1999b). Pup survival continuously decreases from 0.90 at two weeks to 0.19 at one year (Clutton-Brock *et al.* 1999b). These figures are low in comparison with both Dwarf Mongooses *Helogale parvula* and Slender Mongooses in the Serengeti (Clutton-Brock *et al.* 1999b and references therein). However, data are from Kgalagadi Transfrontier Park, which lies towards the edge of the Meerkat's range, thus survival is possibly higher in more vegetated areas (Clutton-Brock *et al.* 1999b). Potential longevity in the wild is ca. 5–15 years (Van Staaden 1994), while in captivity one specimen was 20.6 years of age when it died (Nowak 1999).

Predators, Parasites and Diseases Pups are particularly vulnerable to predators both during the denning period and on foraging sorties (from ca. four weeks), less vulnerable after about three months (Doolan & Macdonald 1997b). Juveniles and pups are preyed by snakes and raptors, including Cape Cobras *Naja nivea*, Martial Eagles, Tawny Eagles *Aquila rapax*, Bateleurs *Terathopius ecaudatus*, Lanner Falcons *Falco biarmicus* and Pale Chanting-goshawks *Melierax canorus* (Doolan & Macdonald 1997b, 1999, Dennis & Macdonald 1999, Clutton-Brock *et al.* 1999a). These predators accounted for ca. 25% of mortalities in young Meerkats (Doolan & Macdonald 1997b). Other larger carnivores (e.g. Lions *Panthera leo*, Spotted Hyenas *Crocuta crocuta* and Black-backed Jackals *Canis mesomelas*) also are a potential threat, as are Ratels *Mellivora capensis*. Jackals, Martial Eagles and Tawny Eagles are the most dangerous predators to Meerkats. Meerkats mob many predators (e.g. Cape Cobras) as a group. Goshawks and other smaller raptors, and small Cape Foxes *Vulpes chama*, are attacked on sight. Black-backed Jackals and Ratels are generally avoided unless Meerkats are cornered. Tendency to mob predators depends on group size: more than five Meerkats will mob a jackal, whereas smaller groups and individuals are more likely to flee to a refuge. Meerkats will attempt to rescue group members and care for injured members.

Lynch (1980) listed a number of parasites taken from animals in the Free State, including fleas and ticks, such as *Amblyomma hebraeum*, *Haemaphysalis zumpti*, *H. leachi*, *Ixodes pilosus*, *Rhipicephalus appendiculatus* and *R. evertsi*; a single *H. zumpti* was taken from an animal in the Northern Cape (Horak *et al.* 2000).

Recently, Alexander *et al.* (2002) described an outbreak of *Mycobacterium tuberculosis*, a human pathogen, in free-ranging Meerkats in South Africa. Animals most at risk of TB infection are groomers (but not groomees), those that receive (but not initiate) aggression, and ♂♂ that rove between groups (Drewe 2010). Meerkats might be highly susceptible to toxoplasmosis (JuanSalles *et al.* 1997).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Relatively widespread within southern Africa, present in several large protected areas, such as Kgalagadi Transfrontier Park (South Africa/Botswana) and Makgadikgadi N. P. (Botswana), and not currently believed to be threatened. Although groups can go extinct during dry years (Clutton-Brock *et al.* 1999a), populations are believed to be stable.

GENUS *Mungos* Banded Mongooses

Mungos E. Geoffroy & G. Cuvier, 1795. Magasin Encyclop. 2: 184, 187.

The genus contains two species: Banded Mongoose *Mungos mungo* and Gambian Mongoose *M. gambianus*, both endemic to sub-Saharan Africa. The Gambian Mongoose occurs only in West Africa, where it overlaps with the Banded Mongoose, which has a much more widespread distribution from Senegal to Somalia and southwards to South Africa. Both species live in open grass-woodlands and avoid closed forest (but may occur in forest belts).

Members of the genus are small, stout, greyish-brown mongooses with short legs and a short, long-haired tapering tail. Their bristle-haired, yellow-speckled coat lacks any underfur. Head and distal parts of fore- and hindlimb shorter-haired and darker than body and tail. Feet five-toed, with toes slightly webbed; soles of hindfoot

naked to the heel. The Banded Mongoose has about a dozen black transverse bands from mid-back to the base of the tail, while the Gambian Mongoose has a 5 mm wide brownish-black stripe on the side of the neck from ear to foreleg. Dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{2/2} = 36$. Upper and lower first premolars are absent.

Ellerman *et al.* (1953) included the genus *Crossarchus* in *Mungos*. Phylogenetic studies of Herpestidae indicate that *Liberiictis* is closer to *Mungos* than *Crossarchus* (Veron *et al.* 2004, Perez *et al.* 2006, Patou *et al.* 2009).

Harry Van Rompaey

***Mungos gambianus* GAMBIAN MONGOOSE**

Fr. Mangué de Gambie; Ger. Gambiamanguste

Mungos gambianus (Ogilby, 1835). Proc. Zool. Soc. Lond. 1835: 102. Gambia.Gambian Mongoose *Mungos gambianus*.

Taxonomy Monotypic. Originally included in *Herpestes*, but placed in the genus *Mungos* by Gray in 1843. Allen (1939) considered it a species of *Crossarchus* due to an external resemblance to the Common Cusimanse *Crossarchus obscurus*. Synonym: *gambiense*. Chromosome number: not known.

Description A small, compact, harsh-haired mongoose. Ears small and round. Muzzle and ring around eyes black. White or yellowish throat and chest separated from grey nape by a bold, 5 mm wide brownish-black stripe on the side of the neck stretching from ear to foreleg. Dorsal pelage brownish-grey, brightly speckled with yellow. Pelage coarse, with no underfur. Ventral pelage scanty and golden to rust-coloured. Upper surfaces of fore- and hindfeet black. Sole of hindfoot naked to the heel. Toes slightly webbed. Strong claws on forefeet. Tail tapering, ending in a black tip. Anal scent glands probably similar to those of Banded Mongoose *Mungos mungo*. Males slightly larger than ♀. Nipple numbers not recorded.

The skull is very similar to that of the Banded Mongoose. Rosevear (1974) remarked on several differences, including the carotid foramen being almost obscured from view by a peculiar, irregularly formed, angular projection (see Hayman 1935) and the much smaller teeth, with $P^4 \sim 15\%$ longer in Banded Mongoose (average length = 4.27 mm in *M. gambianus* cf. 4.93 mm in *M. mungo*) (Rosevear 1974; and see Colyn *et al.* 2000).

Geographic Variation None recorded.

Similar Species

Mungos mungo. There is nearly a complete range overlap with the Banded Mongoose. Back with prominent transversal bands, and no stripe on the side of the neck.

Crossarchus obscurus. There is nearly a complete range overlap with the Common Cusimanse. Shaggy, with dark pelage; muzzle elongated, distance from rhinarium to mouth opening longer.

Distribution Endemic to West Africa, ranging from Senegal and Gambia east and south through Guinea-Bissau, Guinea, Sierra Leone,

*Mungos gambianus*

Côte d'Ivoire, Ghana, Togo, Bénin (probably) and Nigeria (Rosevear 1974, Van Rompaey 1991). There are no confirmed records from Liberia. Jeannin (1936) states that they were distributed in the centre and even common in the north of Cameroon; either they have disappeared or, more likely, these observations are based on confusion with the Banded Mongoose. There is also a record from Yankari G. R. (Afolayan & Ajayi 1980) from far north above the Cross R.; however, its confirmed presence so far east of the Niger R. awaits additional material. Until then, it is assumed that the Niger R. forms the eastern limit.

Habitat Almost exclusively Guinea woodland, but may penetrate into the rather similar Doka belt, with less abundant grasses and dominated by *Isoberlinia* trees (Rosevear 1974). In Gambia associated with denser coastal woodland (Grubb *et al.* 1998) and dry parts of dense, partly swampy riverine forest (T. Wachter pers. comm.). It also occurs on Bonthe I., off the coast of Sierra Leone in areas with sand ridges and sparse grass (Rosevear 1974), and in coastal scrub areas on the Accra Plains of Ghana (Cansdale 1946).

Abundance Considered to be rare in the nineteenth century in Gambia and Senegal by Rochebrune (1883). Cansdale (1946) found them fairly common on the Accra Plains of Ghana and Booth (1960) considered them easily the most abundant carnivore in the Guinea savanna. In Senegal, they are occasionally seen in woodland; daytime frequency of observations along roads was 0.08/100 km (Sillero-Zubiri & Marino 1997). The high frequency of carcasses seen at local markets suggests that National Park of Upper Niger, Guinea, supports a good population (Ziegler *et al.* 2002). Despite these

statements few specimens have been collected and relatively few localities are cited in the literature (Van Rompaey 1991).

Adaptations Diurnal and terrestrial; in Senegal, they were mainly seen in the mornings (08:00–10:00h; $n = 14$) and sometimes in the evening (18:00–19:00h; $n = 4$) (Sillero-Zubiri & Bassignani 2001). The practice of smashing snails, eggs and other hard objects by throwing them against something hard, either horizontally backwards through the hindlegs or vertically down to the ground, has been observed from the age of about three months, without the animal ever having seen such action before (Darchen 1988). Shelter is sought in termite mounds and probably in other abandoned burrows (Sillero-Zubiri & Bassignani 2001).

Foraging and Food Insectivorous. Rosevear (1974) assumes from the small size of teeth that the food is weak and soft, probably almost entirely insects, and according to Grubb *et al.* (1998) food resembles that of the Common Cusimanse. Booth (1960) adds lizards and mice, and Darchen (1988) snakes, to the diet. Forages in packs (Sillero-Zubiri & Bassignani 2001).

Social and Reproductive Behaviour Packs of up to 40 animals may be encountered, communicating while moving through thick cover by frequent twittering, which clearly helps pack cohesion (Booth 1960). In Nigeria they are rarely observed and packs normally contain only 10–15 individuals (Happold 1987); packs of 5–6 individuals are normal in Ghana (Cansdale 1946), while in Côte d'Ivoire and Gambia up to 31 individuals have been seen together (Bourlière *et al.* 1974, T. Wachter pers. comm.). In Senegal, packs consisted usually of 3–10 animals although on one occasion 40 animals were seen together spread over an area of 1000 m² with distances between individuals ranging up to 5 m (Sillero-Zubiri & Bassignani 2001).

Reproduction and Population Structure Unknown. Young animals have been collected at the end of Jun in Sierra Leone, at the end of Sep, and during Jan and Feb in Ghana (Rosevear 1974). Two pairs, kept in captivity, did not reproduce (Darchen 1988).

Predators, Parasites and Diseases There is no information on predation on the Gambian Mongoose. As with Banded Mongooses, raptors must pose the greatest threat. A hookworm, *Arthrocephalus gambiensis*, was found in the intestine of a captive specimen (Ortlepp 1925); another captive specimen died from rachitis (Scott 1928).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Poorly known species, but apparently locally common and present in protected areas such as Niokolo-Koba N.P. in Senegal (Sillero-Zubiri & Marino 1997), National Park of Upper Niger (Ziegler *et al.* 2002) and Comoé N. P., Côte d'Ivoire (Fischer *et al.* 2002). There are no known major threats, although they are sometimes found being sold as bushmeat, as in Guinea (Ziegler *et al.* 2002).

Mungos mungo BANDED MONGOOSE

Fr. Mangué rayée; Ger. Zebramanguste

Mungos mungo (Gmelin, 1788). Syst. Nat., 13th edn, 1: 84. 'Bengala, Persia, aliisque asiae', later restricted by Ogilby (1835: 101) to 'Gambia'.

Thomas (1882: 91) thought it likely that the specimens were obtained from the Cape [i.e. the Cape of Good Hope, South Africa], as did Roberts (1929) and Allen (1939); this was not accepted by Ellerman *et al.* (1953) or Meester *et al.* (1986).

Taxonomy Coetzee (1977) recognized 13 subspecies from the continent, but noted that many of them are morphologically and geographically not well defined. Kingdon (1997) provisionally recognized four distinctive regional populations: *M. m. mungo*, in western Africa; *M. m. zebra*, in the Horn of Africa; *M. m. colonus*, in eastern Africa; and *M. m. taenionotus*, in southern Africa. However, both the physical characteristics and boundaries of regional types await systematic definition, and no subspecies are recognized here. *Mungos mungo* has also been used for the Indian Grey Mongoose, *Herpestes edwardsii* (see Allen 1919 and 1924). Synonyms: *adailensis*, *bororensis*, *caurinus*, *colonus*, *fasciatus*, *gothneeh*, *grisonax*, *marcrurus*, *macrosus*, *mandjarum*, *mungo*, *taenionotus*, *ngamiensis*, *pallidipes*, *rossi*, *senescens*, *somalicus*, *talboti*, *zebra*, *zebroides*. Chromosome number: $2n = 36$ (Wurster & Benirshke 1968, Fredga 1972).

Description A medium-sized, squat mongoose, whitish-grey to dark brown in colour, and easily recognized by a pattern of 10–15 dark transverse bands running across the body from shoulders to rump. Head small and broad with short, pointed muzzle. Rhinarium small and lacking a central slit on the front; upper lip intact. Ears small and rounded. Body covered with coarse hair, short at the head, lengthening toward the rump (reaching a length of 45 mm in eastern specimens). Individual hairs of dorsal pelage light in colour at base, with two broad black bands and a narrow dark tip. Dorsal stripes formed by a matched-up alignment of these banded hairs. Guard coat thick. Ventral pelage very sparse. Limbs generally similar in colour to dorsal pelage. Tail covered in hair, darker toward tip. Five digits on forefeet, four on hind. First digit of forefoot is small, but with an unusually long claw (about 8 mm), used for digging. Other digits on

Banded Mongoose *Mungos mungo*.

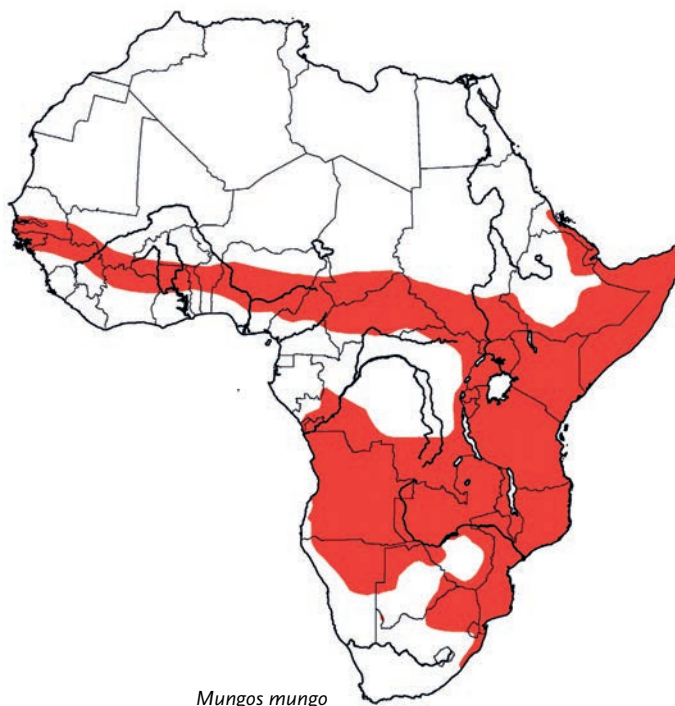

the forefeet are armed with long, curved claws up to 20 mm long. The anal glands open into a subcircular pouch. Females have three pairs of abdominal nipples. There is no sexual dimorphism.

Braincase pear-shaped, broadest at level of ear openings and narrows towards postorbital constriction, which lies well back of the upper portion of the postorbital bars; latter are incomplete, represented by small processes on the zygomatic arch and frontals. Rostrum short and broad. Supraoccipital crest poorly developed; sagittal crest absent. Outer upper incisors considerably larger than the remainder; upper canines slightly curved, short, rounded and sharp, with the lower distinctly recurved. Upper and lower first premolars absent and all cheekteeth have low, rounded cusps (Petter 1969, Skinner & Chimimba 2005).

Geographic Variation There is a wide degree of variation in colouration. For example, in S KwaZulu–Natal (South Africa) specimens that have been attributed to the form *taenionotus* have

Banded Mongoose *Mungos mungo* skeleton.

Mungos mungo

dark reddish-brown upperparts, particularly noticeable between the black bands on the lower back. On the other hand, in specimens attributed to the form *grisonax* of Botswana and Namibia, the upper parts are light grey, with only a faint tinge of reddish-brown between the black bands. Specimens from drier savanna regions tend to be somewhat lighter in colour than those from more lush habitat.

Similar Species

Mungos gambianus. Inhabits moist savannas of West Africa, from Gambia to Nigeria. Brownish-grey mongoose, with dark streaks of fur each side of a lighter coloured neck; no banding pattern. See species profile for discussion on differences in the skull.

Suricata suricatta. Sympatric. Smaller, with shorter tail; dorsal pelage tan to grey with brown banding on back, rump and sides; muzzle short and sharp-pointed.

Distribution Endemic to Africa. Distributed widely across sub-Saharan Africa in a band stretching from Senegal and Gambia to Ethiopia and Somalia, and south to about 31°S in KwaZulu–Natal, South Africa. There is a record of a pack of five Banded Mongooses from the Nossob camp in the Kgalagadi Transfrontier Park (G. Mills pers. comm.). Although fairly widespread in southern Africa, the species appears to be rare in West Africa: it is not recorded from Ghana or Liberia, has never been confirmed in Sierra Leone and Niger, and seems to be known only from the Keneba-Jifarong area in Gambia (Grubb *et al.* 1998). Besides Gambia, Grubb *et al.* (1998) state that there are well-known records from Guinea-Bissau and Nigeria, to which may be added Senegal (e.g. Niokolo-Koba N. P.; Sillero-Zubiri & Marino 1997) and Côte d'Ivoire (e.g. Comoé N. P.; Fischer *et al.* 2002). Grubb *et al.* (1998) conclude that the species may have a disjunct distribution in West Africa. In north-east Africa, their presence has not been confirmed in Djibouti.

Banded Mongooses apparently were introduced to Zanzibar (Pakenham 1984), although neither Stuart & Stuart (1998c) nor Goldman & Winther-Hansen (2003) recorded them during camera-

trapping surveys (despite obtaining images of other elusive species), suggesting they are either now rare or absent.

Habitat Wide range of habitats but primarily found in savanna and woodland, usually close to water. Although commonly found in riverine conditions, it is believed that it is the physiognomy of the vegetation rather than the presence of water that determines their occurrence (Skinner & Chimimba 2005). Often found in habitats containing termitaria, which are used as den sites. Absent from desert, semi-desert and montane regions. Recorded to 1600 m in Ethiopia (Yalden *et al.* 1996).

Abundance Density varies widely between habitats and locations. On the Serengeti plains, Banded Mongooses live at a density of around 3 ind/km² (Waser *et al.* 1995); this is similar to the estimated density of Banded Mongooses in S KwaZulu–Natal (2.4/km²; Maddock 1988). By contrast, a peninsula population in Queen Elizabeth N. P., Uganda, lives at higher densities, averaging 18 ind/km² (Cant 1998, Gilchrist & Otali 2002). Generally less abundant in western regions compared with eastern and south-eastern areas of the distribution. Regional differences in abundance could be related to the specific spectrum of other mongooses present. The greatest overlaps in diet and habitat needs are likely to come from the cusimanses *Crossarchus* spp., the Gambian Mongoose *Mungos gambianus* and the Yellow Mongoose *Cynictis penicillata*.

Adaptations The carnassials are better adapted to crushing than slicing, which, together with the weak zygoma and lack of a sagittal crest, suggests an adaptation to a diet of relatively soft or insectivorous

food (Skinner & Chimimba 2005). They have excellent senses of smell, vision and hearing. Terrestrial predators and humans may be sighted at a distance of 100 m or more, and the animals can distinguish avian predators from other, non-predatory birds (e.g. herons) at great distance. Group members respond to distant predators by vocalizing and by standing upright to gain a better view. When danger threatens at closer range, the animals adopt one of two anti-predator strategies, depending on the type of predator. Individuals respond to avian and large terrestrial predators such as Leopards *Panthera pardus* by giving a high-pitched alarm call that sends the entire group running for cover. By contrast, Banded Mongooses group together to drive off smaller terrestrial predators such as jackals *Canis* spp. or Servals *Leptailurus serval*. Group members bunch tightly together and advance slowly, vocalizing aggressively (Kingdon 1977). Banded Mongooses have been known to rescue group members seized by Martial Eagles *Polemaetus bellicosus* (Rood 1983b) and to rescue a pup from a Nile Monitor *Varanus niloticus* (J. S. Gilchrist pers. obs.).

Dens are typically located in abandoned termitaria, but may also be found in the hollows of tree roots, in sheltered spaces in gullies or underneath rock falls. Largely terrestrial, Banded Mongooses do climb to the tops of termitaria, which they use as vantage points, and are also able to climb trees when under stress. Simpson (1964) recorded a pack being chased by African Wild Dogs *Lycaon pictus* that took to the high branches of a fallen tree.

The likely adaptive significance of the banded pattern on the animals' back and rump has been discussed in some detail by Kingdon (1977), who suggested that the primary adaptive purpose of the striped rump was as an advertisement or target for anal scent-marking, thus reinforcing pack cohesion (especially during interactions with other packs or with some predators). In evidence of this, members of a pack were observed to rub their anal glands on a block of ochre and thereafter transfer the pigment to the banded area: in this way all pack members were shown to share a communal odour. The back-marking response is routine, but strongest during periods of intense excitement, such as arrivals, departures and during interactions or exposure to danger (Kingdon 1977).

Scent plays an important role in maintaining group identity and cohesion, with likely a lesser role in the advertisement of territorial boundaries (Jordan *et al.* 2010). Group members regularly mark each other with a sticky, pungent secretion from the anal glands. Individuals that become lost during foraging trips locate the group by scent, and upon reintroduction to the group the returning individuals are vigorously marked by the other group members. Objects such as large rocks or branches are used as marking posts at which group members anal mark, cheek mark, defecate and urinate. Anal marks have been shown to be sexually dimorphic (Jordan *et al.* 2011a) and to differ between individuals with individuals able to discriminate between scents from different individuals (Jordan *et al.* 2011b). Individuals will overmark areas previously anal marked by other individuals, and intra-sexual overmarking rates are higher than inter-sexual rates within groups (Müller & Manser 2008c, Jordan *et al.* 2011a). Males with higher overmarking rates had higher mating success (Jordan *et al.* 2011b). However, there is no evidence that overmarking is correlated with mating success or dominance in ♀♀ (Jordan *et al.* 2011c). Some observations suggest that ♂♂ can determine the reproductive status of ♀♀ in a neighbouring group by monitoring the scent marks at shared marking posts. After

Lateral, palatal and dorsal views of skull of Banded Mongoose *Mungos mungo*.

smelling the scent of groups containing oestrous ♀♀, ♂♂ will sometimes make forays deep into the home-range of a neighbouring group in search of extra-group copulations (M. A. Cant pers. obs.).

Foraging and Food Diet mainly consists of insects, myriapods, snails, small reptiles, the eggs and young of ground-nesting birds, and wild fruits (Smithers 1971, Rood 1975, Smithers & Wilson 1979, Rautenbach 1982, Hiscocks & Perrin 1990). The analysis of a sample of 14 stomachs from Zimbabwe and Botswana revealed that insects occurred in every stomach, mainly Coleoptera and their larvae, followed by grasshoppers, mole crickets, formicid ants, their eggs and larvae, and caterpillars (Smithers 1971, Smithers & Wilson 1979). Groups also take advantage of human waste food at garbage dumps (Gilchrist & Otali 2002, Otali & Gilchrist 2004).

Banded Mongooses are diurnal, typically emerging from refuges in the early morning and retiring before sunset; no nocturnal activity has been recorded for the species. Each morning, the group embarks on a foraging trip lasting several hours before retiring to rest in the shade. There is usually a second foraging session in late afternoon. Foraging distances average 2–3 km in Uganda (Neal 1970) but may be more extensive, up to 10 km, in the more open savanna of Serengeti N. P. (Rood 1975, 1986). Foraging members of the group fan out and search for food independently, sniffing the ground, turning over leaf litter, and digging in the earth with their front paws. Individuals rarely dig more than a few centimetres below the surface for prey. Dung of large herbivores, especially elephants, is enthusiastically tackled due to the high density of beetle prey within. Group members maintain contact with each other by emitting low grunts every few seconds. Individuals generally do not share food but defend potential food items (foraging holes, scrapes or dung) and food items from other individuals.

Millipedes, frogs and other prey that produce noxious secretions are rolled around in the earth before being eaten. Baxter (1993) recorded a Banded Mongoose feeding on a Greater Red Musk Shrew *Crocidura flavescens* in captivity. The mongoose bit off the shrew's head and then proceeded to bite into the thoracic cavity while pulling downwards, with its forepaws and claws, on the skin, progressively removing the skin with its large, unpalatable subcutaneous glands. Eggs and hard-shelled organisms (e.g. dung beetles and pill millipedes) are cracked open by clasping them between the front paws and throwing them back between the hindlegs onto a rock or other hard surface (Simpson 1964, Eisner & Davis 1967, Eisner 1968, Müller 2010), in much the same way as does the Dwarf Mongoose *Helogale parvula*.

Social and Reproductive Behaviour Banded Mongooses are cooperatively breeding mammals that typically live in groups of 15–20 individuals. Around campsites or other artificial food sources groups may number up to 70 (Pienaar 1964). In Queen Elizabeth N. P., nine groups of Banded Mongooses averaged 16 individuals (>6 months old) and occupied home-ranges ranging in size from 0.3 km² to 2.0 km² (Rood 1975, 1986, Cant 1998, 2000, Cant *et al.* 2001, De Luca & Ginsberg 2001, Gilchrist & Otali 2002). In other, drier regions (e.g. southern Africa) home-ranges are apparently larger (>2 km²; Hiscocks & Perrin 1991a). Groups may utilize up to 40 dens within their home-range, changing between dens every 2–3 days (less often when breeding). All members of a group sleep in the same den overnight and pups remain in the den whilst the group forages during their first 3–4 weeks of life. Favourite den sites include abandoned termitaria,

crevices, gullies and thickets, and even the burrows of springhares *Pedetes* spp. and Aardvark *Oryzomys afer*, but the animals will also den in outhouses and other artificial shelters (Neal 1970, Rood 1975, Hiscocks & Perrin 1991a).

Home-ranges are vigorously defended against neighbouring groups of conspecifics. Encounters between groups usually lead to physical conflict, during which animals may be severely wounded and even killed (Rood 1975, Cant *et al.* 2001). Upon sighting each other, members of rival groups respond by standing erect and giving a distinctive, screeching call, which alerts the rest of their group to the presence of a rival group. The response of individuals to the 'screech' call is determined by the location, with greater response within the exclusive area of home-range than peripheral (overlapping) areas, and by group size, with larger groups more likely to respond and bunch than smaller groups (Furrer *et al.* 2011). Groups also respond to scent marks from other groups, and differentiate between strangers and (familiar) neighbours, with a more intensive response to neighbour scent marks (Müller & Manser 2007).

The sight of a large rival group is sometimes sufficient to cause a small group of mongooses to flee, with members of the larger group chasing behind (Rood 1975, Cant *et al.* 2001). Groups more closely matched in size bunch together and approach each other with caution, stopping frequently to stand upright and stare at their opponents. Typically, members of the two groups approach to within 20 or 30 m of each other before rushing forward, with members of both groups fanning out and engaging in one-to-one fights or chases with their opponents. Face-to-face confrontations between individuals are brief (<5 seconds) and violent, involving repeated bites and scratches with the front paws until one of the combatants bolts. Groups that have become scattered sometimes retreat, bunch together and advance again. In this way, fights between large, evenly matched groups sometimes last for over an hour. On rare occasions, infanticide and kidnapping of pups have been observed between groups. Where inter-group infanticide occurred it was the larger group that was responsible on all but one occasion (Müller & Bell 2009).

There is usually no conspicuous dominance hierarchy in the daily lives of a group, except among ♂♂ when ♀♀ are in oestrus. Levels of aggression are usually low because individuals forage independently on small, scattered invertebrate prey (Rood 1975). When aggression over a food item occurs, the finder or owner is usually the winner (De Luca & Ginsberg 2001). During oestrus, which starts around ten days after parturition, ♂♂ exhibit an obvious dominance hierarchy when competing for access to ♀♀. Females, by contrast, do not interfere with each other or directly compete for matings. Despite a lack of overt aggression among ♀♀ during mating, ♀♀ often form an age-based hierarchy in which older ♀♀ enter oestrus a few days before their younger group-mates, and have larger litter-sizes (Cant 2000, Gilchrist *et al.* 2004). Kingdon (1977) reported a previously healthy adult ♀ in a free-ranging pack being consistently deprived of food items by other pack members after temporarily losing some hindlimb coordination in an accident. Thereafter, this individual ♀ remained subordinate to all other ♀♀ in the group in spite of regaining her health.

Oestrous ♀♀ are closely guarded for 2–3 days by dominant ♂♂. The staggered pattern in which ♀♀ enter oestrus allows the same one or two dominant ♂♂ to guard and mate with all the adult ♀♀ in the group (Cant 2000). Dominant ♂♂ follow oestrous ♀♀ closely, and are aggressive to any ♂♂ that attempt to mate. These dominant

Banded Mongoose *Mungos mungo*.

(or mate-guarding) ♂♂ are generally bigger than the subordinate ♂♂, and obtain the great majority of observed matings, but ♀♀ go to considerable lengths to escape their mate-guard in order to mate with other ♂♂ in the group. For example, if a mate-guarding ♂ stops to eat a prey item such as a beetle, the guarded ♀ will often run off to mate with a non-guarding ♂. Despite synchronous female oestrus preventing total monopolization of mating opportunities by dominant ♂♂, 85% of paternities are assigned to the oldest three ♂♂ in each group (Nichols *et al.* 2010).

Both ♂♂ and ♀♀ actively seek copulations with individuals in neighbouring groups. The rate at which neighbouring groups encounter each other increases during oestrus, and both ♂♂ and ♀♀ have been seen to lead the group deep into a neighbouring group's home-range in pursuit of copulations. Females may accept or pursue these matings with extra-group ♂♂ as a way of avoiding inbreeding depression (Rood 1975, Cant *et al.* 2002). Inbreeding depression may be a particular problem for Banded Mongooses because both ♂♂ and ♀♀ often remain in their natal group beyond the age of reproductive maturity.

Banded Mongooses are unusual amongst the social mongooses/social carnivores because most ♀♀ in each group reproduce. Up to ten ♀♀ may give birth within a group (Gilchrist 2006b). Most ♀♀ (80%) conceived in each breeding event, and most pregnant ♀♀ (93%) carried their litter to term (Gilchrist *et al.* 2004). This low reproductive skew occurs despite evidence that subordinate female reproduction is costly to dominant female reproductive success

(Gilchrist 2006b, Cant *et al.* 2010). Female group-mates exhibit an exceptional degree of birth synchrony. In Uganda, multiple breeding ♀♀ gave birth on exactly the same night in 64% of breeding attempts (Hodge *et al.* 2011). Where ♀♀ gave birth on different days, there was rarely more than a few days between births. The failure rate of asynchronous litters was particularly high (Gilchrist 2006a, b, Hodge *et al.* 2011). There is apparently strong selective pressure for synchrony of parturition because ♀♀ have been known to miscarry or abort in order to synchronize with other ♀♀ giving birth (Gilchrist 2006a). Birth synchrony may have evolved as a way of escaping the threat of infanticide by dominant breeders, since it is likely to reduce the ability of infanticidal ♂♂ and ♀♀ to discriminate between offspring, and birth synchrony also likely reduces competitive asymmetry between pups (Gilchrist 2006a, Hodge *et al.* 2011). Additionally, birth synchrony may help to swamp potential predators and minimize the total period that the communal litter must remain in the natal den.

Offspring are kept underground in the den for the first 3–4 weeks of life. Pups may be transferred between dens two or three times during this period. Each day one or more (average two; Cant 2003) 'babysitters' remain behind at the den to guard the pups while the rest of the group goes off to forage. Babysitters guard pups against predators such as snakes and monitor lizards, and, importantly, against rival groups of Banded Mongooses, which sometimes attack a natal den and, if successful, kill the pups inside (Müller & Bell 2009). Adult ♂♂ babysit most and adult ♀♀ least, with subadults

generally contributing less babysitting than adults (Rood 1974, Gilchrist 2001, Cant 2003). Dominant ♂♂ (with higher likelihood of paternity in the litter) babysit more than subordinate ♂♂, but reduce their contribution during oestrous periods, when they compete for paternity in the next litter (Cant 2003).

At around four weeks old pups start to accompany adults on short afternoon foraging trips, and by five weeks the pups leave the den in the morning with the rest of the group. Typically, each pup closely follows an 'escort' (usually an adult), begging frequently. These associations between pups and adults are usually stable over time, with the same pup following the same adult each day, from emergence until independence (at around 90 days) (Cant 1998, Gilchrist 2004). Current breeders tend to contribute more to escorting than non-breeders, and heavier individuals make greater contributions to pup escorting than lighter individuals, with patterns complicated by sex and age (Gilchrist & Russell 2007). Females are more sensitive to personal condition, reducing pup provisioning in response to personal weight loss more than ♂♂, with older individuals also reducing provisioning more acutely than younger individuals in response to weight loss (Bell 2010). The pup is responsible for maintaining the association by following and defending its escort against approaches from other pups (Gilchrist 2004, 2008).

Adults actively care for pups by contacting, carrying, grooming, playing with and provisioning pups, with escorts providing more food and showing individual recognition and concern for their paired pup (Bell 2008a, Gilchrist *et al.* 2008). Pup begging rate corresponds to hunger, and escorts in good condition are more responsive to change in begging intensity (Bell 2008b). Adults provision pups by dropping or leaving whole or partial prey items. Adults also defend pups against potential predators and pups often shelter under the belly of their escort when frightened or threatened. The closer a pup associates with an escort, the more it is fed, the faster it grows and the higher its probability of survival to independence (Gilchrist 2004, Hodge 2005). Each pup learns to forage via imitation during the period of dependence on their escort (Müller & Cant 2010).

Dispersal occurs via two distinct modes (Cant *et al.* 2001). First, groups of ♂♂, ♀♀ or both are sometimes driven out of their natal groups as the result of intense aggression from other group members. The primary agents of this aggression are dominant ♂♂ and breeding ♀♀ but subordinates of either sex may also contribute to driving individuals out of the group. Evictions occur in especially large groups and the timing (during oestrus or early gestation) suggests that reproductive competition may motivate eviction. Notably, ♀ evictions occur in groups with relatively large numbers of reproductive ♀♀, and it is young reproductive ♀♀ that are evicted, again supporting reproductive competition as the primary driver of eviction (Gilchrist 2006a, Cant *et al.* 2010). Evicting subordinate ♀♀ is costly to the remaining ♀♀. Females give birth to lighter pups when other ♀♀ are evicted during their gestation, pups whose dependent period is disrupted by an eviction are lighter at independence, and the proportion of pups in a litter that survive to independence is reduced by eviction during their dependent period (Bell *et al.* 2012). When ♂♂ and ♀♀ are evicted simultaneously they subsequently split into two same-sex subgroups and disperse separately, presumably to avoid inbreeding. Evicted subgroups have been known to disperse over 25 km from their natal group (Cant *et al.* 2001).

The second mode of dispersal occurs when groups of same-sex individuals leave their natal group voluntarily to join members of the opposite sex. Animals of intermediate age (between one and three years old) are most likely to disperse, whether this is forced or voluntary. In the Serengeti N. P. dispersing ♂♂ have been observed to invade an established group and drive out the resident ♂♂ (Waser *et al.* 1995). In Uganda, two group takeovers by groups of ♀♀ have been observed, both of which involved the eviction of the only ♀ previously in the group. Immigration by single individuals is extremely rare. Dispersing animals attempting to establish a new home-range are frequently involved in fights with resident groups. These fights can lead to severe injuries and an elevated mortality rate among adult ♂♂ (Cant *et al.* 2001).

Vocal communication is conspicuous and diverse. Foraging group members emit a more or less continuous stream of low grunts that serve as contact calls. Responses of other pack members to warning and alarm calls vary depending on pitch and amplitude. The response to conspecific recruitment calls is dependent upon the risk associated with the stimulus, with a more intense recruitment in response to calls elicited by a rival group or snake in comparison to calls elicited by predator faeces (Furrer & Manser 2009). Other distinct calls include a screeching contact call, when individuals become separated from the pack, a rally call, used upon seeing members of a neighbouring group, and threat and aggression calls, used in competition over food. A study of one captive group found that there were nine sonographically distinct calls (Messeri *et al.* 1987), but there are probably a number of other additional specialized calls that are used more rarely in a natural setting. Vocalizations are individualized, enabling discrimination between individuals, and both pups and escorts are more responsive to the calls of their partner than to other group members (Müller & Manser 2008b). Banded Mongooses have been observed to respond to plover (*Vanellus*) alarm calls, but do not differentiate between levels of urgency coded within the calls (Müller & Manser 2008a).

Hamerkop *Scopus umbretta* apparently form feeding associations with Banded Mongooses (Steyn 1991). The birds have been observed to chase and eat any small lizards and frogs that escape from the foraging mongooses. Warthogs *Phacochoerus* spp. sometimes lie down or stand still to allow Banded Mongooses to groom them for ticks and other ectoparasites.

Reproduction and Population Structure In Uganda, groups produced an average of four litters per year (Rood 1975, Cant 2000, Gilchrist *et al.* 2004). In drier areas, breeding is less frequent, with groups producing one or two litters per year (Waser *et al.* 1995). Breeding is not tightly synchronized between groups (Rood 1975). However, breeding is to some extent timed to coincide with the wettest months: in Uganda, the probability that groups gave birth in a particular month increased with that month's rainfall (Cant 1998) and groups will stop breeding altogether during periods of drought. In southern Africa, young appear to be born during the warm, wet summer months from Oct to end Feb, as evidenced by Shortridge's (1934) record of a pregnant ♀ taken in Nov in Namibia, and Rowe-Rowe (1978a) finding litters of 2–8 young during the months of Oct, Dec and Feb. Heavier ♀♀ are more likely to conceive (Gilchrist *et al.* 2004).

Gestation period is around nine weeks. Mean foetal litter-size of pregnant ♀♀ 3–4 weeks before parturition was 3.2 (range 1–6) (pooled data of Cant 2000 and Gilchrist *et al.* 2004). Younger, smaller

♀ ♀ carried fewer, relatively smaller foetuses than their older group-mates (Cant 2000, Gilchrist *et al.* 2004). Abortion or miscarriage is generally rare, but more common in young ♀ ♀ conceiving their first litter (Gilchrist *et al.* 2004) and is commonly induced by eviction, with ♀ ♀ that abort frequently being readmitted to the group (Gilchrist 2006a, Cant *et al.* 2010).

In the Serengeti, reproduction in ♀ ♀ was first observed at two years of age (Waser *et al.* 1995). In Uganda, the average age of first conception was 321 days (Gilchrist *et al.* 2004). An average of 81% of adult ♀ ♀ conceived in each breeding attempt, with 92% of pregnant ♀ ♀ carrying to term (pooled data of Cant 2000 and Gilchrist *et al.* 2004). There was no effect of age on the probability of breeding for adult ♀ ♀ (Cant 2000, Gilchrist *et al.* 2004).

In the Ugandan population, the birth-weight of pups ranged from 20 to 50 g. Eleven pups from one litter captured between 33 and 38 days old averaged 275 g. At 65 days old the pups from this litter weighed 423 g. Ten weeks after emergence (100 days) they averaged 541 g ($n = 7$). At one year, 16 individuals from three different litters weighed 1311 g. High growth rates during development reduce the age at which ♀ ♀ breed for the first time, suggesting that helpers can improve the future fecundity of the offspring for which they care (Hodge 2005). Maternal condition may also have serious implications for the success of their offspring. Females in good condition at conception give birth to heavier pups, and heavy pups receive more care and are more likely to win competitive interactions with other pups (Hodge *et al.* 2009).

In the Serengeti, average annual survivorship was 0.67 (Waser *et al.* 1995). In Uganda, annual survivorship of adults averaged 0.78–0.86 (Cant 1998, Otali & Gilchrist 2004). In both populations, adult ♂ ♂ and ♀ ♀ survived at similar rates. Mortality of pups was high. Twenty-one per cent of communal litters failed to produce a single emergent pup, and only 51% of emergent pups survived to three months of age (Gilchrist 2001, 2006b). Few pups were visibly ill prior to disappearance, and the main cause of pup mortality is apparently predation (Otali & Gilchrist 2004). In the wild, maximum life-span is 13 years for ♂ ♂ and 11 for ♀ ♀. Average expected life-span for individuals reaching adulthood (1 year) is 3.6 years for ♂ ♂ and 3.3 for ♀ ♀. In captivity, Banded Mongooses may live to more than 17 years (Weigl 2005).

In Uganda, the sex ratio was male-biased, from emergence of pups to adulthood (Cant 1998, Gilchrist 2001). The underlying cause of these biased sex ratios is unknown: there is no information on the sex ratio at birth, and there are no detectable differences in survival between ♂ ♂ and ♀ ♀ after they emerge from the den.

Predators, Parasites and Diseases Known predators include Lions *Panthera leo*, Leopards *P. pardus* and African Rock Pythons *Python sebae*. Marabou Storks *Leptoptilus crumeniferus* and Nile Monitor *Varanus niloticus* and even Common Warthog *Phacochoerus africanus* have been observed to kill pups (Otali & Gilchrist 2004). Ticks and fleas are common on adults. The following ixodid tick species were recovered from two animals taken in Kruger N. P., South Africa: *Amblyomma hebraeum*, *A. marmoreum*, *Haemaphysalis leachi*, *H. zumpti*, *Rhipicephalus appendiculatus*, *R. simus* and *R. zambeziensis* (Horak *et al.* 2000). Little is known about diseases, but they are a possible vector of rabies and susceptible to human tuberculosis *Mycobacterium tuberculosis* (Alexander *et al.* 2002).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Banded Mongooses are present in numerous protected areas across their wide range on the African continent, and there is no reason to believe the species is threatened.

Banded Mongoose *Mungos mungo*.

GENUS *Liberiictis*

Liberian Mongoose

Liberiictis Hayman, 1958. Ann. Mag. Nat. Hist., ser. 13, 1: 449.

The genus includes only one species, the Liberian Mongoose *Liberiictis kuhni*, recorded only from Liberia and Côte d'Ivoire (Goldman & Taylor 1990). Phylogenetic studies of Herpestidae indicate that *Liberiictis* is closer to other social mongooses, and that it is closer to the banded

mongooses (genus *Mungos*) than to the cusimanse (genus *Crossarchus*) (Veron *et al.* 2004, Perez *et al.* 2006, Patou *et al.* 2009).

Mark E. Taylor

Liberiictis kuhni LIBERIAN MONGOOSE

Fr. Mangouste de Liberia; Ger. Liberia-kusimanse

Liberiictis kuhni Hayman, 1958. Ann. Mag. Nat. Hist., ser. 13, 1: 448. 'Kpeaplay, north-east Liberia, about 6° 36' N, 8° 30' W'.

Liberian Mongoose *Liberiictis kuhni*.

Liberian Mongoose *Liberiictis kuhni* head, frontal view.

Taxonomy Eight skulls of *Liberiictis kuhni* were obtained in 1957 and 1958 from Gio hunters in NE Liberia at Kpeaple and Gapple by German ethnologist Hans Himmelheber. The type specimen was presented to R. W. Hayman by H.-J. Kuhn of Heidelberg University. Hayman described the genus and species based on these eight skulls, and suggested that *Liberiictis* was related to *Crossarchus*. Its external morphology was only described in 1974 following the collection of two specimens near Tar, Liberia (Rosevear 1974, Schlitter 1974). Another animal was shot by native hunters in the Gbi National Forest in 1988 and the first live specimen was caught in 1989 (Taylor 1992). Synonyms: none. Chromosome number: not known.

Description A medium-sized brown mongoose with long snout, distinctive dark neck-stripe, grizzled stiff guard hairs and buffy-orange underfur. General appearance is a brown mongoose with pale brown and white grizzled chin and chest. Snout is nearly hairless, pink to brown in colour, and long and mobile, extending beyond lower lip. Ears, small and rounded. Hairs of head short (to ca. 8 mm), dark brown and with pale intermediate bands; guard hairs of cheeks and above eyes paler. Whitish stripe extends from back of mouth to below ear and a very dark brown stripe extends from below ear along side

of neck bordered by paler stripes of fur. Guard hairs of throat (ca. 10 mm) pale with dark brown intermediate bands. Guard hairs of body long (ca. 40 mm) with blackish-brown terminal and proximal sections and pale subterminal bands. Underfur ranges from apricot-buff to dark brown. Feet and lower legs uniformly brownish-black. Tail relatively bushy and short (about 45% of HB), tapering evenly from base to tip. Five digits on feet with pollex and hallux reduced. Digits 2–5 on forefeet end in long, curved claws (<18 mm); claw length of hindfeet shorter (<13 mm).

Skull long and narrow with an elongated tapering rostrum; length of rostrum and nasal bones average 38% and 25%, respectively, of the greatest length of skull (Hayman 1958). About 60% of length of skull is anterior to the anterior rim of orbit, while in other mongooses this is about 50%. Dental formula is $I \frac{3}{3}, C \frac{1}{1}, P \frac{4}{4}, M \frac{2}{2} = 40$. Cheekteeth are small in comparison with size of skull and compared with the Common Cusimanse *Crossarchus obscurus*. No carnassial shear; the cusps of the teeth are adapted for puncture crushing, and upper molars are about equal in size (Hayman 1958, Rosevear 1974, Goldman & Taylor 1990).

Geographic Variation None recorded.

Lateral, palatal and dorsal views of skull of Liberian Mongoose *Liberiictis kuhni*.

Similar Species

Crossarchus obscurus. Sympatric. Smaller in size, with shaggy coat but no distinctive neck stripe; condylobasal length about 86.5 mm (cf. *Liberiictis kuhni* >94.7 mm); upper and lower first premolar absent (total dentition of 36 teeth).

Atilax paludinosus. Sympatric, also occurring in forested habitats and usually associated with rivers and water-bodies. Uniform brown fur with no distinctive stripes, and digits that can be widely spread with rugose claws, unlike the Liberian Mongoose that has very long claws well adapted for digging.

Distribution Endemic to West Africa. Currently recorded from NE Liberia and W Côte d'Ivoire. First specimens were based on eight skulls collected from two villages in NE Liberia (Kpeape 6° 36' N, 8° 30' W and Gapele 7° 08' N, 8° 28' W) (Hayman 1958). The mongooses' external characters were described by Schlitter (1974) on the basis of two specimens collected near Tar (6° 13' N, 8° 08' W). Taylor (1989a) collected a specimen, which had been shot by a villager, from a small settlement in the Gbi National Forest (6° 25' N, 8° 45' W) approximately 20 km south-east of Tapeta. A live animal was collected in 1989 from Nimbo When (6° 12' N, 8° 47' W) (Goldman & Taylor 1990). Subsequently, a group of Liberian Mongooses was observed foraging in Tāi N. P., the first record from Côte d'Ivoire (5° 51' N, 7° 23' W) (Taylor 1992, Gartshore *et al.* 1995), later confirmed by the discovery of a dead specimen (Colyn *et al.* 1998). One animal was trapped and radio-collared in Tāi N. P. in 1999, facilitating regular observations of three known groups between 1999 and 2002. In 2011, their presence in Sapo N. P. in Liberia was confirmed by photographic evidence (FDA/FFI/ZSL pers. comm.). The Liberian Mongoose was also sighted in the Nimba Mts in N Liberia (Coe 1975, Schreiber *et al.* 1989). They are likely to occur in suitable habitat in S Guinea.

Liberiictis kuhni

Habitat Occurs in primary and secondary evergreen forests in Liberia and Côte d'Ivoire. Found primarily in swamp forest and stream beds with deep sandy soils where earthworms are abundant. May also be found foraging in forested areas with moist soils or areas that have been cut over. Individuals use higher ground only for travel between foraging areas.

Abundance Declining in many areas due to hunting pressure and loss of quality habitat. Populations in Tāi N. P. estimated at approximately 1.5/km², based on radio tracking and field observations (A. E. Dunham pers. obs.).

Adaptations Reduced cheekteeth, poorly developed masseter muscles and loss of shearing function of premolars and molars are adaptations for eating soft-bodied invertebrates (Pape 1980). Small sharp teeth are adaptations for extracting soil invertebrates and puncture-crushing rather than shearing (Pagel 1985). Elongated mobile snout and large curved claws of the forefeet are used for excavating such prey. Sense of smell is well developed.

Foraging and Food Behavioural observations and scat analyses suggest that the Liberian Mongoose is an earthworm specialist, eating primarily large burrowing species of the family Megascolecidae (some of which may be a metre or more in length, M. E. Taylor pers. obs.). Of 32 scat samples collected in Tāi N. P. all contained worm remains (A. E. Dunham pers. obs.). Remains of caecilians (legless subterranean amphibians) were found in four scats, suggesting that small vertebrates may also be taken if encountered while digging for worms. Insect larvae and fallen fruits are also consumed. Foraging is restricted to riverine wetland areas and swamp forest.

While searching for prey, the Liberian Mongoose digs for earthworms and other soil invertebrates. It has been observed digging like a dog, alternately using its front feet, to excavate soil and then sticking its muzzle into the soil. Sand is often ingested with food.

items (Pagel 1985). Transects in swamp forest suggest mongooses may create an average of 16,700 foraging scrapes per km per day. Groups may plough up large areas of ground in search for worms, creating disturbance of 20–30% of the ground. The result of its foraging activities in a stream bed or swamp forest may result in considerable disturbance of the soil. This physical disturbance may accelerate decomposition and may have important impacts on seedling recruitment and mortality. Groups return to the same area to forage approximately once every three to four weeks. Reported to climb palm trees to forage for worms or beetle larvae occurring in the crowns after the trees have been cut for removing sap for the production of palm wine. A captive ♂ readily consumed ground meat, commercial dry dog food, two-day-old chicks, fresh fish and live insects (Taylor 1992, J. S. Carnio pers. comm., A. E. Dunham pers. obs.).

Social and Reproductive Behaviour Terrestrial and diurnal. Individuals travel and forage alone or in groups of 4–6 animals, though larger groups have been observed (Taylor 1989a, Veron *et al.* 2004). Groups are very quiet, communicating with soft grunting sounds. Adult ♂♂ are frequently observed alone; a radio-collared ♂ frequently travelled between three stable groups of conspecifics, joining them for 1–3 days at a time. Groups are often found in association with Sooty Mangabeys *Cercocebus atys*. This association may be initiated by the mongooses as an anti-predator strategy as no foraging benefit is obtained. The Crowned Eagle *Stephanoaetus coronatus* preys upon both species (Shultz 2002) and the mongooses respond to the monkeys' warning calls by quickly dispersing and running into thick vegetation or under fallen trees. Group members sleep together at night in hollow logs, under fallen trees, or occasionally in termite mounds when flooding is unlikely. Each home-range has numerous den sites that are rarely used on consecutive nights (A. E. Dunham pers. obs.).

An aggressive encounter was observed in Côte d'Ivoire with a group of Common Cusimanses. A group of four Liberian Mongooses initiated the encounter and displaced the larger group of ten cusimanses by advancing and giving threatening growls.

Reproduction and Population Structure In Liberia, three juveniles were collected in Jul and a ♀ was observed lactating in Aug, suggesting that breeding occurs during the wet season (May–Sep) when invertebrates are abundant and near the soil surface.

Predators, Parasites and Diseases Skulls of *Liberiictis* have been found in and under the nests of Crowned Eagles (Shultz 2002). These

eagles exist at high densities in the closed canopy forests of West Africa and are likely the major predator of this species. Leopards *Panthera pardus* occasionally take small carnivores and may also be a threat (Jenny 1996).

The louse *Felicola liberiae* (Mallophaga: Trichodectidae) has been described from the Liberian Mongoose (Emerson & Price 1972); ectoparasites also include ticks (Acarina; *Ixodes* sp.) and fleas (Siphonaptera).

Conservation IUCN Category: Vulnerable A2cd. CITES: Not listed.

Threats include hunting and deforestation from agriculture, logging and mining. They are hunted for food throughout their range with dogs, shotguns and snares. May also be vulnerable to the use of pesticides in forest plantations, as worms are known to accumulate toxins at levels dangerous to mammalian predators. Although present in secondary forests (Taylor 1992), the lack of den sites may restrict distribution. They are known to be present in Taï N. P. in Côte d'Ivoire and Sapo N. P. in Liberia. Further research is required to more accurately determine the limits of their distribution and to better understand the threats facing this species (Schreiber *et al.* 1989).

GENUS *Dologale*

Pousargues's Mongoose

Dologale Thomas, 1926. Ann. Mag. Nat. Hist., ser. 9, 17: 183.

Dologale is a monotypic genus, represented by Pousargues's Mongoose *Dologale dybowskii*. The species is limited, as far as is known, to a narrow belt of savanna–forest mosaic from Uganda westwards across

N DR Congo. The genus was included in *Helogale* by McKenna & Bell (1997), but without comment.

Chris Stuart & Tilde Stuart

Dologale dybowskii POUSARGUES'S MONGOOSE (SAVANNA MONGOOSE)

Fr. Mangouste de Dybowsky; Ger. Listige Manguste

Dologale dybowskii (Pousargues, 1893). Bull. Soc. Zool. De France 18: 51. Nouv. Arch. Mus. d' Hist. Nat., Paris (3) 6:121. 1894. 'Ubangi, Congo Belge', restricted by Moreau *et al.* (1945) to 'on the Upper Kemo, a tributary to the north of the Ubangui, about 6° 17' N, 19° 12' E [Central African Republic].

Pousargues's Mongoose *Dologale dybowskii*.*Dologale dybowskii*

Taxonomy Monotypic (Coetzee 1977). Originally described as *Crossarchus dybowskii* based on specimens collected in Ubangi, Central African Republic. Kershaw (1924) placed specimens from the Sudan in the genus *Herpestes*, whereas specimens from Faradje in NE DR Congo were mistakenly described as a new subspecies of *Helogale hirtula* (Allen 1924). Synonyms: *nigripes*, *robusta*. Chromosome number: not known.

Description One of the smallest mongooses, and bearing a close resemblance to the Dwarf Mongoose *Helogale parvula*. Head is short-snouted and lacks a groove in the upper lip. Pelage overall dark brown but grizzled yellow to light brown. Head colouration is darker and greyer than body pelage. Underparts less grizzled and more uniform in colour. Hair on the legs darker and feet almost black. Overall pelage is short and fine, although longer on the tail. Claws on forefeet are stout, long and curved, indicative of a digging forager. Didier (1948) provides an extensive description of the os penis. Dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{2/2} = 36$; however, one of the specimens from Faradje examined by Allen (1924) had a supernumerary premolar, with P^1 being fully developed on both sides. Haltenorth & Diller (1980) noted that the dental formula is variable (total of 38) with P^1 either present or absent. Nipple numbers not recorded.

Geographic Variation None recorded.

Similar Species

Helogale parvula. Widely distributed in partially wooded habitats from S Somalia and Ethiopia to NE KwaZulu–Natal. The smallest African mongoose, with distinct groove in upper lip; lives in packs and is never solitary.

Distribution Endemic to Africa. Exact range unknown and based on just 31 specimens. Occurs in NE DR Congo (Schouteden 1945), including the Garamba N. P. (Verschuren 1958), Central African Republic, extreme S Sudan and Uganda. It has been pointed out by Schreiber *et al.* (1989) that old specimens in the Paris Natural History

Museum were collected at Sanghe, but it is not clear whether this is the district in Congo, or that in the Central African Republic. Kingdon (1977) published known records, but unconfirmed sightings indicate that it may occur considerably further to the west than present records indicate. Hayman (1936) discusses known distribution.

Habitat Apparently has a fairly wide habitat tolerance in a narrow belt to the north of the Equator. It occupies the thicketed shores of L. Albert, savanna–forest mosaics as well as montane forest grasslands. Kingdon (1977) has suggested that this is a relict mongoose living in the ecotone between high forest and the lower rainfall wooded savanna.

Abundance This species is known from just 31 museum specimens and a handful of possible sightings. The paucity of records can probably be ascribed to confusion with the Dwarf Mongoose and the fact that its known range has seen few scientists or collectors in recent years. There have been no confirmed records for more than two decades.

Adaptations The claws on the front feet are stout and long and are probably an adaptation for digging.

Foraging and Food Given that its claws are suitable for digging it probably has a mainly invertebrate diet. The museum label on one specimen mentions small seeds, small termites and fragments of millipedes in the stomach (H. Van Rompaey pers. comm.).

Lateral view of skull of Pousargues's Mongoose *Dologale dybowskii*.

Social and Reproductive Behaviour Nothing is known about these aspects of its biology. It has been suggested that it may be at least partially diurnal and rest up in holes in trees and termite mounds (Dorst & Dandelot 1970). Kingdon (1977) sighted a mongoose that he felt sure was this species at 09:00h, and which took refuge in a termite mound. This sighting was of a solitary animal and it would seem from the meagre records that there is no indication of its living in groups, like the similar Dwarf Mongoose (in itself of interest, since the species has many features otherwise characteristic of the Mungotinae).

Reproduction and Population Structure No information is available.

Predators, Parasites and Diseases Nothing known, but as with other small mongooses they are probably vulnerable to larger raptors and certain predators. Colyn & Van Rompaey (1989) reviewed frontal nasal parasites in this and other species of viverrid.

Conservation IUCN Category: Least Concern. CITES: Not listed.

The only protected area from which this species has been recorded is Garamba N. P. in NE DR Congo. Lack of knowledge of this species' biology and habitat requirements make this a priority species for study.

Chris Stuart & Tilde Stuart

GENUS *Helogale* Dwarf Mongooses

Helogale Gray, 1862. Proc. Zool. Soc. Lond. 1861: 308 [1862].

Allen (1939) recognized 11 species in the genus *Helogale*; Ellerman *et al.* (1953) listed seven. Most recent authors recognize only two: Somali Dwarf Mongoose *Helogale hirtula* and Dwarf Mongoose *H. parvula* (Coetzee 1977, Wozencraft 1993, 2005), both endemic to sub-Saharan Africa where, in the north, the range of the former overlaps that of the more widespread Dwarf Mongoose. Both live in semi-desert and dry open woodland and grassland with termitaries and avoid closed forest.

Helogale are very small (weight up to 350 g) mongooses of variable colour. Dorsal pelage greyish, yellowish, reddish to light or dark brown speckled with pale tips. Dense buffy to dark buffy underfur. Somali Dwarf Mongoose is overall grizzled grey, has a longer, shaggier pelage, coarser speckling and brown to black digits. The dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{2/2} = 36$. Upper and lower first premolars absent.

McKenna & Bell (1997) included the genus *Dologale* in *Helogale*.

Harry Van Rompaey

Dwarf Mongoose *Helogale parvula*.

Helogale hirtula SOMALI DWARF MONGOOSE

Fr. Mangouste velue; Ger. Somali Zwergichneumon

Helogale hirtula Thomas, 1904. Ann. Mag. Nat. Hist., ser. 7, 14: 97. 'Gabridehari, 60 mi [96 km] West of Gerlogobi', restricted by Moreau *et al.* (1946: 410) to 'south-east Ethiopia (Ogaden) at about 7° 0' N, 45° 20' E'. Further restricted by Yalden *et al.* (1980) to 'Gabridehari (= Gabredarre, Kebridar) 6° 45' N, 44° 17' E'.

Somali Dwarf Mongoose *Helogale hirtula*.

Taxonomy Currently, the Somali Dwarf Mongoose is thought to be the only congener of the Dwarf Mongoose *Helogale parvula*, being sympatric in the northern parts of the latter's range. Coetzee (1977) subdivided this species into two parts that he called the *hirtula* and *percivali* sections. The former embraced *H. h. hirtula* from SE Ethiopia towards Somalia; *H. h. annulata* from the Mogadishu area and extreme S Somalia; *H. h. lutescens* from SW Ethiopia and northern L. Rudolf area of Kenya; and *H. h. powelli*, from the central part of the ex-Italian section of Somalia around Obbia. The *percivali* section embraced *H. h. percivali* from N Kenya and *H. h. tenebrosa* from the Kenya side of Mt Elgon, west of the Rift Valley. The credibility of any of these taxa must be tempered by the very incomplete knowledge of this species and the insufficiency of specimens to demonstrate the limits of individual variation. Synonyms: *ahlselli*, *annulata*, *lutescens*, *percivali*, *powelli*, *tenebrosa*. Chromosome number: not known, but probably $2n = 36$ as in Dwarf Mongoose.

Description A very small mongoose with longer, shaggier hair than the Dwarf Mongoose. Colouring varies, but typically overall grizzled grey with warmer coloured underparts and face. Head has small pointed muzzle with few fine vibrissae. Ears relatively inconspicuous. Body slender and elongated, fur of the tail tapered to a point. Feet dark brown. Walks with soles and claws of all feet on the ground. Forefeet have long, sharp nails that leave a characteristic spoor, though indistinguishable from the Dwarf Mongoose. Sexes similar in size and appearance, but ♂ exhibit external genitalia. Unlike the Dwarf Mongoose, the cheekteeth are more heavily built, and not typically sectorial; space between P^4 and M^1 much less than width of their protoconal lobes (Coetzee 1977). Nipple numbers not recorded.

Geographic Variation The very limited number of specimens and observations must qualify recognition of regional difference, which may well fall within ranges of individual variation that are of unknown extent or significance. Following Coetzee (1977), there appear to be two recognizable populations, one of *H. h. hirtula* type in Somalia, Ethiopia and extreme N Kenya, the other, *H. h. percivali* type, in Kenya.

*Helogale hirtula***Similar Species**

Helogale parvula. Sympatric throughout its range, but with sleeker, redder pelage and with feet that share overall body colour; cheekteeth more lightly built, sectorial and the space between P^4 and M^1 on buccal side usually subequal to or exceeding width of protoconal lobes of these two teeth (Coetzee 1977).

Herpestes sanguineus. Widely distributed in sub-Saharan Africa. Substantially larger, with long body and tail, the latter with a conspicuous black tuft; usually solitary or in twos or threes.

Herpestes ochraceus. Sympatric, but larger, and solitary or in pairs.

Distribution Restricted to the Horn of Africa in S and SE Ethiopia, S Somalia and N Kenya. Laurent & Laurent (2002) state that this species has also been sighted at Dittilou in Djibouti (though not noted by Künzel *et al.* 2000), and Anderson (1949) mentions this species from north of L. Turkana. A single, uncertain sighting in Mkomazi, Tanzania, might extend the species' range into the extreme north-eastern borderlands of Tanzania (J. Kingdon pers. obs.). Within a relatively large overall range this species has a patchy distribution that must be constrained by the presence of its very successful and broadly sympatric congener, the Dwarf Mongoose. Nothing is currently known about what form of partitioning must occur between the two *Helogale* species, but the Somali Dwarf Mongoose is clearly more specifically arid-adapted.

Palatal view of skull of Somali Dwarf Mongoose *Helogale hirtula*.

Habitat Limited to a zone of bush, thicket and shrubby deciduous woodlands dominated by *Acacia* (notably *A. bussei* and *A. reficiens*), *Commiphora*, *Grewia*, *Cordia*, *Euphorbia* and *Sterculia* species, *Balanites orbicularis*, *Boscia coriacea* and *Salvadora persica*, up to around 600 m in Ethiopia (Yalden *et al.* 1980, 1996). Like the Dwarf Mongoose, they use termitaria and stony outcrops as dens. The most likely advantage that they have over Dwarf Mongooses is greater ability to go without water during the long dry season.

Abundance Although Somali Dwarf Mongooses may exist at quite elevated densities, they are only abundant in restricted localities; however, estimates of their abundance, overall or local, are not available.

Adaptations As they must forage for food while avoiding predators there are obvious advantages to group living. The colouring of this species is more decisively cryptic than in the Dwarf Mongoose and implies greater vulnerability to predation. It would be interesting to know whether this species has similar partial immunity to bites from snakes as some other mongooses.

Foraging and Food Invertebrates and vertebrates of a similar range to that taken by the Dwarf Mongoose, but presumably more consistently arid-adapted. Such prey would include beetles, termites and larvae from soil or litter. Presumably social groups spread out, like the Dwarf Mongoose, and forage independently with some individuals serving as sentinels. Very young pups are probably fed by adults, but learn by following other pack members. Seasonal patterns of invertebrate availability and ranging patterns are not known.

Social and Reproductive Behaviour Although known to be a social species that forms packs no details have been observed. Their social structure may be not too far different from the Dwarf Mongoose, with social groups forming dominance hierarchies with single breeding pairs. It would be interesting to know whether this species is as highly territorial as the Dwarf Mongoose and how extensive their territories might be.

Reproduction and Population Structure Nothing is currently known, but probably some similarities to the Dwarf Mongoose. Gestation can be extrapolated as being in the region of 50 days. It is also not known how many litters can be produced during a year, nor the timing of reproduction, nor the annual survivorship of individuals. Considering the importance of understanding the ecological determinants of social structures and their evolution, this species should have some priority for further study.

Predators, Parasites and Diseases Although the major predators of this species must resemble those of the Dwarf Mongoose, notably raptors, reptiles and other carnivores, any differences in its habitat could be significant. If this species occupies relatively denser, less exposed habitat it could be predicted that the pressure to be social could be diminished, with further implications for social behaviour. Nothing is known about disease in this species nor about diseases for which they might serve as a reservoir; further reason for study in an area of great significance for pastoralism.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Although poorly known, the species is believed to have a relatively wide distribution and presumably occurs in several protected areas across its range.

Helogale parvula DWARF MONGOOSE

Fr. Mangouste nain; Ger. Zwergichneumon

Helogale parvula (Sundevall, 1847). Ofv. K. Svenska Vet.-Akad. Forhandl. Stockholm 1847, 3 (4): 121 (1847).
 'Caffraria superiore, juxta tropicum', restricted by Roberts (1951) to 'Zoutpansberg' [South Africa].

Dwarf Mongoose *Helogale parvula*.

Taxonomy Polytypic. Coetzee (1977) presented a provisional breakdown of subspecies, grouping them into three sections; the subspecific taxonomy is confused and badly in need of revision, and Coetzee's (1977) framework is only tentatively followed here. It is likely that the current subspecific classification of *Helogale* is due to idiosyncrasies of collection sites and collected individuals. Synonyms: *atkinsoni*, *bradfieldi*, *brunetta*, *brunnula*, *ivori*, *macmillani*, *mimetra*, *nero*, *ochracea*, *ruficeps*, *rufula*, *undulata*, *varia*, *vetula*, *victorina*. Chromosome number: $2n = 36$ (Fredga 1972).

Description Smallest of the mongooses, with long, slender body and furry tail roughly equal to body in length. Head large with small ears that lie close to the head, and a pointed muzzle. The rhinarium, which encloses the nostrils, has a shallow depression on the front between the nostrils, and divides the hair on the upper lip. Smooth, short, finely grizzled pelage on forehead, back, upper limbs and tail, due to agouti banding of multiple shades on single hairs; grizzling less apparent on underparts. Most individuals reddish-brown overall, though shades of tan or darker brown are also common. Hair on upperparts more sparse than on underparts; body hairs longest toward the hindquarters, up to 15 mm in length (these hairs having broad dark tips), although tail hairs may be longer (to 18 mm). Underfur dense. Tail not tufted, but occasionally has slightly darker pelage at tip. No pronounced black tuft as in the Slender Mongoose *Herpestes sanguineus*, which is also substantially larger than *Helogale*. Plantigrade gait, with soles of feet touching the ground. Five digits on both fore- and hindfeet. The front feet are equipped with long curved claws, up to 10 mm across the curve, and well adapted for digging; those on the hindfeet are shorter (8 mm) (Skinner & Chimimba 2005). Both sexes have cheek and anal glands: the anus and openings of the anal glands are enclosed in a subcircular pouch, the lips of which close to a transverse line. Sexes are alike in size and general appearance, but ♂♂ are

relatively easy to identify by the external genitalia; ♀♀ have two pairs of nipples. Young of the year can be distinguished by size because adult body mass is reached only in the second or third year (Creel & Creel 1991). For the first six months, juveniles can be distinguished by relatively large heads with blunt muzzles. For the first few weeks eyes are blue, but later change to brown.

The braincase is pear-shaped, narrowing in the front to the postorbital constriction; the postorbital bars are incomplete even in adults. The supraoccipital crest is well developed, while the sagittal crest is little more than a low ridge on the top of the braincase. The front chambers of the ear bullae are slightly larger than the hind. The rostrum is very short, relative to total skull length. The upper canines are long and sharp, reaching below the level of the base of the lower (Skinner & Chimimba 2005).

Geographic Variation Coetzee (1977) recognized three sections:

parvula section (southern Africa)

- H. p. mimetra*: N Namibia, NW Botswana, S and W Angola, south of the Cuanza R.
- H. p. nero*: Namibia, from Erongo Mts to SE Kaokoveld.
- H. p. parvula*: South Africa, S Mozambique, Zimbabwe and NE Botswana.
- H. p. ruficeps*: Southern Province and Kafue area of Zambia; possibly into SE Angola.

undulata section (East and north-east Africa)

- H. p. atkinsoni*: N Somalia and adjoining Ethiopia.
- H. p. ivori*: coastal N Mozambique and Tanzania.
- H. p. macmillani*: Ethiopia.
- H. p. rufula*: C Kenya, ranging to Arusha in Tanzania (the form in the Serengeti N. P., Tanzania).
- H. p. undulata*: Tete district and lower Zambezi Valley of Mozambique, adjoining parts of E Zambia, Malawi, inland N Mozambique, and southern highlands and C Tanzania.
- H. p. vetula*: coastal Kenya, Kenya east of the Tana R. and S Somalia.

varia section (central Africa)

- H. p. ochracea*: Uganda.
- H. p. varia*: NE Zambia, through Katanga to NE Angola.
- H. p. victorina*: NW Tanzania; possibly in adjacent Kenya and Uganda.

Similar Species

Helogale hirtula. Sympatric in the Horn of Africa region. Shaggier, paler, greyish pelage and noticeably darker feet; cheekteeth more heavily built, and not typically sectorial; the space between P4 and M1 much less than width of their protoconal lobes (Coetzee 1977).

Dologale dybowskii. Central African Republic, NE DR Congo, S Sudan and W Uganda. A dark, brownish grizzled, dwarf mongoose with shaggier and thicker, less tapered tail.

Herpestes sanguineus. Larger, with pelage and body form very similar to the Dwarf Mongoose, but distinguished on the basis of size, long body and long tail with pronounced black tuft. Often sympatric in areas with Dwarf Mongooses, but is likely to be seen alone or in groups no larger than two or three.

Herpestes flavescens. Largely allopatric, although both are present in the Erongo Mts of Namibia where this species is also black and is often confused with the Dwarf Mongoose (G. Rathbun & M. Griffin pers. comm.). Larger, with relatively longer tail; solitary, diurnal and consumes more vertebrate prey.

Herpestes ochraceus. Sympatric in north-east Africa, but larger, and solitary or in pairs.

Distribution Endemic to Africa, widely distributed in partially woody habitats of intermediate thickness from S Somalia and Ethiopia to NE KwaZulu–Natal in South Africa (around 28°S) and westwards to N Namibia and SW and C Angola and SE DR Congo. Mention of the species as being present in Gambia (e.g. Wozencraft 2005) is in error.

Habitat Most common in open woodlands (e.g. *Acacia–Commiphora* woodland), thickets and wooded savannas, particularly where there are termitaria, rock outcroppings or crevices, or hollow logs for use as dens. Indeed, Waser *et al.* (1995) postulated that the most important determinant of Dwarf Mongoose habitat preference is the density of suitable dens. In many areas, large *Macrotermes* mounds are preferred den sites, and Dwarf Mongooses can be seen warming themselves atop these mounds upon emergence around sunrise, and just before re-entering the den at sunset. They avoid montane regions (usually found to altitudes of 2000 m) and thick forests. Dwarf Mongooses are supplanted by Banded Mongooses *Mungos mungo* in open short-grass

habitats (particularly where termitaries or other den sites are scarce), where they are probably more vulnerable to predation. Although they can persist on home-ranges without water during the dry season, and are found in semi-desert regions, Dwarf Mongooses are not found in highly arid areas.

Abundance Dwarf Mongooses are often the most abundant small carnivores in areas of open woodland or wooded savanna, with densities as high as 8 ind/km² (though more typically around 5 ind/km²; Waser *et al.* 1995). Serengeti N. P. was estimated to hold 94,000 individuals, a number that is orders of magnitude higher than larger Serengeti carnivores (Waser *et al.* 1995).

Adaptations In the skull, the zygomatic arches are relatively heavy to support well-developed masseter muscles used to crunch the exoskeletons of robust invertebrates such as millipedes. The coronoid of the lower jaw is high and wide to accommodate the temporalis muscles, which activate the lower jaw. The carnassials of Dwarf Mongooses are lightly built compared with their congener the Somali Dwarf Mongoose *H. hirtula*, and are not particularly adapted to slicing (consistent with their primarily insectivorous diet). The lower first molar has three high cusps on the front and a broad grinding surface on the back half of the tooth; the remaining molars also have high cusps, also suggesting adaptation to a generally insectivorous diet (Skinner & Chimimba 2005).

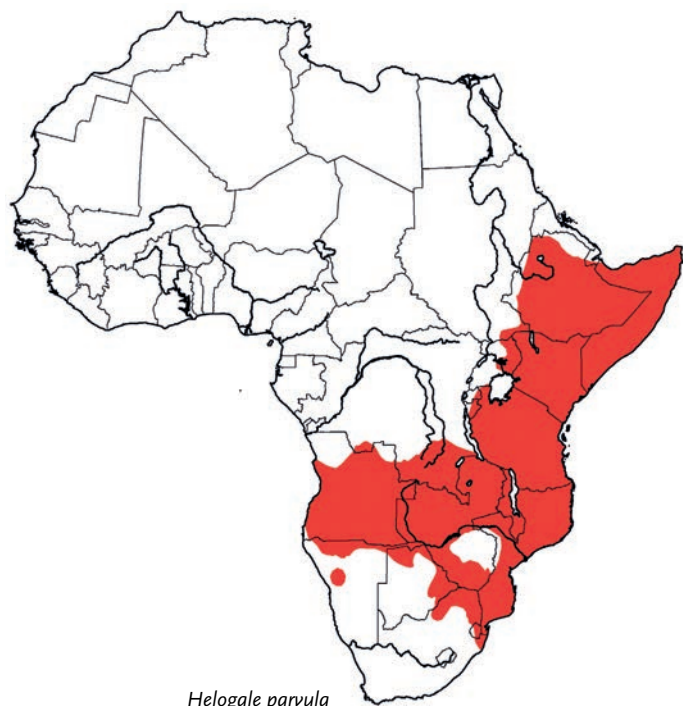

As the smallest of the mongoose family, and given their diurnal activity, Dwarf Mongooses often fall prey to raptors, snakes, small felids and other mongooses. Much of their behaviour and social organization has been shaped by the simultaneous pressures to forage for invertebrates in or on the soil while avoiding predation. Consequently, they live invariably in groups of 2–21 adults (mean of 9), with some individuals serving as guards while others forage (Rasa 1989, Rood 1990).

Dwarf Mongooses commonly are associated with active termite mounds, particularly those of *Macrotermes falciger*. These mounds have a characteristic cone structure, sometimes more than 2 m above ground; the termites cultivate fungus gardens within these mounds, and because the fungus requires a particular temperature to flourish, ventilation shafts are constructed. The latter are not directly occupied by the termites, but the mongooses use these ventilation shafts as night-time dens or daytime cover from predators (Rasa 1985). Dwarf Mongooses will also den in rock crevices and occasionally in hollow logs, but have a strong association with termite mounds, if available.

Like other mongooses, Dwarf Mongooses have adaptations of the neurotransmitter system that makes them relatively immune to bites from snakes with neurotoxic venom (see, for example, Barchan *et al.* 1992), such as spitting cobras, and they often mob and attack such snakes to drive them away. While not immune to their venom, Dwarf Mongooses also vigorously mob snakes with haemotoxic venom, such as Puff Adders *Bitis arietans*.

Decker *et al.* (1992) studied the secretions of the anal glands, and found that ♂♂ had vitamin E present in the anal sac, whereas this compound was absent in the ♀♀. This suggests a possible sex-specific function of vitamin E in the Dwarf Mongoose.

Foraging and Food While they occasionally prey upon small vertebrates such as murids, snakes and lizards, Dwarf Mongooses are almost entirely insectivorous (Shortridge 1934, Skinner & Chimimba

Hologale parvula

Lateral, palatal and dorsal views of skull of Dwarf Mongoose *Helogale parvula*.

2005). In a sample of 27 stomachs from southern Africa, Coleoptera, Orthoptera and Isoptera remains had the highest percentage occurrence. Prey identification in scats or stomach contents is hampered by the fact that Dwarf Mongooses masticate their food thoroughly.

Dwarf Mongooses forage for surface-active insects such as beetles, termites and grasshoppers, but very commonly dig up insects and larvae from the soil or litter, alternating bouts of digging, sniffing and listening intently. Packs spread out over an area of roughly 10–200 m² and forage independently within the area, moving slowly as a loose unit, with some individuals pausing to watch for predators. Flying insects are caught in the air with the forepaws, or, if on the ground, with a pounce with both forefeet pinning the insects to the ground. Large insects, such as locusts, are pinned down with a foot, bitten on the head and usually eaten headfirst. Some authors note that the lips are pulled back when Dwarf Mongooses eat stinging insects (Rasa 1973a), but they are often quite nonchalant about eating stinging prey such as scorpions, despite apparently being stung.

Murids, such as multimammate mice (*Mastomys* spp.), when these are taken, are pinned down with the forefeet and killed with a bite to the head. The head is eaten first and then the trunk, but only after skinning, by means of hooking the neck skin with the foreclaws and pulling it down, simultaneously pulling on the neck with the mouth. The entrails are extracted with the teeth. Small snakes are bitten a short distance behind the head then dropped, and repeatedly bitten, then shaken violently until they are quiescent, when they are pinned down with the forepaws and eaten head first. Whereas single animals will prey upon small snakes, larger snakes are usually attacked by the whole group (Rasa 1985). Larger prey, such as large snakes, may be shared by the group, but Dwarf Mongooses rarely share prey with other adults (Rasa 1985). They commonly share food with juveniles, allowing youngsters to learn the job of finding and obtaining prey in gradual steps.

Dwarf Mongooses have been observed standing up on their hind-legs on a rock, beneath a Red Ivory tree *Berchemia zeyheri*, grasping the thin, terminal branches with their forepaws, and pulling these towards them in order to remove the berries with their mouths (Hiscocks & Perrin 1991b). Rasa (1985) also observed them eating eggs; those from small birds are bitten open at the end and the contents licked out, while larger eggs such as those from francolins (*Francolinus* spp.) are clasped in front of them on the ground and thrown backwards under the body and upwards so that the egg is propelled against a hard object to break it open. They then either lick up the contents or use their paws to scoop the contents and then lick these. Dwarf Mongooses do not use this method often, in comparison with Banded Mongooses, which sometimes smash invertebrates in the same manner.

Social and Reproductive Behaviour Dwarf Mongooses are a highly social and cooperative species, found exclusively in groups, except for individuals in the process of dispersing. Packs comprise both related individuals and unrelated immigrants; in the Serengeti N. P., where the species has been the focus of a long-term study, packs average nine adults (range 2–21), with slightly more adult ♀♀ than ♂♂, plus young of the year from one to four sequential litters (Waser *et al.* 1995). Packs are structured by a rigid dominance hierarchy, comprising a single dominant breeding pair with a life-long bond (usually the oldest individual of each sex), and with subordinates reproductively suppressed and helping to raise the young of the dominants (Rood 1978, 1980, 1983a, 1990, Creel *et al.* 1992, Creel & Waser 1994, Keane *et al.* 1994).

Dwarf Mongooses are, like other social mongooses such as the Banded Mongoose and Meerkat *Suricata suricatta*, remarkably cooperative, with pack members collectively defending a shared territory, and most members engaging in behaviour such as watching for predators while others forage, babysit, jointly mark the home-range and allogroom. Relations within packs are amicable and strong, as evidenced, for example, by reports of alpha ♂♂ rescuing pack members from danger (Rood 1983a), and the provision of food and care for incapacitated animals (Rasa 1976b). More routinely, most adults of a pack groom, feed and carry the pack's young, and frequently engage in social grooming with other adults.

Groups are territorial, and will usually attack non-resident mongooses on their territory (though see Rasa 1985). Home-ranges in Serengeti N. P. averaged 27.4 ± 3.3 ha (Rood 1978), and there is some fidelity to these: of seven packs that ranged over a 2.2 km² study area in Serengeti N. P., two were still using the same core areas and dens after five years. Dwarf Mongooses jointly mark their territories, particularly objects near the termite mounds that they use as sleeping quarters. Scent-marking is achieved using both anal and cheek glands, which they rub on objects (and also on partners and offspring); marking with the everted anal gland is achieved in the typical anal drag fashion, or by means of a handstand. It is not unusual to see several packmembers simultaneously leaping onto their forefeet and grabbing a branch with their hindfeet to deposit anal marks. Faeces and urine are deposited in communal latrines. There is little overlap between territories (Rasa 1987), although ranges of adjacent packs may overlap slightly. These may serve as sites of confrontation between neighbouring groups, sometimes leading to injuries. In the short term, larger packs usually displace smaller packs in these conflicts, but this does not necessarily cause long-term changes in territory boundaries.

The alpha ♀ usually initiates pack movements each morning. If other pack members try to initiate movements, they are often ignored. Before moving out, guards, or babysitters, are posted to look after the pups that are too young to accompany the group on their foraging trips. Litters may occasionally be left unguarded for a few hours, but usually at least one pack member stands guard until the young are old enough to leave the den around 5–6 weeks; as many as three or more pack members may remain with the pups while the group forages (Rasa 1977a, 1986, Rood 1978). Babysitters remain at the den for several hours, foregoing foraging, until relieved by another set of babysitters (Rood 1978). The breeding ♀ is actually the least likely adult to be found guarding the young during a foraging bout.

Foraging groups remain in close vocal contact while foraging and moving, and also post guards, which watch for predators while others forage. Sentinels will move to a vantage point, such as a termite mound, from which to scan the area (Rasa 1986). If the sentinel sounds an alarm call, usually in response to a bird of prey, the group will freeze, or head straight for the nearest cover if the danger proves immediate (Rasa 1985). In the absence of any danger, the sentinel will return to foraging after a few minutes. Pack members share sentinel duty, with certain male members contributing more time than others. Different alarm calls are used for different predators: the notes are particularly distinct for terrestrial ('tchrr!') versus aerial ('tchee!') predators. Dwarf Mongooses respond to the alarm calls of other species such as hyraxes and hornbills (Rasa 1985), which also respond to mongoose alarm calls.

Dwarf Mongooses are commonly found sunning themselves in the early morning or afternoon near the entrances of the residence-mounds, during which they commonly indulge in allogrooming and autogrooming. Mongooses normally groom themselves and others by nibbling with their incisors. They appear to enjoy grooming in much the same way that some domestic cats enjoy being petted. Trapped mongooses are often relatively free of ectoparasites, suggesting that allogrooming may function in social behaviour in addition to its more typical function. Allogrooming pairs are usually of the same sex, and typically similar in social rank within the pack. Most adults also groom youngsters of both sexes.

As noted earlier, only the dominant pair generally breeds; mongooses that achieve alpha status usually have a tenure of several years. If one of the alpha pair dies, then the individual is replaced from within the pack by the oldest adult of the same sex. During the peak of oestrus, the alpha pair consorts all day, the dominant ♂ seldom being found more than a few centimetres from the ♀ (Rasa 1973b, 1987, Rood 1980), and the ♂ shows a marked increase in aggression towards other ♂♂ (Rood 1980, Rasa 1987). At this time, the pair may engage in as many as 50 mounts per hour (Creel *et al.* 1992, 1993), and may copulate as many as 2386 times, apparently ejaculating in 10% of these (Rasa 1985). Copulation takes a mean of 21 sec ($n = 67$; Rood 1990), the longest recorded being 11 min. The alpha ♀ will occasionally mate with subordinate ♂♂, even during the peak of oestrus (Rood 1980, Creel *et al.* 1992); subordinate ♀♀ mate with ♂♂ of all ranks.

Despite mating, most female subordinates fail to establish pregnancy, their oestrogen levels returning to baseline. In ♀♀, reproductive suppression operates either by blocking ovulation (most probable), fertilization or implantation, though not by abortion of established pregnancies (Creel 1996). Adult subordinate ♀♀ quickly obtain full

Dwarf Mongoose *Helogale parvula*.

reproductive activity after becoming dominant ♀♀, either by dispersing or by inheriting a pack following the death of the prior alpha ♀ (Rood 1980). In ♂♂ reproduction is suppressed mainly by aggressive interference with the mating attempts of subordinates, and reproductive hormone levels in subordinates are not depressed, although their testes are significantly smaller. Subordinates are more likely to mate with other subordinates (Creel *et al.* 1992).

Although subordinate ♀♀ are reproductively suppressed, 12% (usually older subordinates) still become pregnant every year, accounting for about 27% of pregnancies (Creel & Waser 1991). Most of these pups are killed by the alpha ♀ (Rasa 1973b, Rood 1983a); however, their offspring are sometimes raised if they avoid infanticide by the dominant ♀, and particularly if raised in joint litters. Genetic data reveal that 15% of all offspring are produced by subordinate ♀♀, and that subordinate ♂♂ sire approximately 25% of the pups (Keane *et al.* 1994). Occasionally, the pregnancies of subordinates are synchronized with those of the dominants, and then pups may be raised in a joint litter (Creel & Waser 1991, Keane *et al.* 1994). The mean size of joint litters (3.2 offspring at emergence) is significantly larger than that of alpha-male-only litters (2.4 offspring). In such cases, despite the presence of an additional lactating ♀, the dominant's production of mature offspring is reduced by 22% in joint litters; thus the dominant's young do not survive better as a result of communal nursing (Creel 1996). Another form of communal nursing occurs: for every four subordinates that lactate following pregnancy, one ♀ lactates without pregnancy (Rood 1980). This extreme form of alloparental care is known to occur in the wild only in female Dwarf Mongooses and male Dayak Fruit Bats *Dyacopterus spadiceus* (Francis *et al.* 1994).

Young usually are born in termitaria. Adults of both sexes contribute to raising offspring in many ways, by feeding, grooming, guarding and 'babysitting' them (Rasa 1973, 1977, 1989, Rood 1978, 1983a); subordinate pregnant ♀♀ will even suckle young of the alpha pair (Rood 1980, Creel *et al.* 1991). If the group moves to another mound, the subordinates carry the pups until they can walk themselves, from about 3.5 weeks of age. Cooperative breeding is, therefore, highly evolved in Dwarf Mongooses, to the point that unaided breeding pairs very rarely raise any offspring to independence (Creel 1990). The

energetic investment in reproduction is unusually high, both in terms of the number of offspring produced, and the growth rate of individual offspring. Without non-breeding helpers, these costs cannot be sustained. Of 237 breeding attempts in a Serengeti population, only 12 (5%) were made by unaided pairs, and only one (<0.5%) of these pairs raised any offspring to independence (Creel & Creel 1991). On this basis, it is fair to call the species an obligately cooperative breeder.

Both sexes disperse, usually as young adults and often as a group of littermates of the same sex, or a same-sexed group of similar ages. Males are more likely than ♀♀ to disperse (and to disperse farther), and the risks associated with dispersal account for the better survival of ♀♀, which yields a female-biased sex ratio among adults, even though slightly more ♂♂ are born (see Reproduction and Population Structure) (Waser *et al.* 1994a). Dispersal is important because immigrants are more likely to become dominants and reproduce earlier than are individuals who remain within their natal packs. For example, out of a sample of 31 individually known mongooses that achieved alpha status, 25 (13 ♀♀ and 12 ♂♂) were immigrants, compared with six that did not disperse and remained within their natal packs; similarly, seven ♀♀ that emigrated to other packs and attained alpha status bred at two years of age, compared with three ♀♀ that failed to disperse and only bred at four years of age (Creel & Waser 1994, Waser *et al.* 1994a).

Young of the year are initially fed by adult packmates (not only the parents), and learn to forage by following an adult and observing, at first being fed directly, but later being allowed to do the final digging or capture. Food availability varies seasonally and drives seasonal patterns of reproduction, with breeding during the wet season, when invertebrate availability is higher.

As mentioned elsewhere, Dwarf Mongooses use different alarm calls in response to different predators, probably because the best response differs for attacks by raptors and terrestrial predators. While moving and foraging, each mongoose frequently makes a quiet call ('boop') that allows the group to stay in contact even if they cannot see one another. When playing, young mongooses make a wide range of twittering, bird-like noises.

Dwarf Mongooses associate with many other species to reduce predation risk. Although they are frequently present in the same area, they do not share burrows with Banded Mongooses in the same manner as Yellow Mongooses *Cynictis penicillata* and Meerkats. Dwarf Mongooses are sometimes found in association with insectivorous birds such as drongos (*Dicrurus* spp.) and Lilac-breasted Rollers *Coracias caudatus*, but the strongest associations are between mongooses and two bush hornbills (*Tockus* spp.), with the birds awaiting the emergence of the mongooses in the morning before foraging together (and sometimes, if the mongooses are later than usual, the hornbills call down their holes to wake them up!). Hornbills benefit by catching flying insects disturbed by the mongooses, while the mongooses benefit from alarm calls given by the hornbills from their higher vantage point (Rasa 1983, 1985). Rasa (1985) also mentions their association with rough-scaled plated lizards inhabiting the termite mounds and which feed on faecal pellets of the mongooses.

Reproduction and Population Structure In Serengeti N. P. litters are born almost exclusively between the months of Nov and May, with occasional litters in Oct and Jun (Rood 1980); this annual peak is timed so that most litters are born during periods

of substantial rainfall and with at least one month of good rainfall to come, and such that lactation coincides with months of highest insect abundance (Waser *et al.* 1995). In southern Africa, all evidence points to their breeding during the summer wet season when insects are plentiful (Skinner & Chimimba 2005).

Oestrus lasts 1–7 days, and ♀♀ come into oestrus in tight synchrony, with subordinates entering oestrus a day later than the alpha ♀, suggesting that subordinates begin follicular activity in response to dioestrus in the dominant ♀ (Rood 1980, Creel *et al.* 1992, 1993). Gestation lasts 49–53 days (Rasa 1973b, 1987, Rood 1980), with a mean litter-size of 3.3 offspring at emergence from the den (approximately 2–3 weeks after birth) (Creel *et al.* 1992); in captivity, up to seven young may be born. Rood (1990) found that large groups had significantly larger litter-sizes than small groups. Neonates weigh 21.3 g on average, so that an average litter weighs 20% of the mother's mass (Creel & Creel 1991). Alpha ♀♀ may conceive during the postpartum oestrus, and, typically, 2–4 litters (mean = 2.4) are produced during a period of 5–6 months in the wet season, which translates into a ♀ producing pups equivalent to roughly 10% of her own mass each month, for several months in a row (Rood 1980, Creel & Creel 1991, Creel & Waser 1994). Lactation lasts 56 days on average, with pups growing 2.6 g/day (growth being positively affected by the number of adult and yearling helpers in the pack, and by rainfall; Creel & Creel 1991), while the ♀ is often pregnant with her next litter. As noted above, this heavy energetic investment in reproduction cannot be sustained without dominant ♀♀ spending significantly more time foraging than other pack members during the breeding season and without assistance from non-breeding helpers, who assist by feeding pups and guarding them while the breeding ♀ forages (Creel 1990, Creel & Creel 1991, Creel *et al.* 1991, 1995a).

In Serengeti N. P., the sex ratio at birth was slightly biased (52.5%) in favour of ♂♂ in a sample of 846 pups. By the age of two years, the sex ratio is female-biased, due to higher mortality in ♂♂, who are more likely to disperse and suffer increased mortality when not associated with a pack (Creel & Waser 1994, Waser *et al.* 1994a). Mean annual survival in Serengeti N. P. was 0.68 for 182 ♂♂ and 0.74 for 165 ♀♀ beyond the age of one (Waser *et al.* 1995). For juveniles, annual survival from emergence to their first birthday was 0.41 and did not differ by sex. Dwarf Mongooses are sexually mature as yearlings, but very few young adults reproduce, owing to social suppression of reproduction; only 1% of yearling ♂♂ attained dominant breeding positions compared with more than 70% for six-year-olds (Creel *et al.* 1992). Maximum longevity observed in the wild is ten years for ♂♂, 14 for ♀♀ (Waser *et al.* 1995); a captive specimen lived for 18 years (Weigl 2005).

Predators, Parasites and Diseases Major predators include raptors, particularly Pale Chanting-goshawks *Melierax canorus*, Martial Eagles *Polemaetus bellicosus*, Tawny Eagles *Aquila rapax* and Bateleurs *Terathopius ecaudatus*; monitor lizards; snakes, particularly Puff Adders *Bitis arietans* and spitting cobras (*Naja* spp.); and other small carnivores such as White-tailed Mongooses *Ichneumia albicauda*, Egyptian Mongooses *Herpestes ichneumon*, Banded Mongooses (particularly on young), Servals *Leptailurus serval*, Black-backed Jackals *Canis mesomelas* and Ratels *Mellivora capensis* (Rasa 1983, Rood 1990).

As described above, the selection pressure of predation has been an important force in the evolution of sociality in mongooses. Dwarf

Mongoose are small, diurnal, forage in the soil for invertebrates and occupy relatively open habitats. These factors combine to leave a solitary animal very vulnerable to predation when foraging, and sociality allows for a system in which a sentinel keeps watch while others feed, and then feeds in its turn. Other social mongoose species, like the Banded Mongoose, tend to be small, diurnal, prey on invertebrates and occupy open habitats with substantial predation risk (Rood 1986). Solitary mongooses tend to be larger, more nocturnal, occupy thicker habitats and prey on vertebrates.

Little is known about diseases, but they may be affected by some of the viral pathogens known to affect other carnivores, such as canine distemper, rabies and parvovirus. There is also little information available on parasites, but leishmanial parasites have been isolated from this species (Mutinga *et al.* 1982) and Levine *et al.* (1975) recorded at least two species of coccidian parasites, *Isospora garnhami* and *I. hoarei*.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Dwarf Mongooses have a wide distribution, attain high densities and have small territories such that even small protected areas can harbour large populations. They are often the most common carnivore in the habitats they occupy, and because of their abundance and wide distribution, may have greater than appreciated effects on ecosystems, despite their diminutive size.

GENUS *Crossarchus*

Cusimanse

Crossarchus F. Cuvier, 1825. In: E. Geoffroy Saint-Hilaire & F. Cuvier, Hist. Nat. Mammifères 3 (47): 1–3.

The genus contains four species: Alexander's Cusimanse *Crossarchus alexandri*, Ansonge's Cusimanse *C. ansongei*, Common Cusimanse *C. obscurus* and Cameroon Cusimanse *C. platycephalus*. *Crossarchus platycephalus* has been considered a subspecies of *C. obscurus* (Wozencraft 1989a, 1993), but Goldman (1984) and Colyn & Van Rompaey (1994b) considered them distinct species (and see Wozencraft 2005).

The genus is restricted to areas of lowland forest between SW Guinea and E DR Congo and W Uganda with isolated populations on Mt Elgon, E Uganda and NE Angola. Common Cusimanse inhabits the West faunal region and Cameroon Cusimanse the West Central region; these two allopatric species are separated by the Volta R. (western Dahomey Gap). Further east, Ansonge's Cusimanse and Alexander's Cusimanse mainly inhabit the lowland forests of the Congo basin.

Members of the genus are small, darkish-brown with a coarse, shaggy pelage ticked with yellowish-white to reddish-brown; hairs on head and face lighter than on body. Ears short and round. All members have a long snout (less pronounced in Ansonge's Cusimanse). No longitudinal groove on upper lip. Head and distal parts of fore-

and hindlimb shorter-haired than body and tail; brownish underfur long but shorter than guard hairs. Tail shorter than head and body length and tapers from base to tip. Legs short; five-toed feet, slightly webbed, with long claws. Plantigrade gait. Area between digital pads and plantar pads naked in fore- and hindfeet; posterior 30% of hindfoot naked. Paired anal scent glands. The genus name, *Crossarchus*, comes from the Greek *crossotos* fringed, and *archos* anus, and refers to the wrinkled folds of the circumanal glandular sac. Ectotympanic portion of bulla larger than entotympanic. Dental formula is $I^{3/3}, C^{1/1}, P^{3/3}, M^{2/2} = 36$. Upper and lower first premolars are absent.

Crossarchus was considered synonymous with *Mungos* by Hill & Carter (1941) and a subgenus of *Mungos* by Ellerman *et al.* (1953). Molecular data place *Crossarchus* as sister taxon to *Helogale* (Perez *et al.* 2006, Patou *et al.* 2009).

Harry Van Rompaey & Marc Colyn

Facial features of three *Crossarchus* species.

Crossarchus alexandri ALEXANDER'S CUSIMANSE

Fr. Mangué d'Alexandre; Ger. Kongokusimanse

Crossarchus alexandri Thomas & Wroughton, 1907. Ann. Mag. Nat. Hist., ser. 7, 19: 373. 'from Banzyville, Ubanghi' [= Mobayi, Zaire (= DR Congo), 4° N, 21° 11' E (Goldman 1984)].

Alexander's Cusimanse *Crossarchus alexandri*.

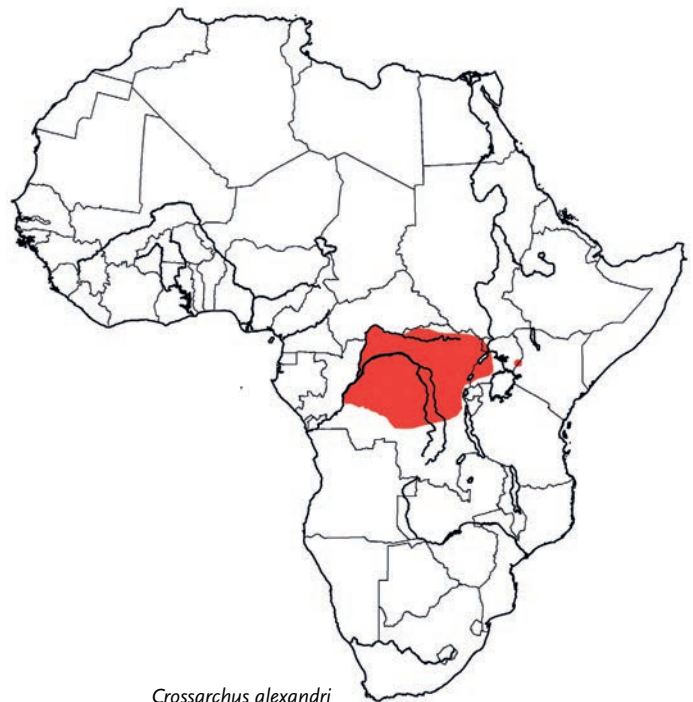

Taxonomy Monotypic. A specimen collected by Emin Pasha in NE DR Congo was mistaken for and described as *C. obscurus* by Thomas (1888). The species has also been confounded with the genus *Mungos* (e.g. *Mungos obscurus alexandri*; Mertens 1925). Species named after the collector of the type specimen, Boyd Alexander. Goldman (1984) described *C. alexandri minor* from extreme E DR Congo and Uganda, including an isolated montane population on Mt Elgon. Recognition of this subspecies, described solely on the basis of smaller cranial measurements, was not supported in the study of Colyn & Van Rompaey (1994b). Synonyms: *minor*. Chromosome number: not known.

Description A small, shaggy-haired, short-legged, long-nosed mongoose. General colour brownish-black, grizzled with grey. Hair on head short; muzzle greyish-buff; lips and cheeks pale buff. Crown blackish-brown; ears pale brown. Snout elongated. Back and flanks covered with long guard hairs (50–60 mm long). Guard hairs grey at the base with upper half black and a whitish tip. Underfur more brownish with hairs brown at base and lighter at tip. Ventral pelage more brownish than back and flanks. Nuchal crest (hairs ca. 60–80 mm long) starting from the crown to the shoulders, continuing in a mid-dorsal crest to the base of the tail. Pair of whorls on back of neck. Fore- and hindlegs short-haired and black; long, sharp claws, especially on forefeet. Tail (ca. 70% of HB) tapering and long-haired at the base, similarly coloured as body. Three pairs of nipples.

Geographic Variation None recorded.

Similar Species

Crossarchus ansorgei. Sympatric. Smaller; pelage less shaggy; snout shorter (length of rostrum ca. 31.5% of condylobasal length; Van Rompaey & Colyn 1992); posterior portion of bulla more inflated.

*Crossarchus alexandri*

Xenogale naso. Sympatric. Larger size and smoother, short-haired pelage; does not live in groups.

Distribution Endemic to central Africa. Confined to the rainforest in DR Congo on both sides of the Congo R., in the north limited by the Ubangi R. and in the south by the Kasai R.; also present in W Uganda. A disjunct population lives on the slopes (between 1500 and 2900 m) of Mt Elgon, E Uganda. Alexander's Cusimanse is present in two faunal regions (East-central and South-central) showing no

Alexander's Cusimanse *Crossarchus alexandri*.

subspeciation, implying that the species survived the last interpluvial in a single faunal region. We hypothesize that Alexander's Cusimanse was formerly isolated in a refugium on the right bank of the Congo R., and that colonization of the South-central region occurred comparatively recently (Holocene) and during a limited time span (Colyn & Van Rompaey 1994b).

In SW Central African Republic, natives use a distinct name to refer to an uncommon mongoose, living in groups, in the area. The presence of a species of *Crossarchus* is suspected (Ray 2001).

Habitat Lowland and montane rainforest. Not known to occur in the forests of the Central Rift. Lives in thick undergrowth and prefers swampy areas (Kingdon 1977). Commonly found near villages in Ituri Forest (J. C. Ray pers. comm.).

Abundance There is no direct information on abundance. The fact that Alexander's Cusimanses make up nearly half of the carnivore bushmeat in NE DR Congo (Colyn *et al.* 1987) suggests that they are widespread and abundant in this region. In the Ituri Forest, Bambuti pygmies hunting with dogs captured Alexander's Cusimanses with greater frequency than other carnivores (76 individuals in 53 hunts, or 67% of all carnivores) (Hart & Timm 1978).

Adaptations Nocturnal according to Rahm (1966) but generally considered as diurnal by the Mbuti pygmies (Carpaneto & Germi 1989, J. C. Ray pers. comm.). It is possible that in the forest undergrowth

Lateral view of skull of Alexander's Cusimanse *Crossarchus alexandri*.

the distinction between day and night is less important than it is in the open (Kingdon 1977). Terrestrial, but they may climb sloping trees and are more adept climbers than the Banded Mongoose *Mungos mungo* (Kingdon 1977); one specimen while fleeing ran up a tree and tried to hide among creepers about 10 m high (R. W. Hayman pers. comm.). Long nose and long, strong claws on the forefeet are adaptations for foraging on the forest floor and opening rotting tree trunks. They are also able to dig their own holes (Kingdon 1977). Communication in dense vegetation is facilitated by an elaborate vocal repertoire and scent-marking, as in the Common Cusimanse *C. obscurus*.

Foraging and Food Frugivorous and carnivorous (Rahm 1966). Stomachs contained frogs, slugs and insects, chiefly crickets, grasshoppers and caterpillars. They are also recorded taking worms and fruit (Kingdon 1977) and butterflies, millipedes, earthworms, termites, snakes, carrion, bananas and oil palm fruits (Carpaneto & Germi 1989). While foraging, individuals push their noses into crevices and scrape and scratch continually.

Social and Reproductive Behaviour A social species, Alexander's Cusimanses have been observed foraging in packs of as many as ten (Carpaneto & Germi 1989) to 20 individuals (Kingdon 1977), grunting and twittering continually. Any alarm excites a loud chatter, after which they run off in silence. Hand-stands are executed in order to mark tree trunks and branches some 25 cm off the ground with the secretion of the anal gland. Captives tend to drop their faeces and urinate in one place and respond to the faeces and urine of other animal species by scratching and then superimposing their own urine or anal deposit (Kingdon 1977). Up to ten individuals sleep together in holes in trunks of dead trees (Carpaneto & Germi 1989). There is no information on their home-range.

Reproduction and Population Structure One ♀ collected mid-Apr contained six embryos (Verschuren 1972). According to the Mbuti pygmies there are 3–4 young per litter (Carpaneto & Germi 1989).

Predators, Parasites and Diseases There is no information on predators or diseases. Nematodes *Subulura schebini* and *Spirura congolense* (Vuylsteke 1956), the nymph of a pentastome *Armillifer armillatus* (Fain 1961), and a louse *Suricatoecus* sp. (Emerson & Price 1967), have been found on specimens from DR Congo.

Conservation IUCN Category: Least Concern. CITES: Not listed.

Overall not considered threatened, but numbers probably declining due to forest loss and bushmeat hunting. Alexander's Cusimanses comprised nearly half (42.3%) of the carnivore bushmeat in a study in NE DR Congo (Colyn *et al.* 1987). It is sometimes caught in traps but mostly hunted with dogs (Carpaneto & Germi 1989). The Mt Elgon population may be threatened by hunting and habitat degradation (Kingdon 1997).

Crossarchus ansorgei ANSORGE'S CUSIMANSE (ANGOLAN CUSIMANSE)

Fr. Mangué d'Ansorge; Ger. Ansorge's Kusimanse

Crossarchus ansorgei Thomas, 1910. Ann. Mag. Nat. Hist., ser. 8, 5: 195. Dalla Tando (Ndala Tando, 09° 18' N, 14° 54' E, Angola).

Taxonomy Species named after the collector of the type specimen, W. J. Ansorge. Two subspecies are recognized (see Colyn & Van Rompaey 1990). Synonyms: *nigricolor*. Chromosome number: not known.

Description A small, dark brown, light-speckled mongoose with a relatively short muzzle. Hairs on muzzle, chin and a mask-like zone around the eyes very short. Whorl present on the back of the neck. Ears short and rounded. Body, limbs and tail a relatively uniform dark brown. Area between digital pads and plantar pad naked in fore- and hindfeet. Claws long (forefeet 8–12 mm; hindfeet 6.5–9 mm) and curved, especially on forefeet. Tail shortish (ca. 66% of HB). Presumably three pairs of nipples.

Geographic Variation

C. a. ansorgei: Angola, escarpment zone north of the Cuanza R. General colour reddish-brown, with crown and ears blackish, and chin and cheeks pale brown; light rings on guard hairs; underfur dense, hairs tipped with tawny or tawny-ochraceous; forelimbs black and hindlimbs tawny; feet black; tail mixed reddish and black basally, more blackish distally.

C. a. nigricolor: DR Congo, probably limited to the forest blocks between the Congo/Lualaba and Kasai rivers. General colouration sepia black, with chin and muzzle short-haired and dirty white continuing in a small stripe above the eyes; white to yellowish-ochreous stripe, 1 cm in width, extends from corner of mouth under external ear to side of neck; ears with a whitish tuft at internal base; back, flanks, neck and head covered with black hairs

(up to 35 mm long) annulated with white to yellowish-ochre band near the top; underparts, tail and limbs completely blackish; tail bushy with hairs up to 4.5 cm long, tapering from base to tip.

Similar Species

Crossarchus alexandri. Sympatric. Larger; shaggier pelage; longer snout (length of rostrum 34–36% of condylobasal length; Van Rompaey & Colyn 1992); anterior portion of bulla more developed.

Xenogale naso. Sympatric. Larger size and smoother, short-haired pelage; does not live in groups.

Ansorge's Cusimanse *Crossarchus ansorgei*.

Distribution Endemic to central Africa. Found only in Angola and DR Congo. In Angola, known only from a single specimen (the type) collected in 1908 in the northern part of the escarpment zone in the southernmost portion of the Dembos forest, north of the Cuanza R. (Crawford-Cabral 1989a). In DR Congo, present in the rainforest south-east of the Congo/Lualaba R., where collected from five localities: Amadjabe (00° 04' S, 25° 17' E), Baringa (00° 45' N, 20° 52' N), Ikela (01° 11' S, 23° 16' E), Kodoro (01° 16' N, 20° 06' E) and Yaenaro Plantation (00° 12' N, 24° 47' E) (Coetzee 1977, Colyn & Van Rompaey 1990). Expected to occur down to the Kasai R., but unlikely to range as far as central Kivu, as suggested by Coetzee (1977). Ansorge's Cusimanse, present in the South-central region, has not been able to colonize higher altitude forests in the East-central region (Colyn & Van Rompaey 1994).

Habitat All specimens have been collected from deciduous rainforest. Unlike Alexander's Cusimanse *C. alexandri*, it is not known to visit cultivated or inhabited land (Colyn 1984).

Abundance Up until 1984, this species was known only from two specimens, the type and the specimen from Baringa. However, they have since been found to be quite common in the Tshopo Sub-region (part of Orientale Province, south of Kisangani, DR Congo). During bushmeat surveys conducted in the 1980s in the eastern Congo basin, this species accounted for only 10% of carnivores. By contrast, Alexander's Cusimanse accounted for 42%. Their relative rarity as prey

Crossarchus ansorgei

Lateral, palatal and dorsal views of skull of Ansorge's Cusimanse *Crossarchus ansorgei*.

implied that although Ansorge's Cusimanse formed social groups of similar size to those of Alexander's Cusimanse, Ansorge's Cusimanse groups must have been more difficult to hunt, travelled over much larger home-ranges or, more likely, were specialized in some unknown way for survival in a sub-region or vegetation sub-type (Colyn *et al.* 1987).

Adaptations Diurnal and terrestrial. Strong claws on the forefeet are adapted for foraging on the forest floor and opening rotting tree trunks. The respects in which this species differs from the commoner and sympatric Alexander's Cusimanse are not known, but its shorter, thicker snout implies a less specialized diet and, possibly, a more conservative position in the *Crossarchus* radiation.

Remarks There is a paucity of information available on the ecology of this species. Food includes small vertebrates, insects, larvae and eggs. Two captive individuals refused fruits, mushrooms and berries (Colyn 1984). They are social, living in groups of up to 20 animals (Colyn 1984). According to native hunters in NE DR Congo, their behaviour is similar to that of Alexander's Cusimanse.

Conservation IUCN Category: Data Deficient. CITES: Not listed.

There is a paucity of information available for this species, which makes it a clear priority for research, particularly to determine its current population status and to determine the extent of its geographic range. In particular, a survey for the disjunct population in Angola is urgently needed since the nominate subspecies is known only from the holotype collected in 1908. Threats to this species are not clear, but probably include habitat loss and bushmeat hunting (as mentioned, Ansorge's Cusimanse accounted for 10% of the

carnivores hunted as bushmeat in DR Congo; Colyn *et al.* 1987). Recorded from Salonga N. P. in DR Congo (Schreiber *et al.* 1989).

Crossarchus obscurus COMMON CUSIMANSE

Fr. Mangouste brune; Ger. Dunkelkusimanse.

Crossarchus obscurus (F. Cuvier, 1825). In: E. Geoffroy-St. Hilaire & F. Cuvier, Hist. Nat. Mammifères 3 (47): 1. 'côtes occidentales de l'Afrique, et vraisemblablement des parties qui sont au midi de la Gambie'; restricted by G. Cuvier (1829: 158 in Wozencraft 1993) to 'Sierra Leone'.

Common Cusimanse *Crossarchus obscurus*.

Taxonomy Monotypic. Thomas (1895) described *Crossarchus somalicus* as 'a new banded mongoose from Somaliland', a form that Wozencraft (1993) included as a synonym of *C. obscurus*; *somalicus* is actually a synonym of *Mungos mungo* and not related to this species or genus. Synonyms: *punctatissimus*. Chromosome number: $2n = 36$ (Fredga 1972).

Description A small-sized mongoose with long nose, strong claws, short legs and dark brown pelage (the specific name, *obscurus*, is Latin for dark or dusky, referring to pelage colour). Nose extends considerably beyond lower lip; longitudinal groove on upper lip is absent. Paired cheek glands between ears and mouth in both sexes. Ears pale brown, short and round; capable of closing by movement of posterior ridges

(Ewer 1973). In some museum specimens there are whorls posterior of the ears and crown, where the hairs spread out around a circular patch with no hair, and a crest between ears along nape. Hairs that form the crest stand erect and are ca. 5–12 mm in length, shorter anteriorly and longer posteriorly. Both whorls and crest, which are present in both sexes and appear not to be seasonal, are more pronounced and frequent in museum specimens of Cameroon Cusimanse *Crossarchus platycephalus*. In 13 adult museum specimens from Sierra Leone, Liberia, Côte d'Ivoire and Ghana, whorls were clearly present in eight specimens (six with one whorl and two with two whorls); the crest was clearly visible in seven specimens. Rosevear (1974: 285), examining specimens of *Crossarchus* spp. from West Africa, noted that 'one of the most characteristic features of the *Crossarchus* pelage is the presence of a pair of large whorls on the back of the neck ... but though these are for the most part very conspicuous they are not always so and may, exceptionally, apparently be wholly lacking'. Whorls and crest have not been observed in live specimens in Tai N. P., Côte d'Ivoire, based on field observations of 54 individuals (A. E. Dunham pers. obs.), or in Tiwai Island Wildlife Sanctuary, Sierra Leone, based on observations of 12 captured individuals (A. L. Olson pers. obs.). The hairs of the head are short (to ca. 3 mm), medium to dark brown, with pale tips; hairs of cheeks and around eyes paler. Dorsal guard hairs ca. 15–20 mm in length posterior of ears, 25–30 mm at mid-body, and 30–35 mm at rump. Guard hairs of body and tail coarse and dark brown with pale tips, giving an overall speckled appearance. Guard hairs along anterior half of back with tips (ca. 4–5 mm) ranging from pale buff

Lateral, dorsal, and palatal views of skull of Common Cusimanse *Crossarchus obscurus*.

to yellowish-buff, with some specimens being considerably more speckled than others. Guard hairs of rump mostly with reddish-brown tips, thus rump appears darker than anterior half of back; rump more blackish-brown in some specimens, where pale tips are few or absent. Hairs of underfur finer than guard hairs and ca. 15–20 mm in length, basal band dark brown, subterminal band (ca. 4–5 mm) pale buff, most often with a reddish-brown terminal band (ca. 4–5 mm). Ventral pelage finer, less dense, shorter and paler than dorsal pelage. Legs dark brown to blackish-brown. Tail (ca. 52% of HB) densely haired tapering evenly from base to tip, with guard hairs ca. 30–35 mm in length at base of tail and ca. 25–30 mm at tip. Guard hairs of tail dark brown with reddish-brown tips or blackish-brown. Forelimbs plantigrade; hindlimbs appear to be semi-digitigrade. Digital, interdigital, thenar and hypothenar pads of forefoot and hindfoot well developed. Claws on forefeet long (9–12 mm, $n = 8$), shorter on hindfeet (4–7 mm, $n = 8$). Paired anal scent glands in both sexes, with external orifices on either side of anus; between the orifices lie fine longitudinal ridges that pass into the central depression of the anal sac. Three pairs of nipples. Sexes similar in colour and size.

Geographic Variation None recorded.

Similar Species

Crossarchus platycephalus. Allopatric in Benin, Nigeria, Cameroon, Equatorial Guinea, N Congo and SW Central African Republic. Similar size; skull broader with shorter palate and tympanic bullae and longer maxillary and mandibular toothrows in Cameroon Cusimanse; posterior margin of palatine with posteromedial spinous projection in most adult specimens (evenly emarginated in most specimens of Common Cusimanse); guard hairs along anterior half of back with reddish-brown tips (pale buff to yellowish-buff

in Common Cusimanse); guard hairs longer along mid-back and rump; underfur with pale yellowish-buff subterminal band, most often with a reddish-brown terminal band (terminal half of underfur is pale buff in Common Cusimanse).

Liberiictis kuhni. Liberia and adjacent Côte d'Ivoire only (and possibly S Guinea). Similar in body form, but larger in size; neck stripe present; upper and lower first premolar present.

Xenogale naso. Allopatric, occurring only in rainforests from SW Guinea to Ghana. Larger, and not group living.

Mungos gambianus. Sympatric over most of the range, albeit generally confined to woodland habitat. Dorsal pelage brownish-grey, brightly speckled with yellow; distinctive dark brown neck-stripe; tapered tail with black tip.

Distribution Endemic to West Africa. Occurs in rainforests of SW and SE Guinea (including the Kounounkan massif; Barnett *et al.* 1996), Sierra Leone, Liberia, Côte d'Ivoire and Ghana, and extending just east of R. Volta (recorded at Breniasi; see Grubb *et al.* 1998). Kingdon (1997) incorrectly gives the distribution of Common Cusimanse as occurring in Nigeria, west of the Cross R., but only the Cameroon Cusimanse is found in Nigeria.

Habitat Found primarily in dense undergrowth of rainforest from sea level to ca. 1480 m (Mt Nimba, Guinea). Also found in farm bush, logged forest and plantations. In Sierra Leone, found mainly in southern forested parts, but has been recorded from Western Area F. R. and Loma Mountains F. R., which are rainforest but beyond the southern forest zone (Grubb *et al.* 1998). In Côte d'Ivoire, also found in humid savanna zone, including Mt Sangbé, Mt Péko and Maraouhé National Parks (A. E. Dunham pers. obs.), and Siensou, and in gallery forests of savanna in Comoé N. P. (Hoppe-Dominik 1990). In Ghana, also found on the Accra Plain (observed foraging in a dry open area of grassland and thicket), including Monkey I. (Grubb *et al.* 1998).

Crossarchus obscurus

Abundance Presumed common within its range. Widespread in Côte d'Ivoire, occurring in all national parks: recorded as common in Comoé N. P. and Mt Sangbé N. P. (Hoppe-Dominik 1990), and population density in riparian forest of Taï N. P. was estimated at 13.2 ind/km² (A. E. Dunham pers. obs.). In old secondary rainforest on Tiwai I. (a 12-km² island in Moa R., Sierra Leone), estimated density was 17 adults/km² (A. L. Olson pers. obs.).

Adaptations Long nose and long forefeet claws are adaptations for foraging within soil and leaf litter. Ability to close ears is an adaptation for frequent digging. Dark brown fur blends well with forest floor. Long coarse hairs of neck and shoulders stand erect during aggressive encounters, making animals appear larger in size. Sight, hearing and smell are well developed. Communication in dense vegetation is facilitated by an elaborate vocal repertoire and scent-marking.

There is no permanent den site, and groups often choose a new shelter every night; one group used 21 different shelters during the 38 nights in which shelters were located, another group 12 shelters over 18 nights (Olson 2001). Animals enter shelters at dusk, during rain and for mid-day resting periods. They take refuge in hollow trees and logs, under fallen trees, in thick vegetation, in burrows made by other animals (often with several entrances), or occasionally in termite mounds in the dry season. In Tiwai Island Wildlife Sanctuary groups take refuge at night in trees, approximately 13 m from the ground (5–25 m, $n = 18$) (Olson 2001). Individuals climb trees using vines to reach sections with many lianas and suspected of having a hollow; trees averaged 32 m in height (22–50 m, $n = 17$) and 85 cm in diameter (20–140 cm, $n = 20$), and the most commonly used tree was deciduous *Piptadeniastrum africanum*. Cusimanses are not adept at descending; on occasion individuals descending trees fell 5 m or more. In Taï N. P., all den sites observed during 16 months of study were located within 2 m of the ground (A. E. Dunham pers. obs.).

Foraging and Food The most common food items include large millipedes, ants, earthworms and termites. Diet also includes other forest-floor invertebrates (including beetles, spiders, snails, woodlice, centipedes, grasshoppers, crickets and insect larvae), crabs, small vertebrates (frogs, snakes, lizards, birds, lizard and bird eggs, and small mammals up to the size of Forest Giant Pouched Rats *Cricetomys emini*), and fallen fruits (*Parinari* sp. and *Sacoglottis* sp.).

Forages largely during the day (but also after dark) individually or in groups of up to 24 individuals. In Taï N. P., groups often forage in association with Diana Monkeys *Cercopithecus diana* or Sooty Mangabeys *Cercocebus atys*; these mixed-species groups may travel as a unit for up to 6 h per day. When foraging, individuals turn over small stones and pieces of wood and scrape and root through leaf litter, and also tear up rotting logs. They often dig with forefeet and long nose when foraging for soil invertebrates. Small invertebrates dug out of the ground usually are given a quick shake as they are picked up (Ewer 1968). Small vertebrate prey are killed with a single bite orientated at the back of the neck and are not shaken. Group hunting for larger vertebrate prey is common. Booth (1960: 66) reports 'the Giant Rat (easily as big as the Cusimanse) is driven from its hole by one member of the party, who goes down after it; then the others pounce as it emerges'. This hunting method has been observed in the cusimanse in W Côte d'Ivoire for several rodent species. In Taï N. P., a group of 14 individuals was observed,

on four occasions, to surround and kill a cobra (one cobra measured 2.5 m in length).

Cusimanses commonly eat millipedes that, in defence, emit a noxious substance (containing benzoquinines) that can irritate sinuses and eyes. When millipedes are found, cusimanses stomp on them with their front feet and rub them in soil until the irritating substance has dissipated. Sooty Mangabeys and Diana Monkeys usually avoid eating millipedes but, in Taï N. P., they have been observed to steal them from cusimanses after the millipedes have been sufficiently processed by the cusimanses.

In some species of mongooses eggs are opened by being hurled with the forefeet back between the hindfeet and against a hard surface, while bouncing the hindfeet off of the ground. A captive Common Cusimanse ♀ observed by Naundorff (1936) exhibited this behaviour using a hard ball and other rolling objects. This behaviour has also been reported with eggs in some captive cusimanses (A. L. Olson pers. comm.), but has not been observed in wild animals in Côte d'Ivoire (A. E. Dunham pers. obs.) and was not reported by Ewer (1973) or Goldman (1987) in their captive specimens.

Social and Reproductive Behaviour Gregarious, highly social and territorial. Groups consist of adults of both sexes and juveniles, possibly representing one or more family units, each with a mated pair and surviving young of one or more litters. Groups are relatively stable, but temporary fission of groups is common during Jun–Aug. Groups rarely stay in the same place for more than two or three days. Animals cover 25–33% of their forested home-range within a day, often revisiting areas in the same day (Olson 2001, A. E. Dunham pers. obs.). Home-ranges appear to vary with habitat and group size: home-ranges observed in Côte d'Ivoire were about 140 ha in size with slight overlap (A. E. Dunham pers. obs.), whereas populations on Tiwai I. have overlapping home-ranges averaging 28 ha (Olson 2001).

Common Cusimanses do not have permanent latrines but groups often deposit faeces and anal gland secretions at the same time in the same area, near frequently used den sites or near territory borders. Secretions of anal glands are also deposited on vertical objects by a hand-stand or leg-lift and on horizontal surfaces by an anal drag; hand-stand secretions are usually preceded with secretions from cheek glands. Marking group members with anal gland secretions is also common, primarily using the leg-lift posture. Cheek gland secretions are occasionally used to mark other individuals (Olson 2001). Both anal and cheek scent-marking are performed by both sexes. In a captive pair both sexes used anal marking most often, with the ♀ showing a lower marking frequency than the ♂ (Dücker *et al.* 1990). The frequency of marking increased in a captive ♂ before mating (Ewer 1973). Individuals mark urine and faeces of other species with anal gland secretions and urine (Ewer 1973, Olson 2001). Olson (2001) suggests a recognition/advertisement function for both cheek and anal gland secretions. Ten compounds were found in the anal gland secretions of two ♀♀ that were not found in a ♂ (Decker *et al.* 1992).

Aggressive encounters among conspecifics are occasionally observed, often over preferred food items or between bordering groups, with the aggressor growling and baring teeth. Fighting is ritualized and biting appears to be directed towards pale cheek patches. An aggressive encounter was observed in Côte d'Ivoire with a group of four Liberian Mongooses *Liberiictis kuhni*, which initiated the encounter and displaced the larger group of ten Common Cusimanses.

Common Cusimanses are easily tamed and frequently kept as pets. The following behaviours have been reported from captive individuals: upon hearing loud rustling or crackling sounds animals retreat to cover. Observed comfort movements include yawning and stretching. Individuals kept as pets have been known to attack dogs much larger than themselves without hesitation (Rosevear 1974). A threat display consists of the hair being fully erected, back arched and limbs extended; the individual moves forward at a walk, moving from side to side, and may alternate moving forwards and backwards; tail is held sloping downwards (with maximal piloerection) and with each step is swung from side to side (Ewer 1973). Tail wagging has been observed during play, when animals are disturbed, and before aggressive encounters (A. L. Olson pers. comm.).

Play behaviour has been observed in both captive and wild individuals. Play is frequently seen among juvenile conspecifics and is occasionally initiated by juvenile Sooty Mangabeys (A. E. Dunham pers. obs.). Aeschlimann (1965: 40) observed six individuals in Côte d'Ivoire 'playing tag in an open space' with a group of Campbell's monkeys *Cercopithecus (Mona) campbellii*.

Copulatory behaviour has been observed in a captive pair on ten separate occasions (C. A. Goldman pers. obs.). The ♂ clasps the female's back just forward of the pelvic region with the forefeet and grasps the ♀ at the back of the neck with his mouth; true neck biting does not occur. The male's pelvic thrusts are frequently accompanied by growls of 2–3 sec duration. Mounting occurs in bouts lasting up to 1 min, with the longest series of bouts observed being 45 min. Copulation was initiated and terminated by the ♂.

When newborn pups are in a den, subgroups leave for short foraging trips while others stay and guard the young. Breeding ♂♂ and ♀♀ provide most offspring care. Non-breeding adults of both sexes assist in guarding pups, carrying them between foraging sites, and respond to begging of pups by offering worms and millipedes (processed and with carapace opened).

Vocal repertoire includes a contact call, lost call, predator alarm, juvenile begging cry, snake alarm, greeting call and a threat growl. The most commonly heard is a whistling call used to maintain contact while in thick vegetation, increasing in volume and frequency when an individual is separated from the group. A contact call is often heard when the group begins to move after a long foraging bout or resting period and is initiated by the leading individual. When a snake is found, a loud whistling call is made and cooperative hunting begins. Grunting and tail wagging are observed during friendly greetings between individuals. A bark alarm has been heard in the presence of Crowned Eagles *Stephanoaetus coronatus*.

Common Cusimanses commonly initiate associations with groups of Sooty Mangabeys or Diana Monkeys, using the monkeys as sentinels. In response to eagle alarm calls by the monkeys, the cusimanses retreat for cover in hollow logs or dense vegetation.

Reproduction and Population Structure Females are polyoestrus; one captive ♀ came into oestrus on nine occasions in 13 months (Ewer 1972). Births in captivity have been recorded for all months of the year, but breeding appears to be seasonal in the wild. Births are most commonly observed in Côte d'Ivoire during Jan–Feb and May–Jun (A. E. Dunham pers. obs.). In Tai N. P., a ♀ in each of three neighbouring groups gave birth to young within the same week in Jun. Gestation is approximately eight weeks (53–60 days) (A. E.

Dunham pers. obs.). Litter-size 2–5 (usually four). At birth, young measure ca. 90–100 mm in head and body length and ca. 30 mm in tail length: eyes are closed, body fully haired with underfur, nose is short and forelimbs are large. Eyes open by Day 12 and guard hairs appear noticeable by Week 5 (Goldman 1987). Young leave the birthing den at Week 2 and are frequently carried from den to den as the group moves throughout the territory to forage; adults provision young with solid food from Week 4 to Week 7 (A. E. Dunham pers. obs.). Young are sexually mature at about nine months (Haltenorth & Diller 1980). Mortality of young in their first year appears to be quite high; in a wild population in W Côte d'Ivoire, five of 11 young (of three litters) died during their first six months (A. E. Dunham pers. obs.). Longevity in captivity is 12–13 years (Goldman 1987, Weigl 2005).

Ewer (1972) observed moulting in a captive ♀ obtained and reared in Ghana: shedding occurred throughout the year with distinct peaks May–Jun and Oct–Nov, corresponding with the beginning and end of the cooler wet season (May–Oct).

Predators, Parasites and Diseases Skulls of the Common Cusimanse have been found in and under the nests of Crowned Eagles; they are estimated to comprise 5% of the diet of Crowned Eagles in Tai N. P. (Shultz 2002). Crowned Eagles exist at high densities in the closed-canopy forests of West Africa and are likely the major predator of the Common Cusimanse. Leopards *Panthera pardus* occasionally take small carnivores and may also be a threat (Jenny 1996); one cusimanse was found among 215 Leopard scats in Tai N.P. (Hoppe-Dominik 1984). Ectoparasites of *Crossarchus* spp. from West Africa include ticks, chewing lice and fleas; endoparasites include protozoa, flukes and pentastomes (Goldman 1987 and references therein).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Common Cusimanses are vulnerable to hunting with dogs and snares, which may pose a threat in some areas; in the Classified Forest of Diécké, Guinea, they were also one of the most commonly trapped small carnivores in three villages sampled (Colyn *et al.* 2004). In some parts of the range, clearance of land for agriculture may be resulting in some localized declines. None the less, they are relatively widely distributed, fairly common, present in several protected areas (such as Western Area F. R., Comoé N. P., Maraouhé N. P. and Tai N. P.), and not believed to be threatened.

Crossarchus platycephalus CAMEROON CUSIMANSE

Fr. Mangué de Cameroun; Ger. Kamerunkusimanse

Crossarchus platycephalus Goldman, 1984. Can. J. Zool. 62: 1618. Eséka, Cameroon.Lateral view of skull of Cameroon Cusimanse *Crossarchus platycephalus*.

Taxonomy Monotypic. Considered conspecific with Common Cusimanse *Crossarchus obscurus* by Wozencraft (1989, 1993), but recognized as a distinct species by most other authors (Schreiber *et al.* 1989, Van Rompaey & Colyn 1992, Colyn & Van Rompaey 1994b, Colyn *et al.* 1995, Kingdon 1997; and subsequently Wozencraft 2005). Happold (1987) made no mention of *Crossarchus platycephalus* and listed *Crossarchus obscurus* as the only species of *Crossarchus* recorded from Nigeria. The common name Flat-head Cusimanse (Kingdon 1997, Stuart & Stuart 1997a, Wozencraft 2005), which derives from the specific name (Greek *platys* for broad and *kephale* for head, referring to broad shape of skull) does not accurately reflect the shape of the skull of *Crossarchus platycephalus* (which is wide when compared with *Crossarchus obscurus*, and not flat), and is not deemed an appropriate common name. Chromosome number: not known, but likely the same as Common Cusimanse *Crossarchus obscurus* ($2n = 36$).

Description Small-sized mongoose with long nose, strong claws, short legs and dark brown pelage. Nose extends considerably beyond lower lip. Ears pale brown, short and round. Museum specimens have whorls posterior of ears and crown, where hairs spread out around a circular patch with no hair, and a crest between ears along nape. Hairs that form the crest stand erect and are ca. 5–15 mm in length, shorter anteriorly and longer posteriorly. Both whorls and crest, which are present in both sexes and appear not to be seasonal, are more pronounced and frequent in museum specimens of Cameroon Cusimanse than in Common Cusimanse. In 22 adult museum specimens from Nigeria, and Cameroon, whorls were clearly present in 19 (12 with one whorl, six with two whorls, and one with three whorls); the crest was present in 17 specimens. Rosevear (1974: 285) examined specimens of *Crossarchus* spp. from West Africa and noted that ‘one of the most characteristic features of the *Crossarchus* pelage is the presence of a pair of large whorls on the back of the neck ... but though these are for the most part very conspicuous they are not always so and may, exceptionally, apparently be wholly lacking’. Hairs of head short (to ca. 3 mm), medium to dark brown, with pale tips; hairs of cheeks and around eyes paler. Dorsal guard hairs ca. 15–20 mm in length posterior of ears, 25–35 mm at mid-body and 35–45 mm near rump. Guard hairs of body and tail coarse and brown with pale tips, giving an overall speckled appearance. Tips of dorsal guard hairs (ca. 3–4 mm) reddish-brown, darker reddish-brown

towards rump and tail. Hairs of underfur finer than guard hairs and ca. 15–20 mm in length, basal half dark brown, terminal half pale yellowish-buff. Ventral pelage finer, less dense, shorter and paler than dorsal guard hairs. Legs dark brown to blackish-brown. Tail (ca. 53% of HB) tapers evenly from base to tip and appears less densely haired than in Common Cusimanse, with guard hairs ca. 30–35 mm in length at base of tail and ca. 20–25 mm at tip. Guard hairs of tail dark brown with dark reddish-brown tips. Claws on forefeet long (8.5–11 mm, $n = 18$), shorter on hindfeet (5–8 mm, $n = 18$). Paired anal scent glands in both sexes, with external orifices on either side of anus; between the orifices lie fine longitudinal ridges that pass into the central depression of the anal sac. Sexes similar in colour and size.

Geographic Variation None recorded.

Similar Species

Crossarchus obscurus. Allopatric in Guinea, Sierra Leone, Liberia, Côte d’Ivoire and Ghana. Similar in size; skull narrower with longer palate and tympanic bullae and shorter maxillary and mandibular toothrows in Common Cusimanse; posterior margin of palatine evenly emarginated in most adult specimens (posteromedial spinous projection present in most specimens of Cameroon Cusimanse); guard hairs along anterior half of back with pale buff to yellowish-buff tips (reddish-brown in Cameroon Cusimanse); guard hairs shorter along mid-back and rump; terminal half of underfur pale buff (in Cameroon Cusimanse, underfur with pale yellowish-buff subterminal band, most often with a reddish-brown terminal band).

Xenogale naso. Sympatric in west of range, particularly Nigeria and Cameroon. Larger, with longer limbs and longer tail; coat more uniform in colour; solitary.

Distribution Endemic to Africa. Occurs in rainforests of Benin, Nigeria, Cameroon, Equatorial Guinea, N Congo and SW Central African Republic (Colyn & Van Rompaey 1994b, Colyn *et al.* 1995, Djagoun *et al.* 2009). Not known from the rainforests of Gabon.

Habitat Found in undergrowth of rainforest from sea level to ca. 1600 m (near Buea, Cameroon), often near water. In Nigeria, also found in relic forest in derived savanna (Happold 1987) and areas of fragmented forest mixed with farmland (Angelici *et al.* 1999a); widespread in the Niger Delta, including the largely deforested lowland zone east of Orashi R., but absent from marsh forest and coastal zones (Powell 1995, 1997). In Benin, besides forested areas, found in agricultural fields, fallows and plantations, which may be exploited more in the dry season (Djagoun *et al.* 2009). Two skulls of Cameroon Cusimanse from Ekom, Cameroon, indicate that it is not limited to the Atlantic coastal basin, but also occurs in the Congo basin (Colyn *et al.* 1995).

Crossarchus platycephalus

Abundance There is no direct information on abundance, although they were the most frequently observed of three mongoose species in Lama Classified Forest in S Benin (Djagoun *et al.* 2009).

Adaptations Long nose and long forelimb claws are adaptations for foraging within soil and leaf litter. Sight, hearing and smell are well developed. Communication is facilitated by an elaborate vocal repertoire and scent-marking.

Foraging and Food Diet includes forest floor invertebrates (e.g., locusts, earthworms, ants, maybug larvae, millipedes), and land and river crabs, small vertebrates, fruits (including palm nut *Elaeis guineense*) and berries. Individuals kill prey with a single well-directed bite, crunch the prey up rapidly, and then resume foraging (Happold 1987). An individual was observed wading in shallow water turning over rocks with the aid of its long nose in search of a river crab, which when caught was grabbed with mouth and tossed to the river bank and eaten (Durrell 1958). Stomachs of nine specimens from Mamfe Division, Cameroon, contained only remains of crabs and insects (Sanderson 1940).

Forages largely during the day individually or in groups. Group members apparently travel one behind the other (Bates 1905). At night, individuals may visit cleared land and farms in search of food (Sanderson 1940). Foraging individuals scratch and dig in soil and litter with their elongated noses (Happold 1987), and will climb sloping trees. Two individuals attacked a 2.0–2.5 m long Black Cobra *Naja melanoleuca* some 3 m above ground in a tree (Struhsaker & McKey 1975).

Social and Reproductive Behaviour Gregarious and highly social. In Cameroon, groups usually comprised five to eight individuals, with one captured specimen travelling in a group of nearly 25 individuals, which is reported to be much larger than usual (A. I. Good in litt.). Refuge is taken under fallen logs, in hollow trees

Frontal view of skull of Cameroon Cusimanse *Crossarchus platycephalus*.

with openings near the ground, in thick vegetation, or in burrows. Easily tamed and frequently kept as pets.

Reproduction and Population Structure Births occur throughout the year in Nigeria (Happold 1987). One female specimen from Cameroon had three embryos (Perret & Aellen 1956), another had five embryos (Eisentraut 1963).

Predators, Parasites and Diseases Predators may include larger carnivores and birds of prey. Ectoparasites of *Crossarchus* spp. from West Africa include ticks, chewing lice and fleas; endoparasites include protozoa, flukes and pentastomes (Goldman 1987 and references therein).

Conservation IUCN Category: Least Concern. CITES: Not listed.

Cameroon Cusimanse is reported to occur in Monte Alén N. P., Equatorial Guinea (C. Lasso, in Colyn *et al.* 1995), Nouabelé-Ndoki N. P., Congo (Ososky 1998), and in Dzanga-Sangha Special Reserve, SW Central African Republic (Ray 2001). This species, like other species of cusimanses, is hunted for bushmeat by local villagers; cusimanses accounted for 3.6% of total animals harvested during an 18-month period (1999–2000) in SW Cameroon (Nzouanga & Willcox 2000). They were also recorded widely in bushmeat markets in Equatorial Guinea (Juste *et al.* 1995, Kümpel 2006) and S Benin (Djagoun & Gaubert 2009).

Measurements

Crossarchus platycephalus

HB: 346 (299–407) mm, n = 25

T: 181 (156–210) mm, n = 25

HF c.u.: 68 (61–76) mm, n = 23

E: 24 (20–26) mm, n = 18

WT: 1108 (505–1500) g, n = 6

GLS: 72.5 (68.1–76.9) mm, n = 37

GWS: 38.3 (34.8–41.7) mm, n = 35

Museum specimens (AMNH, CMNH, FMNH, MCZ, MNHN, NMNH, SMNS, ZFMK, ZMB)

ORDER PHOLIDOTA – Pangolins

Pholidota Weber, 1904. Die Säugetiere. Einführung in die Anatomie und Systematik der recenten und fossilen Mammalia. G. Fischer, Jena.

Giant Pangolin *Smutsia gigantea*.

| | | |
|--------------------------------------|-----------|--------|
| Manidae (2 genera, 4 species) | Pangolins | p. 387 |
|--------------------------------------|-----------|--------|

Pholidota contains one extant Family, Manidae, comprising eight species in Asia and Africa (given recognition of the Philippine Pangolin *Manis culionensis* as a distinct species; Gaubert & Antunes 2005, Schlitter 2005). Many classifications recognize only a single genus, *Manis*; however, morphological evidence suggests that such an arrangement under-represents morphological diversity, with resulting subdivision of this genus into perhaps as many as six different genera (see Pocock 1924, Allen 1939, Emry 1970, Meester 1972, Patterson 1978, McKenna & Bell 1997, Gaudin & Wible 1999). A comprehensive phylogenetic analysis of the Order, involving seven of the extant forms and nearly all well-known fossil taxa, supports three monophyletic, extant genera (Gaudin *et al.* 2009).

The name Pholidota is from the Greek words *pholis* or *pholidos*, meaning horny scale. The names Manidae and *Manis* are from the Latin word *manes*, meaning spirit of the dead or ghost, referring to the pangolin's quiet nocturnal habits (Gotch 1979). The most obvious characteristic is the protective covering of large overlapping scales on dorsal and lateral aspects of the head and body, and dorsal and ventral aspects of the broad, often prehensile tail. According to earlier authors like Weber (1892), scales are composed of keratinized epidermis on a flattened and caudally directed corium papilla. Tong *et al.* (1995) describe scales as agglutinated hairs made up largely of

alpha- and beta-keratin that gives each scale elasticity and plasticity. Inter-specific variations exist for the extent of scale distribution on the limbs and head, in scale size, topography and colour, from dark brown to yellow-brown. Soft skin with sparse hair covers the ventral aspect of the head, body and inside of the legs. A subcutaneous fat layer is present (Heath 1992a). Scales and skin can comprise as much as 1/5 to 1/3 of the total body mass (Kingdon 1971). Hindlimbs are stout, forelimbs have long robust claws reminiscent of South American anteaters. Five clawed digits are present on each foot. As a defence mechanism, pangolins roll into a sphere with only scaled surfaces exposed to predators. Some species have scent glands near the anus that produce secretions with an obnoxious odour (Grassé 1955, Kingdon 1971).

The skull is pear- or cone-shaped, widest behind the ear openings, tapering off evenly forward to the nasals and abruptly behind to the occiput. Interparietal bones are absent in adults, but present in the juvenile Sunda Pangolin *Manis javanica* (Jollie 1968) as well as in the extinct *Patriomanis americanus* (Emry 1970). With the exception of the Chinese Pangolin *M. pentadactyla* (Emry 2004), the jugal bones are absent, and the zygomatic arches are represented by short processes at either end that never join (see Emry 1970, 2004, Kingdon 1971, Gaubert & Antunes 2005, M. Heath pers. obs.). There are no postorbital processes. The lacrimal is absent in all species except the Tree Pangolin *Phataginus tricupis* and Long-tailed

Ground Pangolin *Smutsia temminckii* foetus.

Pangolin *P. tetradactyla* (Emry 1970). The nasals and supra-occipitals (= fused interparietals, Jollie 1968) are large and the pterygoids are separate and external to the bullae. Bullae are rounded in African, but not Asian, species (Gaudin & Wible 1999). The lambdoid crest is rudimentary or absent in all extant pangolins, and there is a small median vertical crest descending from the centre of the lambdoid crest (Emry 1970). Pangolins have no teeth, but in the position of the tooththrows there are narrow raised ridges of bone on the upper jaw. The mandible consists of a simple thin bony structure, joined in front, with two small bony processes one on either side extending outwards near the junction. The palate is long and narrow. The condyles are simple flattened sections that hinge on the internal faces of the hind process of the zygoma, to which they are attached by cartilage. The total number of vertebrae in the Ground Pangolin *Smutsia temminckii* is 48 whereas the Long-tailed Pangolin has 47 caudal vertebrae alone, and a total of over 70 (Jentink 1882).

Many characteristics are associated with procuring and eating their specialized diet of termites and ants (Grassé 1955, Heath 1992a). Acute olfactory sense is used to find prey and differentiate prey from non-prey ant and termite species. Forelegs have long robust nails used for digging and prying apart ant and termite nests. The eyes are small, black and protected by thick eyelids. Ear openings are present, but the ear pinnae are small or absent. The mouth opening is small, jawbones thin and teeth absent. A long, slender tongue coated with sticky saliva is used for lapping up ant and termite prey. Tongue total length ranges from 30 cm in Tree Pangolins to 25–40 cm in Ground Pangolins and 70 cm in Giant Pangolins (Doran & Allbrook 1973, Heath 1992a), and extends past the mouth 10–15 cm in Ground Pangolins (M. Heath pers. obs.) and 30 cm in Giant Pangolins (Doran & Allbrook 1973). Diameter of the tongue is 0.5–0.7 cm in Ground Pangolins (M. Heath pers. obs.) to 2 cm in Giant Pangolins (Nene 1978).

The pangolin's exceptionally long tongue passes from the oral cavity, through the neck and thorax, to the abdomen. The usual attachment to the hyoid in the neck is substituted with an attachment to the caudal end of the xiphoid process in the abdomen (Doran &

Giant Pangolin *Smutsia gigantea* dorsal myology.

Allbrook 1973, Chan 1995). There is some inter-specific variation in the shape and attachment of the tongue and the xiphisternum (Patterson 1978). In the Tree Pangolin this proximal region of the tongue, which is solid muscle and fascia, is 'U-shaped', extending caudally to the right iliac fossa and then turning cranially to terminate under the right side of the diaphragm (Chan 1995). According to Kingdon (1971), muscle attachment is provided by a xiphisternum that is formed from the last pair of cartilaginous ribs and extends from the sternum along the ventral abdominal wall to the pelvic region. From its abdominal attachment, the tongue extends rostrally to the thorax, where the tissues form a glossal tube and a freely moving tongue, which together extend through the neck and oral cavity. When retracted the free tongue resides in the glossal tube (Doran & Allbrook 1973, Chan 1995) and folds into a pocket in the throat (Kingdon 1971, Doran & Allbrook 1973). Chan (1995) hypothesizes that the tongue is extended by hydrostatic pressure. In addition to guiding the tongue, the glossal tube likely provides additional mucous membrane to cover the extra surface area gained during elongation and protrusion. When elongated the surface area of the tongue is twice its resting value and the mucous membrane of the glossal tube is turned inside out, collapsing the glossal tube (Chan 1995).

There are large salivary glands in the pharyngeal and cervical regions that extend almost to the shoulder (Doran & Allbrook 1973, Kuehn

Tree Pangolin *Phataginus tricuspis* and Giant Pangolin *Smutsia gigantea* dissections showing tongue muscles and spatulae extending into abdomen.

1986). These glands secrete a tenacious mucus (pH 9–10, Fang 1981) onto the surface and into the sheath of the tongue (Heath 1992a). The unchewed food is macerated in the stomach, which is undivided in the Sunda Pangolin (Grassé 1955), but has two chambers in the Chinese Pangolin (Fang 1981). Stomachs examined from 100 adult Chinese Pangolins contained as much as 0.5 kg of termites (Fang 1981). The first, thin-walled, larger chamber (~4/5th the total size) is for storage (Fang 1981). The second chamber has thick muscular walls, and a special rough hard semi-spherical tissue near the pylorus (Fang 1981), which is covered in cornified denticles (Grassé 1955). During muscle contractions the structure grinds food before it passes into the intestine (Grassé 1955, Fang 1981).

Females have two small pectoral nipples located in the axillary region of the forelegs. The penis is well developed. At sexual maturity the testes descend through the inguinal canal and enlarge in a fold of skin in the groin (rather than a scrotum). One young per year, rarely two, are produced. Individuals remain solitary in well-defined home-ranges, except for short periods during mating or when ♀♀ are caring for offspring (Pagès 1975, Heath & Coulson 1997a).

Adult body mass ranges from 1.5 kg in arboreal species to 33 kg in the largest ground species (Giant Pangolin), with head and body length ranging from 300 to 950 mm and tail length from 350 to 880 mm. All species tested have a low body temperature (26–35 °C) and a metabolic rate only one-quarter to one-third that of more typical eutherian mammals (see Heath & Hammel 1986). Three notable

cardiovascular adaptations are: (a) greater oxygen affinity of blood and haemoglobin than in more typical eutherian mammals of similar size (Weber *et al.* 1986), (b) retia mirabilia in the vasculature at the axis of the limbs, and (c) several blood vessels that run parallel to the spinal chord the full length of the body (Kingdon 1971).

Pholidotes may have diverged from other eutherian mammals as early as the Cretaceous (Springer *et al.* 2005; but see Rose *et al.* 2005). At one time pangolins were included in the order Edentata, along with armadillos, sloths and South American and African anteaters. It is now believed that the resemblance of pangolins to other ant-eating mammals (e.g. Xenarthra, Tubulidentata) is likely due to convergent evolution (Griffiths 1968, Eisenberg 1981, Rose *et al.* 2005; but see Nováček & Wyss 1986). In contrast, some researchers (Matthew 1918, Patterson 1978, Patterson *et al.* 1992, Gaudin 1995) have suggested that Pholidota and Xenarthra share a common ancestor in the extinct North American Palaeonodonta. However, Emry (1970) argued that Palaeonodonta are ancestral to Pholidota and not Xenarthra (see also Glass 1985, Rose & Emry 1993, Rose *et al.* 2005), and the analysis of Gaudin *et al.* (2009) provides support for the monophyly of Palaeonodonta and Pholidota in a clade they termed the Pholidotomorpha. Studies involving comparisons of amino acid sequences of α -crystalline A protein from the eye lens (De Jong *et al.* 1985) and cephalic arterial patterns (Bugge 1979) further indicate that Xenarthra and Pholidota are not closely related. Instead, uniting the Pholidota with the order Carnivora in the Superorder Ferae is now supported by abundant genetic (Liu *et al.* 2001, Murphy *et al.* 2001, Waddell *et al.* 2001, Springer *et al.* 2005, Meredith *et al.* 2011) and some morphological evidence (Szalay & Schrenk 1998, Liu *et al.* 2001).

Fossil records are few. There are three fossil species recorded from middle Eocene Europe: *Eomanis waldi* (Storch 1978, Koenigswald *et al.* 1981), *Euromanis krebsi* (Storch & Martin 1994, Horovitz *et al.* 2005), and *Eurotamandua joresi* (Storch 1981). *Cryptomanis gobiensis* is a newly described genus and species from the late Eocene of the Inner Mongolia region of N China (Gaudin *et al.* 2006). There is also one record from the early Oligocene of Egypt (unnamed, Gebo & Rasmussen 1985). From the latest Eocene, there is one fossil record from North America: *Patriomanis americana* (Emry 1970, 2004, Patterson 1978), which closely resembles fossil pangolins in the genus *Necromanis* from the Oligocene–Miocene of Europe (Koenigswald & Martin 1990, Koenigswald 1999). There are more recent Plio-Pleistocene pangolin records from Europe, Africa and southern Asia, including three referable to *Manis*: *M. palaeojavanica* (Dubois 1907) from Java, which is larger than any extant *Manis* species, and two species of questionable validity, such as *M. lydekkeri* from India (Dubois 1908) and *M. hungarica* from Hungary (Kormos 1934). The oldest pangolins from Africa are Pliocene in age (Botha & Gaudin 2007), not including the aforementioned record from Egypt.

Based on external characteristics of extant species, Pocock (1924) suggested that Asian species are more primitive than African species, and Patterson (1978) suggested that pangolins emigrated in the late Oligocene from Eurasia to Africa. A European origin for Pholidota was strongly indicated in the cladistic analysis by Gaudin *et al.* (2009). These authors noted that the fossil record would seem to support a European origin for the modern forms, with subsequent dispersal first into sub-Saharan African and then to southern Asia.

Family MANIDAE
PANGOLINS

Manidae Gray, 1821. London Med. Repos. 15: 305.

Hypothetical pangolin ancestor with scales spreading from tail to body.

| | | |
|-------------------------------|------------------|--------|
| <i>Phataginus</i> (2 species) | Tree Pangolins | p. 388 |
| <i>Smutsia</i> (2 species) | Ground Pangolins | p. 395 |

The family comprises eight extant species distributed in Asia (four species) and Africa (four species) in a variety of habitats, from rainforests to savannas and semi-desert regions. The Philippine Pangolin *Manis culionensis*, from Palawan and adjacent islands in the Philippines, has traditionally been considered a subspecies of the Malayan Pangolin *Manis javanica*, but is now considered to represent a separate species (Feiler 1998, Esselstyn *et al.* 2004, Gaubert & Antunes 2005; and see Schlitter 2005).

The simplest classification of the family maintains a single genus, *Manis*, often subdivided at the subgeneric level (Jentink 1882, Simpson 1945, Ellerman & Morrison-Scott 1951, Mohr 1961, Meester 1972, Meester *et al.* 1986, Schlitter 1993, 2005). In contrast, Pocock (1924) and Allen (1939) presented a classification including three subfamilies and six genera. Other authors have suggested classifications between these extremes. Patterson (1978) suggested a subdivision at the subfamily or generic level for the Asian and African groups, and further

From left, pelvis of a) Tree Pangolin *Phataginus tricuspis*, b) Giant Pangolin *Smutsia gigantea*, c) Ground Pangolin *Smutsia temminckii*.

subdivision at either the generic or subgeneric level for the African arboreal and ground pangolin groups. McKenna & Bell (1997) proposed subdivision at the subfamily level for the Asian and African groups, maintaining the genus *Manis* for the Asian species, and recognizing three genera to separate the African ground pangolins (*Smutsia*), the Tree Pangolin (*Phataginus*) and the Long-tailed Pangolin (*Uromanis*); this classification was also adopted by Kingdon (1997). The comprehensive morphology-based analysis by Gaudin *et al.* (2009) divided the extant species into three well-supported, monophyletic genera, and is the approach followed here: *Manis* for the Asian pangolins, *Smutsia* for the African ground pangolins and *Phataginus* for the African tree pangolins (a treatment also proposed by Koenigswald [1999] and supported by Gaudin & Wible [1999]). The latter two genera form a monophyletic African assemblage in the subfamily Smutsiinae.

The four Asian pangolin species inhabiting South-East Asia, the Indian Pangolin *Manis crassicaudata*, Chinese Pangolin *M. pentadactyla*, Malayan Pangolin and the Philippine Pangolin, are characterized by the following features: ear pinna present, hair bristles between scales, dorsal medial row of scales extending to tip of tail; outside of fore- and hindlimbs covered with scales; fifth digit of hindfoot as large as first digit; and xiphisternum relatively short and expands into a spade-shaped plate (Jentink 1882, Pocock 1924). In the four African species, the ear pinna are reduced or absent; there is no hair between scales; a dorsal medial row of scales splits in the tail region into two rows of alternating asymmetrical scales; and the xiphisternum is elongated and divided into two branches that extend to the level of the caudal ribs and pelvis (Jentink 1882, Pocock 1924, Kingdon 1971, Patterson 1978).

In the two arboreal species, the Tree Pangolin *Phataginus tricuspis* and Long-tailed Pangolin *P. tetradactyla*, in contrast to the two species of African ground pangolin, the body is slight, with tail longer than head and body, scales are thin and light-weight, there is hair instead of scales on outer surface of foreleg, and the ventral terminus of tail has skin pad rather than scales (Jentink 1882, Kingdon 1971). A lacrimal bone is present (Emry 1970), the epitympanic recess is inflated posteriorly and laterally in the squamosal bone (Patterson 1978), and the eyes are large (Pocock 1924, Patterson 1978). When walking quadrupedally, weight is taken on palms of forefeet, not on the outer margins as in *Smutsia*, and the tail functions as a fifth limb (Kingdon 1971). The claws of the hindfeet are nearly as long as claws of the forefeet (Jentink 1882).

GENUS *Phataginus* Tree Pangolins

Phataginus (Rafinesque, 1821). Ann. Gén. Sci. phys., Bruxelles 7: 214.

Often treated as a subgenus of *Manis* (e.g. Meester 1972, Schlitter 1993, 2005), or raised to genus level and including all African species (Patterson 1978, Grubb *et al.* 1998). Following the revised classification of Gaudin *et al.* (2009), *Phataginus* is here considered to include two arboreal species, the Tree Pangolin *Phataginus tricuspis* and the Long-tailed Pangolin *P. tetradactyla*, both ranging mainly in the forested regions of West and central Africa. An inter-specific comparison of 67 cranial morphological characteristics in Pholidota (Gaudin & Wible 1999) earlier found that the two African arboreal pangolins share more derived similarities than do the African ground pangolins.

The Long-tailed Pangolin is unique in possessing more than 47 tail vertebrae (and a total of more than 70; Jentink 1882), more numerous than any other mammal (hence the common name). It resembles the Tree Pangolin in size and in elongation of the tail, but is distinguished by its longer tail length (twice that of head and body cf.

Tree Pangolin *Phataginus tricuspis* skeleton.

with 1.5 times length of head and body in the Tree Pangolin) and the very numerous scales (19–22 rows) on the body in the Tree Pangolin.

Martha Heath & Jonathan Kingdon

Phataginus tetradactyla LONG-TAILED PANGOLIN

Fr. Pangolin à longue queue; Ger. Langschwanzschuppentier

Phataginus tetradactyla (Linnaeus, 1766). Syst. Nat., 12th edn, 1: 53. 'America Australia' [West Africa].Long-tailed Pangolin *Phataginus tetradactyla*.*Phataginus tetradactyla*

Taxonomy Monotypic. Included in *Manis* by some authors (e.g. Schlitter 2005) and in the genus *Uromanis* by others (Pocock 1924, Kingdon 1997, McKenna & Bell 1997), but here included in the genus *Phataginus* following the classification of Gaudin *et al.* (2009). The specific name *longicaudatus* (Brisson, 1756), which is sometimes used for this species, is unavailable (see Mohr 1961 and Meester 1972 for discussion). Synonyms: *africana*, *ceonyx*, *guineensis*, *hessi*, *longicaudatus*, *macroura*, *senegalensis*. Chromosome number: not known.

Description Small, arboreal scaly anteater with very long tail, and black face and underparts. Head long and slender with a blunt, mostly bare and somewhat bird-like snout. Nostrils in moist, slightly down-turned nose have elongated form, unlike the Tree Pangolin *Phataginus tricuspis*. Eyes prominent and surrounded by thick, swollen eyelids. Ear openings bordered by raised fleshy ridges. Cheeks, throat, underside and limbs well covered in coarse black hair. Scales cover forehead, back, limbs and tail; on forelimbs the scales approach the wrist but are absent from the upper surface of forefoot. Body scales larger, less numerous (10–13 rows on body) and more heavily built than in the Tree Pangolin, and also darker and less striated (but have conspicuous pale margins). Both fore- and hindlimbs are well clawed. The elongated tail, which is as much as twice the head and body length, has sharply pointed scales, especially along the margins of its flattened underside (there are 44 marginal scales on tail, and 34–35 scales on the uninterrupted portion of the dorsal medial row of the tail, followed by two rows of 9–10 scales each; Jentink 1882), and terminates in a sensitive pad (Kingdon 1971).

Geographic Variation None recorded (see Hatt 1934).

Similar Species

Phataginus tricuspis. Broadly sympatric. Pale- or white-bellied arboreal pangolin, distinguished by very numerous (19–22 rows on body, but 34–37 marginal scales on tail), smaller, light-weight, serrated ('three-cusped') scales; tail length about 1.5 times head and body length. Hatt (1934) discusses diagnostic differences in the skull.

Distribution Endemic to Africa, occurring in forested regions of West and central Africa. Grubb *et al.* (1998) note that there seems to be no confirmed record from west of Sierra Leone, where it is thought to be very rare, although Senegal is often cited as the western limit (e.g. Meester 1972). From Sierra Leone the species ranges eastwards through SE Guinea (Ziama and Diécké; see Barnett & Prangley 1997 for discussion), Liberia, Côte d'Ivoire and SW Ghana, there being an apparent gap in distribution until W Nigeria. Their presence in Nigeria is probably underestimated because of possible confusion with the Tree Pangolin, but the species is certainly present in S Nigeria, both west and east of the Niger R. (see Angelici *et al.* 1999a, 2001). They then occur eastwards through S Cameroon throughout much of the Congo basin forest block to the Semliki valley (and thus, just possibly, but marginally, into Uganda) (Malbrant & MacLachy 1949, Rahm 1955, 1966). Several authors (Mohr 1961, Meester 1972) give the range as far south as Namibe in Angola, but this is in error and the species has to date not been confirmed from this country (though its presence in Cabinda is plausible; J. Crawford-Cabral pers. comm.).

Lateral, palatal and dorsal views of skull of Long-tailed Pangolin *Phataginus tetradactyla*.

Habitat The most arboreal of the forest pangolins, found in riverine and swamp forests, typically dominated by palms, including rattans, and specialized swamp trees such as *Uapaca*, *Pseudospondias* and *Mitragyna*. Their distribution is very localized, and they are never far from permanent water and water-courses. In SE Nigeria, besides being recorded both in primary and secondary rainforests, altered forests (bush) and swamp forests, they have also been found in farmlands (agricultural areas of former lowland rainforests) (Angelici *et al.* 1999a, 2001). Sleeps in tree hollows or hollowed-out insect nests.

Abundance No quantitative data, and the least frequently recorded of all African pangolins, though it may be less rare than available records suggest. The species is extremely shy, almost strictly arboreal, and mainly restricted to little-known and little-penetrated habitats. It is possible that densities are highest in the most extensively flooded areas, with numbers dropping off in areas of range overlap with the Tree Pangolin.

Adaptations A long, prehensile tail is likely to have been one of the primary adaptations of early proto-pangolins and in this respect this might be one of the more conservative species. Even so, an increase in the number of tail vertebrae to 47, the greatest number in any mammal, represents a clear adaptation to a super-arboreal existence and the tail demonstrably serves as a very effective fifth limb, easily able to sustain the entire animal's weight for sustained periods. The species' near-restriction to seasonally flooded and permanently flooded swamp forests implies a still more derived condition, as does the small, finely modelled, probe-like snout. It is likely that the Long-tailed Pangolin's primary advantage is its ability to subsist on the very abundant ants and termites that escape floodwaters by nesting or hiding in treetops above the flood-line. In this respect it may parallel the arboreal *Tamandua* anteaters of the Amazon flood-plain.

These specializations are relevant to the task of interpreting where and in what ways the Long-tailed Pangolin and Tree Pangolin can

have overlapping ranges yet minimal competition for both physical and dietary resources. One dimension of this separation concerns preferred foraging periods, with the Long-tailed Pangolin supposedly more diurnal and the Tree Pangolin emphatically nocturnal. Another, very basic difference centres on preferred foraging substrates: treetops for the former species, the forest floor for the latter. This, in turn, has a strong bearing on what species of ants and termites are to be found and consumed. Insects living in seasonally flooded forests are always adapted to survive the flood period of their life-cycle. Greater exposure to much higher risks of predation, plus frequent, and drastic, alternations in temperature and humidity have armed these insects with formidable chemical defences and exceptional physiological adaptability. In an already highly specialized anteater, the Long-tailed Pangolin must have made still further biochemical, physiological and behavioural adaptation to survive on a super-abundant, but formidably well-protected prey. This barrage of specializations in both predator and prey invites further biological/chemical study.

Foraging and Food Tree ants (*Crematogaster* and *Cataglyphis*) that occur in swampy areas have been reported as preferred food but further study of diet and digestive adaptations would be very interesting because it seems likely that these are among the most highly specialized of pangolins, theoretically subsisting on particularly well-protected ant species. The ants are eaten on branches or broken out of their tree nests and hollows. Some termites are also likely to be taken.

Reports differ widely as to foraging periodicity, with some baldly stating nocturnal, others diurnal. However, Mbuti pygmies in Ituri and the Semliki valley are very familiar with both species as common prey animals (mostly climbing up trees to catch them by hand, dislodging them with sticks or smoking them out of hollows). With this intimate familiarity, they recognize the Tree Pangolin as exclusively nocturnal and the Long-tailed Pangolin as both diurnal and nocturnal (Carpaneto & Germi 1989). On the opposite side of the Congo basin, Pagès (1970) came to a similar conclusion, considering the Long-tailed Pangolin more diurnal than the other species.

Social and Reproductive Behaviour Little known, but this species uses habitual routes and sleeping holes within a well-known home-range (Pagès 1970). Animals follow urine and glandular scent trails. In this way predominantly solitary ♂♂ presumably monitor the condition of ♀♀. So far as is known, ♀♀ spend much of their time with or close to their current offspring but seem to have few other sustained social relationships.

Reproduction and Population Structure Breeding is aseasonal and almost continuous as the ♀ conceives again within 9–16 days of giving birth. Gestation has been estimated at about 140 days (Pagès 1970, 1972a). A single young is born, which is well developed, weighing 100–150 g and measuring 30–35 cm in total length. The young is born in a hole where it may be left during its first week while the mother forages. Thereafter it clings to the mother's rump or tail and begins to glean ants at about two weeks; the young departs at the birth of a new infant. Full adult size is attained at around 15 months (Pagès 1970, 1972a).

Predators, Parasites and Diseases Leopards *Panthera pardus* are known predators, with remains of pangolins having been found in

scats at several sites in Gabon (Henschel *et al.* 2005, 2011). Being partly diurnal and with greater exposure in treetops, this species might be more vulnerable to large eagles and pythons than the Tree Pangolin. It is also possible that they are occasionally killed by Chimpanzees *Pan troglodytes*. In Ituri, Mbuti pygmy hunters rely on mobbing birds (probably honeyguides or barbets) to alert them to the presence of these pangolins (Carpaneto & Germe 1989.) Such mobbing presumably derives from competition for holes and can be predicted to increase the pangolin's vulnerability to other predators as well.

Conservation IUCN: Least Concern. CITES: Appendix II.

As with other pangolins, exploited to some degree both for meat and for medicinal purposes, although they are far less commonly recorded in bushmeat markets than the other species. In 2004, Long-tailed Pangolins formed only 335 kg in terms of harvested biomass (including either whole animals and/or animal parts) from five markets monitored in Gabon, cf. 2053 kg for Tree Pangolins (Projet Gibier Gabon pers. comm.). It should be noted, however, that away from the coast, extensive areas of swamp forest are relatively scarce in Gabon. Long-tailed Pangolins have also been recorded in international trade (Bräutigam *et al.* 1994); according to CITES trade reports for the period 1996–2011, trade in live animals, specimens or skins is reported

in nearly every year, with 40 specimens exported from the Central African Republic in 2000 (www.cites.org). None the less, being small, shy and inhabiting types of forest that are largely inaccessible, this relatively widely distributed species is thought to be secure.

Measurements

Phataginus tetradactyla

HB (♂ ♂): 314 (286–342) mm, n = 4

HB (♀ ♀): 302 (292–311) mm, n = 3

T (♂ ♂): 641 (594–707) mm, n = 4

T (♀ ♀): 633 (606–670) mm, n = 3

Phataginus tricuspis TREE PANGOLIN (AFRICAN WHITE-BELLIED PANGOLIN)

Fr. Petit Pangolin; Ger. Weißbauchschuppentier

Phataginus tricuspis (Rafinesque, 1821). Ann. Gén. Sci. phys., Bruxelles 7: 215. 'Guinée', West Africa.

Tree Pangolin *Phataginus tricuspis*.

Taxonomy Included in *Manis* by many authors (with *Phataginus* sometimes considered a subgenus), but here treated along with the Long-tailed Pangolin *P. tetradactyla* in the genus *Phataginus*, to the exclusion of the two ground pangolins (contra Patterson [1978] and Grubb *et al.* [1998], who included all African pangolins in this genus). Meester (1972) recognized two subspecies, with the form *mabirae* from Uganda considered distinct. No subspecies are considered

valid here. Synonyms: *mabirae*, *multiscutata*, *tridentata*. Chromosome number: not known.

Description An arboreal scaly anteater typified by very numerous striated scales and a long tail. Forehead scaled, anterior muzzle bare-skinned with moist, carnivore-like nostrils; face lightly furred with black patches below the eyes. Eyes retractable and surrounded by

thick lids. Ear pinnae absent but the ear opening can be partially closed by a small flange and is surrounded by a fringe of light-coloured fur. Lower jaw very slender, tongue measures some 30 cm in length (Doran & Allbrook 1973). Neck, back limbs and tail covered in very numerous, light-weight, tight-fitting scales, which end at the elbows on the forelimbs but extend to the toes on the hindlimbs; there are 19–22 rows of scales on the body, 34–37 marginal scales on tail, and the uninterrupted part of the dorsal medial row of the tail has 30–33 scales, followed by two rows of 3–6 scales (Jentink 1882). Sparse white hairs on belly, thicker black hair on limbs and face. Prominent anal glands with powerful and unpleasant scent. All four feet are placed palm downwards. Hindfeet relatively long-toed and well provided with claws. Tail has flat lower surface covered in fine, pale, reticulate scales; upper surface with rounded profile and sharply pointed scales along lateral margins. Tip furnished with a finger-like pad on the underside. Body proportions change with growth: young have a short, blunt face, a long strong tail and particularly well-developed forelimbs. One pair pectoral mammae.

Geographic Variation None recorded (see Hatt 1934).

Similar Species

Phataginus tetradactyla. Broadly sympatric. Very long-tailed species (tail twice head and body length) with larger, fewer (10–13 rows) and darker scales, but with 44 marginal scales on tail; intensely black underside; reportedly less nocturnal than the Tree Pangolin. Hatt (1934) describes differences in the skull.

Distribution Endemic to Africa, ranging from Guinea in West Africa through Sierra Leone and much of West Africa to central Africa as far east as SW Kenya and NW Tanzania and as far south (west of L. Tanganyika) as NW Zambia (Mwinilunga District) and N Angola (Hill & Carter 1941, Schouteden 1948, Rahm 1966, Kingdon 1971, Ansell 1978, Grubb *et al.* 1998). Suggestions of the species' occurrence in N Mozambique, Malawi and NE Zambia can be rejected (Smithers & Lobão Tello 1976, Ansell 1982). Senegal often given as

the westerly limit but Grubb *et al.* (1998) found no confirmed records from Senegal, Gambia or Guinea-Bissau. Continues to survive on Bioko I. (Cabrera 1929, Fa *et al.* 2000).

Habitat In West Africa, found in patches of primary forest in both the savanna/forest mosaic and in the Guinea savanna, and in central Africa throughout the lowland forest block. Also favours secondary growth and can survive in cultivation, fallows and forest mosaics (Kingdon 1971). In S Nigeria the species seems widespread in both primary and secondary rainforests, altered forests (bush) and in farmlands (agricultural areas of former lowland rainforests) (Angelici *et al.* 1999a). Sodeinde & Adedipe (1994) also noted that Tree Pangolins were often reported caught on abandoned or little-used oil palm trees in secondary growth. This suggests that the species can adapt to at least some degree of habitat modification. Akpona *et al.* (2008) suggested that the distribution of pangolins in the Lama F. R. in Benin may be more sensitive to forest age than to its composition.

Lateral, palatal and dorsal views of skull of Tree Pangolin *Phataginus tricuspis*.

Tree Pangolin *Phataginus tricuspis* myology.

*Phataginus tricuspis*

The species is broadly sympatric with the Long-tailed Pangolin and there is some habitat overlap but the latter shows a marked preference for swamp forest (Kingdon 1997, Angelici *et al.* 2001).

In Gabon, sleeping sites or refuges were usually hollows in trees, generally 10–15 m above the ground. Occasionally individuals sheltered in shallow burrows in the ground, often in termite mounds (Pagès 1975). In Benin, pangolins were mostly found in hollows in trees of the species *Dialium guineense* and *Ceiba pentandra* in closed natural forests (Akpona *et al.* 2008).

Abundance Commonest and most extensively distributed of forest pangolins. Data are scarce but forest secondary growth being cleared for plantations in Uganda supported ‘substantial’ numbers of Tree Pangolins, suggesting relatively high densities in suitable habitat. A study in Lama F. R. recorded 38 pangolins at a density of 0.84/km² during the dry season, and noted that the number of observations did not differ significantly between plantations and natural forest (Akpona *et al.* 2008). In Gabon, Pagès (1975) regarded this as the commonest of the three pangolin species found in the country (the other two being Long-tailed Pangolin and Giant Pangolin *Smutsia gigantea*). Likewise, in Nigeria, this is the most common of the pangolin species (Angelici *et al.* 1999a, b).

Adaptations Predominantly nocturnal, and equally at home in trees and on the ground; indeed, by means of radio-tracking Pagès (1975) found most feeding took place on the ground. Like other pangolins, they curl up into a ball when threatened, although the relatively flimsy scales are unlikely to be of much of a deterrent against most large predators and their main line of defence, if discovered, probably resides in the repulsive secretions of their anal glands combined with snake-like wheezings, defecation, and the squirting of urine (Kingdon 1971). However, their preference for very dense vegetation and thickets must diminish the likelihood of predation by larger carnivorous animals.

Tree Pangolin *Phataginus tricuspis* poised to strike with claws.

Tree Pangolins have poor vision, except at very close quarters, but they are very sensitive to sound and vibrations and will roll up into a ball at any sudden noise. Their primary sense is olfactory and the search for both food and social contacts is clearly mediated through scent. The prehensile tail with its sensitive, finger-like tip provides a versatile climbing organ, clinging to branches, probing for an attachment, twining around branches or extending out as an apparent balancer. On broad trunks the long, flat lower surface of the tail and the sharp points along its margins press against the surface and take the animal's weight. While climbing, the fore- and hindlimbs move as pairs, with the clawed forelegs probing the surface for a purchase. Once these and the tail are hooked, the hindlimbs come forward together and animals can hump their way up a vertical trunk quite rapidly, a movement that resembles that of a caterpillar. When descending a large tree, the pangolin spirals down the trunk at an angle, gaining much support from the grip of its long, spiny-sided tail (Kingdon 1971). There are interesting reports (see Grubb *et al.* 1998) of them rolling into a ball while still in a tree and dropping to the ground, perhaps a novel method of descending trees during emergencies (such as a branch breaking). When walking on the ground, the back legs take most of the weight, but when walking quadrupedally the weight is taken on palms of forefeet, not on the outer margins as in *Smutsia* (Kingdon 1971).

Foraging and Food Diet comprises forest species of ants and termites, particularly army ants (*Dorylus* and *Mirmicaria*) and adults and nymphs of the termite genera *Nasutitermes* and *Microcerotermes* (Kingdon 1971). Both arboreal and terrestrial termitaries and ants nests are attacked but the much greater availability of the latter makes it likely that foraging on the ground and on fallen tree trunks provides the bulk of their diet (Pagès 1975). Colonies are broken open with the sharp foreclaws, whereupon the pangolin feeds with great rapidity, darting the sticky tongue in and out while the insects swarm over the animal. Continuous movement and shivering of the scales serves to shed attacking soldiers and sweeps of the tail over the ground appear to concentrate insects and assist their consumption. After feeding, animals scratch themselves with their hindlegs, at which time localized

Tree Pangolin *Phataginus tricuspis*.

tracts of scales are erected or depressed to allow claws or the tongue access to any insects that may be concealed close to the skin (Kingdon 1971).

Social and Reproductive Behaviour Commonly solitary, especially ♂♂, but Pagès (1965) often found pairs curled up together in the hollows left by torn-off branches, at some 15 m height or more. On one occasion she found a pair together with a weaned juvenile. In captivity, up to six captives will sleep together and walk in single file with a follower occasionally clambering onto another's tail. Captive adult ♂♂ confined together have been observed to fight one another with synchronized slashes of the foreclaws and in two instances one contestant was killed (Pagès 1965).

Movement may follow regular routines, particularly arboreal routes, as suggested by claw scratch marks on regularly used trunks and branches and the observation of individuals using the same diurnal resting places (such as a tree fork) for weeks at a time (Pagès 1965, Kingdon 1971). Indications are that ♂♂ are territorial, with large mutually exclusive home-ranges (20–30 ha in Gabon), and the home-range of each ♂ overlaps with that of several ♀♀. Female

home-ranges appeared to be considerably smaller, with some overlap between them (Pagès 1975).

It has been noted that Tree Pangolins are scent-oriented animals and highly sensitive to sound and vibrations. All social contacts depend on scent. A young captive that had formed an attachment to its keeper was observed, after separation, to follow a very irregular path in its search for renewed contact. When separated again the animal repeated every detail of its former path but with much greater speed and assurance (Pagès 1965). This and the regular return of a released captive to visit its captors, over a period of some six months, suggests that these pangolins tend to make stronger social attachments than are normal for a strictly solitary species. They make a wheezing snort when touched or surprised (Kingdon 1971).

Reproduction and Population Structure Tree Pangolins breed continuously, and in Gabon adult ♀♀ were seldom found that were not pregnant (Pagès 1965, 1972b), which suggested that the period of inactivity between pregnancies was virtually non-existent or very short. Gestation is thought to be in the region of 150 days. At birth young are pink and hairless, except for a ring of hair around the

eyelids (elsewhere hair only appearing after three weeks), and total length is about 290 mm and weight 100 g. Young are born well developed and active (Kingdon 1971). During the day mothers sleep curled up around their sucking offspring but one captive would leave her young in a corner while she went away to take food in the evening (Kingdon 1971). Like other pangolins, the young will travel attached to the mother's tail, usually close to its root and facing either direction. Young probably become independent of mothers within three or four months of birth but young captives eagerly seek contact with any other pangolins or even with human captors (Kingdon 1971).

Predators, Parasites and Diseases Leopards *Panthera pardus* (see Henschel *et al.* 2005, 2011), African Golden Cats *Profelis aurata*, African Rock Pythons *Python sebae*, jackals *Canis* spp., Ratels *Mellivora capensis*, Chimpanzees *Pan troglodytes* and large owls, even eagles, are likely predators. A subadult killed by a carnivore in Uganda had been carefully skinned out and the viscera, glandular area and cape of scales rejected; it is possible that young animals may be less cautious and have a less developed arsenal of scents to defend themselves (Kingdon 1971). In Ghana, Ntiemoa-Baidu *et al.* (2005) found that one species of ixodid tick, *Amblyomma compressum*, was particularly associated with this species, and, with the exception of one specimen of *Haemaphysalis parvata*, was the only tick species recorded on each of 26 pangolins investigated. The species is reported to host a variety of internal parasites.

Conservation IUCN: Near Threatened. CITES: Appendix II.

While known to occur in a number of protected areas throughout its range, Tree Pangolins are subject to widespread and often intensive exploitation for bushmeat and traditional medicine (e.g. Anadu *et al.* 1988, Fa *et al.* 2000). Indeed, it is by far the most abundant pangolin found for sale in bushmeat markets (Bräutigam *et al.* 1994); for example, during the course of six months' fieldwork in Cameroon in 2002–2003, this species was the fourth most harvested species across 47 sites sampled, after the Brush-tailed Porcupine *Atherurus africanus*, Blue Duiker *Philantomba monticola* and Giant Pouched Rat *Cricetomys emini* (Fa *et al.* 2006). Likewise, in a study in Equatorial Guinea around the village of Sendje (including within Monte Alén N. P.), the Tree Pangolin was the fifth most common mammal species in terms of offtake (carcasses), after the Blue Duiker, Brush-tailed

Porcupine, Black Colobus *Colobus satanas* and Giant Pouched Rat (Kümpel 2006).

As elsewhere, Tree Pangolins are widely used in traditional medicine. Akpona *et al.* (2008) recorded that some organs, such as the skin, heart, intestine and head, are used for treating asthma and cardiovascular and dermatological diseases. A study investigating the utilization of pangolins in traditional Yorubic medicine in SW Nigeria recorded that Tree Pangolins were used to treat a range of medical conditions, including infertility, gastrointestinal disorders, rheumatism, venereal diseases and back pain, but also for conferring invisibility, as love potions, and for appeasing/warding off witches or evil spirits. Some of these uses specifically required juvenile or even pregnant animals (Soewu & Ayodele 2009). Angelici *et al.* (1999b) have reported that the dried tail of the Tree Pangolin is sometimes used to mark and tattoo human skin during the initiation of young unmarried women in some bush-hamlets in SE Nigeria.

Tree Pangolins are recorded in international trade (Bräutigam *et al.* 1994); for example, according to CITES trade reports, during the period 1996 to 2011, Togo exported 30 live specimens in 1996, 16 in 2002, 16 in 2007, and 25 in 2008 (www.cites.org). The scale of illegal international trade, including to Asian markets, is certainly much greater.

Jonathan Kingdon & Michael Hoffmann

GENUS *Smutsia* Ground Pangolins

Smutsia Gray, 1865. Proc. Zool. Soc. Lond. 1860: 360, 369.

Often considered a subgenus of the genus *Manis* (e.g. Meester 1972, Schlitter 1993, 2005), but here considered a distinct genus (following Pocock 1924, Rahm 1966, Kingdon 1997, McKenna & Bell 1997, Gaudin *et al.* 2009) represented by two species of African ground pangolin, the Giant Pangolin *Smutsia gigantea* and the Ground Pangolin *S. temminckii*. In contrast to the two species of arboreal African pangolins, both are characterized by a stout body, short and stumpy hindlegs, a tail shorter than head and body length, the outside of fore- and hindlimbs covered with scales, and scales covering the

ventral aspect of tail terminus rather than having a terminal pad (Jentink 1882, Pocock 1924, Meester 1972). A lacrimal bone is absent (Emry 1970) and the eyes are small (Pocock 1924, Patterson 1978). When walking quadrupedally, the weight is taken on the outside edge of the wrist (Kingdon 1971). Claws of the hindfeet are smaller than those of the forefeet (Jentink 1882).

Martha E. Heath & Jonathan Kingdon

Smutsia gigantea GIANT PANGOLIN

Fr. Pangolin géant; Ger. Riesenschuppentier

Smutsia gigantea (Illiger, 1815). Abh. Phys. Klasse K. Preuss Konigl. Acad. Wiss. pp. 84. Type locality not indicated.Giant Pangolin *Smutsia gigantea*.

Taxonomy Monotypic. Included in *Manis* by several authors (with *Smutsia* sometimes considered a subgenus), and referred to *Phataginus* by Grubb *et al.* (1998), but here included in the genus *Smutsia*, along with the Ground Pangolin, *S. temminckii*. It is possible that, with further information on the dating of their divergence, observed anatomical and molecular differences between bipedal *S. temminckii* and graviportal *S. gigantea* might justify subdivision of this genus. Synonyms: *africanus*, *wagneri*. Chromosome number: not known.

Description Largest and heaviest of all living pangolin species. Also distinctive for its elongated muzzle and powerful, well-clawed forelegs. Pale, pinkish-grey head is naked except for plate of closely fitted scales covering forehead and upper muzzle and fringes of hair around the eyes and auditory meatus. Vestigial and immobile ear cartilages beneath the skin but no external ears. External auditory canals remain widely open unless compressed by lateroventral folds of skin (that usually come into play when the animal curls up). The relatively small black eyes are surrounded by well-muscled, swollen eyelids. When animals become active, eye-bulbs swivel outwards, allowing each eye to look straight down the barrel of the muzzle (apparently permitting a good measure of bifocal vision). When folded up in defence or to sleep, the eyes appear to retract back into their shallow orbital sockets.

External surfaces of the body are covered in keratinous, overlapping scales (17+ rows) that grow from the skin in conformity with an obliquely angled, linear grid, with the largest scales along the middle

of the back, flanks, shoulders and thighs. Sizes and shapes of scales on limbs are graduated and modified to allow maximal flexibility to the limbs without loss of protective armament (especially when the animal is curled up). The soft skin of the underside and inner surfaces of limbs is naked, pinkish or very pale grey. Forefeet have five claws but outer two are vestigial and effectively non-functional. Of the three central claws, the central is the longest and most robust: the two that flank it are flatter and slightly shorter. Claws can be extended forwards and splay when digging but fold backwards and inwards when the animal is walking. Hindlimbs have five toes also but these are short and blunt and aligned along the front of graviportal, elephant-like feet. Giant Pangolins are normally quadrupedal and effectively take their weight on the outer margins of their curled up wrists. Large anal glands produce a white waxy secretion with a powerful odour (Kingdon 1971). There are two pectoral nipples.

When an animal is fully curled up, the muscular tail is broad enough at its base to cover all the space between infolded legs and sufficiently long to reach up, over the tucked-in head, to the shoulders. Outer margins of the tail are bordered by 15–19 sharply angled, pointed scales that interdigitate with the large, thick scales of the convex dorsal surface and the smaller, thinner scales of the slightly concave lower surface. Tip of the tail is slightly pointed and protected by thick, closely interlocking scales.

Geographic Variation None recorded.

Lateral, palatal and dorsal views of skull of Giant Pangolin *Smutsia gigantea*.

Similar Species

Smutsia temminckii. No overlaps in ranges of the two *Smutsia* species have been confirmed; frequently restricted to drier, more open woodlands and savannas. Smaller, with shorter, more rounded tail (HB typically less than 700 mm); fewer rows (11–13 rows) of body scales and 11–13 scales on margin of tail (Jentink 1882, Meester 1972, Heath 1992b). Ground Pangolins are mostly bipedal, and do little digging, so forelimbs are much reduced compared with Giant Pangolins (Kingdon 1971, Heath 1992b).

Distribution Endemic to Africa. Recorded from Senegal (Dupuy 1968) – though there is no evidence of its presence in Gambia – thence eastwards through Guinea, Sierra Leone, Liberia (including the vicinity of Mt Nimba; Coe 1975), Côte d'Ivoire (Rahm 1956) and Ghana, where they have also been reported in the north in Mole N. P. (Grubb *et al.* 1998). No information from Togo, although Grubb *et al.* (1998) map older records from Ghana near Fazao-Malfakassa N. P. on the border with Togo. Sayer & Green (1984) recorded the species from Batia on the border of Pendjari N. P. in the north of Benin in the 1970s, and referred to sightings in neighbouring Burkina Faso and Niger; however, the species was not included by Lamarque (2004) in his work on the large mammals of the WAP complex of protected areas. Presence in Nigeria is unclear, and is not mentioned by Happold (1987), but it may occur in the south. Indications are that Giant Pangolins were more continuously distributed in West Africa up until fairly recently. From the eastern bank of the Sanaga R. in Cameroon the species is fairly continuously distributed throughout the Congo basin to Uganda (Hatt 1934, Schouteden 1948, Malbrant & MacLachy 1949, Rahm 1966, Pagès 1970, Kingdon 1971). Reported as extinct in Rwanda (Bräutigam *et al.* 1994).

In Kenya, L. S. B. Leakey (pers. comm.; referred to in Kingdon 1971) observed it on the lakeshore in W Kenya, close to the Uganda border. Among a number of verbal descriptions and reports from W Tanzania, notably in the Bukoba and Kigoma regions, Kingdon (1971) published an authenticated record from the Mahale Mts, where their presence has been confirmed by camera-traps (C. A. H. Foley pers. comm.). A. R. Archer (pers. comm.) reported a possible sighting from near the base of the Udzungwa Mts in the late 1960s

Smutsia gigantea

(marked with a '?' in Kingdon's 1971 distribution map), but there have been no confirmed records despite much survey work.

No records from Sudan or Burundi, but the animal is known to the Azande people on both sides of the DR Congo–Sudan border. Northern limits of the distribution are not well known but can be expected to broadly coincide with those of the tropical lowland rainforest. The northern banks of the rivers Kasai and Tshuapa apparently define its southern limits within the central forest block. Also present on Bioko I.

Habitat Primarily a forest species, the Giant Pangolin is also found in forest mosaics and in high rainfall secondary grasslands where it can shelter in thicket-covered termitaries. Its tracks are commonly found along the margins of papyrus and other swampy areas and it is totally water-dependent. In S Buganda, animals were known to range from the exposed, ironstone plateaus that cap most low hills down through cultivated and forested hillsides to the swamp forests and papyrus beds that filled valley bottoms. While all these habitats were foraged over, hillside food resources were probably the most intensively used (Kingdon 1971).

It commonly rests under piles of plant debris, in thicket, under fallen tree roots or in partially opened termitaries. It also uses the holes of other animals, notably the Aardvark *Orycteropus afer*, but can also dig long, deep burrows, up to 40 m long and up to 5 m below the surface. More usually, burrows are short, sometimes with side-galleries. An enlarged sleeping chamber may be within a burrow or within an excavated termitary. Entrances are usually plugged from within (Kingdon 1971).

Abundance No data available. The quantity and availability of termites and ants, proximity to water, levels of predation from humans and large carnivores, and frequency of fires are likely influences on relative abundance. An activity cycle from midnight to very early morning has inhibited any easy assessment of relative abundance and a detailed study of this species is overdue.

Giant Pangolin *Smutsia gigantea*.

Adaptations The spread-eagled agility, strongly prehensile tail and strong clinging reflexes of very young Giant Pangolins are clear indications of arboreal origins for this heavily terrestrial pangolin. Powerfully functional, clawed forelimbs are a further indication of an arboreal inheritance, and Giant Pangolins use them to open up hard termitaries and fallen tree trunks, one respect in which it is unlike the Ground Pangolin, which, as a biped and ground surface feeder (in habitats where other ant/termite eaters are common), is indicative of the Ground Pangolin being one step further removed from its arboreal ancestry. The need for large muscular shoulders and powerful claws alters the weight distribution in a Giant Pangolin. Thus a preponderance of bone and muscle at the front end is the primary reason why the Giant Pangolin is predominantly quadrupedal while the Ground Pangolin is frequently bipedal (Kingdon 1971). This difference is particularly evident in the structure of the pelvis, which is massive, elongated and horizontal in the Giant Pangolin. By contrast, the Ground Pangolin's pelvis is more lightly built, shorter and more vertical, better suited to providing a central fulcrum that can support the cantilevered weights of tail and forequarters (Kingdon 1971).

Large, parallel blood vessels run down the length of the vertebral column in pangolin species. Giant Pangolin tails are sufficiently long and robust to serve as a body prop while all four limbs are engaged in digging (Kingdon 1971). Tails are used as clubs when harassed, and the 'tail complex' can make rapid side movements that splay and 'scissor' the long, very sharp scales near the tail's base. These movements and the blades and points on the lateral scales of the tail catch or cut any

animal attempting to probe into a curled-up pangolin. Booth (1960) reported a hunter's encounter with a Giant Pangolin with the head of a dead Leopard held fast in the curl of its tail, and, in Liberia, hunters also warn of the danger it poses, reporting that it 'will wrap you in its tail and drag you to Monrovia!' (R. Hoyt pers. comm.).

The skull is composed of exceptionally dense, thickened bone, a thickening that is clearly protective in function. In common with other pangolins, several cranial bones are absent, notably the zygoma, a reduction that is associated with effective elimination of the chewing muscles (temporalis and masseter), and the jaws lack any teeth. Food passes down directly to the pyloric region where a structure resembling the gizzard of a bird grinds up the chitinous bodies of ants and termites with small stones and sand; this structure is particularly large and well developed in this species (Mohr 1961, Doran & Albrook 1973).

The tongue is exceptionally slender and long (70 cm) and can extend out of the mouth for some 30 cm (Doran & Allbrook 1973). As with other pangolins, the tongue is retracted into a pouch in the throat. This results in a visible lump in the throat, and the profile of a feeding animal's throat can be seen to flex prominently with every ingestion of insects. Likewise, rapid extension and retraction of the tongue is further assisted by the tongue's base extending back into the chest cavity where muscular extensions of the tongue base attach to a spatulate, cartilaginous extension of the sternum. This cartilage and its muscular attachment are free to slide and swing about along the walls of the abdominal cavity with every extension and retraction of tongue and muscle.

Foraging and Food Feeds predominantly on colonial species of termites, notably *Macrotermes*, *Cubitermes*, *Apicitermes*, *Protermes* and ants, such as *Palthothyreus* and *Anomma*, many of which are exposed by speedy excavation of nests and galleries (Vincent 1964, Pagès 1970). Termites and ants are harvested by very rapid extrusions and retractions of the tongue, which is coated with an exceptionally viscous salivary slime (the pangolins' dependence on frequent drinking may well be influenced by their copious production of specialized saliva). Although ants and termites are the main food, other insects may also be taken. L. S. B. Leakey (pers. comm.) reported watching a Giant Pangolin, semi-submerged in lakeside water, whipping its tongue over the surface of the water to corral and ingest water beetles (Dytiscidae) that were swimming there.

Judging from captives in Uganda, animals are most active between midnight and 05:00h (Kingdon 1971) but there are likely to be seasonal and, perhaps local, environmental differences in foraging patterns. Hunters in Liberia report activity patterns from 20:00h to early morning (R. Hoyt pers. obs.). Frequent periods of inactivity have been reported, sometimes very prolonged (Y. Ssenkebuge pers. comm.). This suggests that extensive fat in the abdomen and on the body and limbs of some specimens may signify an ability to wait out periods of food scarcity, possibly in some form of aestivation.

Social and Reproductive Behaviour Normally solitary, but ♀♀ are frequently accompanied by their latest, single young, which does not usually become independent until the next infant is born. Social relations are primarily mediated by scent, and both sexes have anal glands, with those of the ♂ being proportionately large. Presumably all faeces are scented but it is possible that a continuous trail of scent is also laid in spite of marking gestures being inconspicuous. Enlarged anal glands in ♂♂ and marking behaviour imply they may be territorial. In Buganda a distinctively marked individual ♂ was observed to traverse a very limited locality (and regularly used a semi-exposed resting-place in a termitary) for about two years (Kingdon 1971). These limited observations suggest that home-ranges are likely to be small.

Resting pangolins sleep with their muzzles pressed up close to their anal glands. Although Giant Pangolins hiss loudly when harassed, they appear to be largely mute (Kingdon 1971).

Reproduction and Population Structure Breeds throughout the year but may have a peak in some regions. Two birth records of single young from Uganda are from Sep and Oct (Kingdon 1971). Hatt (1934) reported fetuses in specimens from DR Congo in Nov and Dec. Total length and weight of newborns is up to 450 mm and just over 500 g, respectively. Young is born with soft scales and eyes open; it is very active, but unable to take its weight on its legs, scrambling around spread-eagled (Kingdon 1971). A one-day-old pangolin put near its mother immediately worked its way onto the base of her tail; the tail of a newborn is strongly prehensile and the animal has a very strong clinging reflex (Kingdon 1971). Longevity in the wild or captivity is not known.

Predators, Parasites and Diseases Leopards *Panthera pardus* (see, for example, Henschel *et al.* 2005), African Rock Pythons *Python sebae* and crocodiles are all natural predators of Giant Pangolins.

Conservation IUCN: Near Threatened. CITES: Appendix II.

Giant Pangolins are present in a number of protected areas across their range, including National Park of Upper Niger (Guinea), Sapo N. P. (Liberia), Taï N. P. (Côte d'Ivoire), Mbam Djerem N. P. (Cameroon) and Salonga N. P. (DR Congo). As with other pangolins, they are subject to widespread exploitation for bushmeat and traditional medicine and are regularly recorded in bushmeat markets (Bräutigam *et al.* 1994). Colyn *et al.* (1987) found that this species comprised one-tenth of the total number of pangolins (~100) on sale as bushmeat in rural areas around Kisangani. Fa *et al.* (1995) noted that survey records of Giant Pangolin meat in the markets of Bioko were misleading, as only 10% made it to market. In Liberia, only 25% of the harvest is sold, as local hunters preferred it to other species (R. Hoyt pers. obs.). Yet, this species alone accounted for nearly 2% of the total harvested biomass in communities where it had not yet been extirpated. Harvest rates in six communities adjacent to Sapo N. P. were found to be unsustainable (R. Hoyt pers. comm.). In 2004, Giant Pangolins formed 5019 kg in terms of harvested biomass (including either whole animals and/or animal parts) from five markets monitored in Gabon, cf. 2053 kg for Tree Pangolins *Phataginus tricuspis* and 335 kg for Long-tailed Pangolins *P. tetradactyla* (Projet Gibier Gabon pers. comm.).

Formerly protected in some areas as a totemic animal (e.g. for the Olugave clan in Buganda), the breakdown of such taboos now sanctions interference. Local protection afforded by totems in W Côte d'Ivoire have also broken down due to refugee movements throughout the region as a result of conflicts in Liberia and Côte d'Ivoire (L. Bonnehin pers. comm.).

The species is occasionally recorded in international trade, including one instance of four live specimens reported as exported from Togo in 1984 (Bräutigam *et al.* 1994). There are no reports of trade in live specimens in the CITES trade reports between 1996 and 2011, but the true scale of the illegal international trade is unknown. As this species appears to be heavily exploited throughout its range, it is likely threatened with extirpation wherever human populations are high or marketing networks along forest roads and rivers are in operation. Its large size, low reproductive rate and terrestrial habits make it particularly vulnerable to overexploitation. Additional research is certainly required to inform and enhance the currently inadequate conservation situation for this species.

Measurements

Smutsia gigantea

TL (♂♂): 1438 (1370–1530) mm, n = 5

TL (♀♀): 1298 (1185–1365) mm, n = 7

T (♂♂): 674 (650–700) mm, n = 5

T (♀♀): 596 (545–675) mm, n = 7

HF: n. d.

E: n. d.

WT: 30.0–35.0 kg*

***Smutsia temminckii* GROUND PANGOLIN (TEMMINCK'S GROUND PANGOLIN, CAPE PANGOLIN)**

Fr. Pangolin terrestre du Cap; Ger. Steppenschuppentier

Smutsia temminckii (Smuts, 1832). Enumerationem Mammalium Capensium, Dessertatio Zoologica Inauguralis.

J. C. Cyfveer, Leidae, 105 pp. In the vicinity of Kuruman, Northern Cape, South Africa.

Ground Pangolin *Smutsia temminckii*.

Taxonomy Monotypic. Included in *Manis* by most authors (with *Smutsia* usually considered a subgenus), and referred to *Phataginus* by Grubb *et al.* (1998), but here included in the genus *Smutsia*, along with the Giant Pangolin *S. gigantea*. Synonyms: *hedenborgii*. Chromosome number: not known.

Description Medium-sized, corpulent, streamlined mammal covered with thick pantile-like overlapping yellowish-brown scales giving them a reptilian appearance. In some individuals the scales on the head, shoulders and forelegs are tinged reddish-brown on the tips. Head and shoulders blend into each other so that there is no visible neck. Head small, muzzle pointed and forehead covered with small scales extending beyond the eyes about two-thirds to the nose tip. Lateral and ventral surface of the face is dark grey with sparse short hairs and without scales. Mouth small and toothless with a very delicate lower jaw. The large oval nostrils can be tightly sealed. Eyes small and bulbous surrounded by thick protective eyelids with few fringing hairs. Ear openings large, without pinnae and vertically elongated with soft fluffy hairs inside.

Scales cover the entire body (11–13 rows, and 11–13 scales on margin of tail) except the throat, belly and insides of the limbs, which are sparsely covered with short hairs. Scales on the back point to the posterior in parallel rows, which continue towards the distal end of the tail. Scales on forelimbs also point to the posterior and are arranged in vertical rows, whereas on the hindlimbs the scales point down. Scales of juveniles and subadults terminate with a small point. Tail heavy, very muscular, dorsally convex, ventrally slightly concave and entirely covered with scales. Base of tail is as broad as the hindquarters, which is the widest part of the body, distal end broadly rounded.

Scales on the lateral region of the tail are sharply pointed and folded in half so that one half is positioned dorsally and the other half ventrally. All scales, particularly the larger ones on the back and tail, are honed to a very sharp edge from continually rubbing against underlying scales.

Forelimbs short and strong with five small compact digits on each forefoot, the first with a short claw, the central three with long curved robust claws (the centre claw measuring up to ca. 6 cm) and the fifth with a claw up to ca. 3 cm. Hindlimbs shorter and stockier than the forelimbs with five digits on each hindfoot, each digit with a small nail-like claw. The soles of the hindfeet are cushioned pads that are rounded in front and taper off slightly to the rear resembling miniaturized elephant's hindfeet. Ground Pangolins spend much of the time walking bipedally on the hindlimbs, forelimbs tucked close to the chest, occasionally touching the ground with the knuckles and the tip of the tail to maintain balance. The pelvis is more vertical than in other pangolin species, emphasizing the greater use of the hindlimbs for bearing weight (Kingdon 1971).

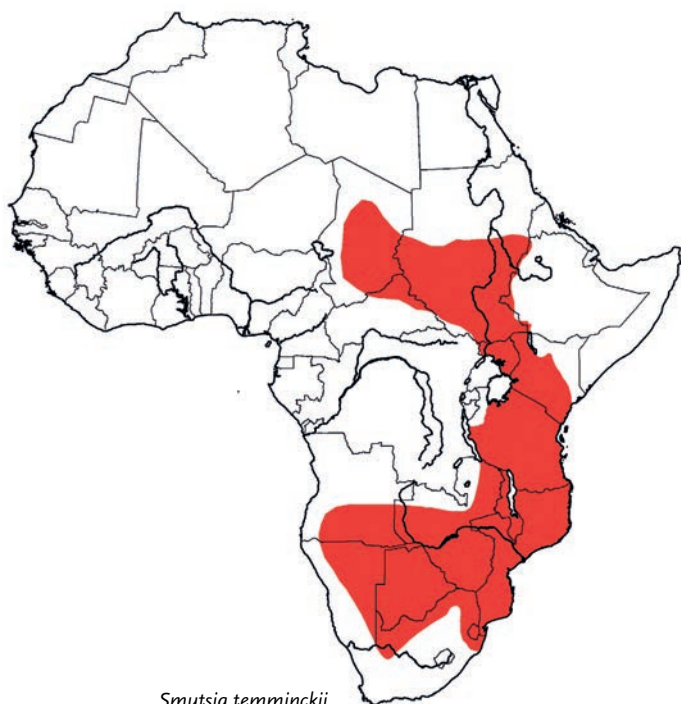

There is no obvious sexual dimorphism, although ♂♂ are slightly heavier (Heath & Coulson 1998). Prominent anal glands are present, which exude a waxy secretion with an unpleasant smell. Testes in ♂♂ are large, situated in a fold of skin in the groin area, anterior to a well-developed penis, and not descending into a scrotum. Females have one pair pectoral nipples.

Geographic Variation No subspecies have been described. There may be some variation in size of animals recorded from across the range.

Similar Species

Smutsia gigantea. No overlap in distribution has been recorded. Larger, with longer, more pointed tail (head and body length more than 700 mm); there are 17 rows of body scales and 15–19 scales on margin of tail (Jentink 1882, Meester 1972, Heath 1992b). The Giant Pangolin is largely quadrupedal, and uses forelegs extensively for digging, thus forelegs are similar in size and power to hindlegs (Kingdon 1971).

Distribution Endemic to Africa. The most widespread African species recorded from E Chad (Malbrant 1952), through S Sudan (Sweeney 1974, Stuart 1980), much of East Africa and southern Africa as far south as the Northern Cape and North West Province of South Africa and NE KwaZulu–Natal (they appear to have vanished from the Free State over the last 15 years; Friedmann & Daly 2004). The northern limits of distribution are not well defined. Malbrant (1952) cited a record from Ouanda Djallé in extreme NE Central African Republic, noting it was likely to be fairly widely distributed in the northern part of the country. Malbrant (1952) also mentions a record for Ennedi in NE Chad, while Yalden *et al.* (1996) remark on a definite collection of this species from the Sennaar region of Sudan, close to the north-western border of Ethiopia. They are also confirmed from the Omo R. basin region of SW Ethiopia (Schloeder & Jacobs 1996).

*Smutsia temminckii*

and so probably do occur, marginally, in the western border regions of Ethiopia (Yalden *et al.* 1996). Their presence in Somalia is doubtful (Funaioli & Simonetta 1966). Records from West Africa undoubtedly refer to the Giant Pangolin (see Grubb *et al.* 1998).

Habitat Inhabits mainly savanna woodland in low-lying regions with moderate to dense scrub (e.g. *Brachystegia–Julbernardia* and *Colpospermum mopane* woodlands) where average annual rainfall is between 250 mm and 1400 mm. Also occurs in flood-plain grassland, rocky slopes and sandveld up to 1700 m altitude (Coulson 1989), but does not inhabit forest or desert. Most important habitat requirements are a sufficient population of the various ant and termite prey species, and available dens or above-ground debris to shelter in. Prefers regions with a mosaic of soil types including loam or clay soils with a firm consistency to support the nest galleries of prey species and sandy soils or rocky outcrops, which are more suitable for den sites.

Abundance Ground Pangolins are rarely encountered since they are mostly nocturnal and usually frequent habitats with relatively thick undergrowth. Individuals seen during the day are usually juveniles or subadults. Their inconspicuous nature has resulted in their abundance being underestimated throughout their range. For example, in South Africa, there were only 73 sightings of Ground Pangolins in Kruger N. P. over a period of 20 years (Anon. 1978). Their estimated density in Kruger N. P. region is 0.24/km² (J. M. Swart pers. obs.) and although their density is expected to be higher in Zimbabwe, since 159 sightings were reported there in one year (Coulson 1989), estimated density in the Gokwe district of Zimbabwe is only 0.15/km² (Heath & Coulson 1997a). Abundance in other regions of Africa is not known.

Adaptations The most prominent characteristic of Ground Pangolins is their armour of hard, sharp, pantile-like overlapping scales, which primarily provides protection against predators; also, though

providing little insulation, they protect the skin against abrasions and injuries from sharp objects such as rocks, branches and thorns. Scales constitute a high investment since they could make up one-third of the animal's body weight (Kingdon 1971).

Ground Pangolins stand motionless at any sign of danger and since their brown colour blends with the undergrowth they are easily overlooked. When stressed they curl into a tight sphere concealing their vulnerable head and abdomen, often lashing the tail in a scything action over the body. The scales also assist in removing parasites such as ticks and mites from between the scales, by the abrasive action of the scales assisted by mud, coarse sand or fresh herbivore dung. Ground Pangolins wallow in mud or fresh dung when available; occasionally, they seek out a patch of coarse sand, which they loosen with their sharp claws and impregnate with urine, thereby creating their own wallow. When wallowing they wriggle about on their back while contorting the body and flicking the tail back and forth over the head ensuring that the mud, dung or coarse sand is packed between the scales (J. M. Swart pers. obs.).

The tail is by far the strongest appendage and once clamped in position around the body it is impossible for a predator to prise open an adult without sustaining injury. Since Ground Pangolins walk bipedally, the weight of the tail counterbalances the weight of the head and body so that they maintain a horizontal body posture. The tail is also used as a lever or support when climbing over and down obstacles or steep embankments. Ground Pangolins are predominantly terrestrial, but they will clamber over fallen logs and are also capable swimmers.

Ground Pangolins are anatomically adapted for a myrmecophagous diet. Strong forelimbs with long claws are used for digging to expose ant or termite nest galleries. A small head, slender muzzle and small mouth with thin mandibles afford them greater flexibility when positioning the head while feeding from excavated ant and termite nests. Although they have no teeth, a gizzard-like pyloric region in the stomach uses muscular action to grind the ants and termites with the aid of small stones and sand that are passively ingested (Weber 1892). A long, rod-shaped tongue, slightly flattened towards the tip, can be extended 20–30 cm beyond the lips into ant and termite underground galleries. The tongue is repeatedly inserted with a quick darting action driven by a complicated network of muscles. Muscle attachment is provided by a xiphisternum, which is formed from the last pair of cartilaginous ribs and extends from the sternum along the ventral abdominal wall to the pelvic region (Kingdon 1971). The xiphisternum then curves to the dorsal abdominal wall forming a free-floating spatulate attachment near the kidneys (Kingdon 1971). The length of the tongue, including the muscular apparatus, is longer than the head and body (Kingdon 1971). Large salivary glands secrete copious sticky saliva into the tongue sheath and onto the tongue so that their prey adheres to the tongue. When not used, the tongue is retracted into a throat pouch.

Ground Pangolins have an acute olfactory sense enabling them to locate their ant and termite prey through the soil surface. Their hearing is fairly good but is probably restricted to the lower frequency range since they have no external pinnae. Their eyesight is poor since they are often seen bumping into obstacles (J. M. Swart pers. obs.) and they usually forage in dense undergrowth with the head very low to the ground where the visibility is generally very poor and where good eyesight would be of little benefit. Large pedal glands are situated under the soles of the hindfeet, which are usually

Lateral, palatal and dorsal views of skull of Ground Pangolin *Smutsia temminckii*.

damp from the secretion. The secretion has a fairly pungent odour and appears to be used mainly for orientation in the short term.

Ground Pangolins have adapted to survive on a diet of relatively poor nutritional value by being active for shorter periods and limiting their activity to periods when their food intake can be maximized. They save energy by being active for ca. four hours a day (Swart 1996) and spend the rest of their time resting or sleeping in an underground burrow or occasionally in dense undergrowth. Furthermore, they usually forage at night when the temperature is cooler (11–25 °C) and their ant prey is less active above ground and more concentrated in their underground galleries. To augment these behavioural adaptations they also have a lower resting metabolic rate: the mean resting metabolic rate of four free-ranging pangolins studied in South Africa was 2.34 ml O₂/kg/min (J. M. Swart pers. obs.), ca. half that of other eutherian mammals of the same size according to the Kleiber equation for determining the metabolic rate of eutherian mammals of different sizes (Kleiber 1961). Pangolins also often occur in areas where standing water is available seasonally and are able to survive long periods without sources of free water (Stuart 1980).

Foraging and Food Highly selective myrmecophages, feeding almost exclusively on underground aggregations of ants and termites close to the soil surface. Occasionally, they lick up ants or termites from a dead log, from the soil surface, from under leaf litter or even from a dung pile. A tame individual followed by Sweeney (1956) in Sudan often seized cowpats or pieces of termite-ridden wood, rolled onto its back and broke them up while licking the termites from its chest. However, this unusual behaviour was not observed in other studies.

Ground Pangolins usually walk following a haphazard zig-zag path with the nose held close to the ground while sniffing continuously to locate their underground prey. Sniffing intensity increases when prey is located and following a short dig with the front claws to expose the nest galleries the long, rod-shaped tongue is rapidly inserted to

extract the prey. Feeding bouts are generally short, averaging only 40 sec with the majority less than one minute (Swart *et al.* 1999), probably attributed to the swarming and aggressive nature of their prey. The majority of feedings (ca. 99%) are from ant or termite aggregations below the soil surface, ca. 72% are from a shallow dig ca. 4 cm deep, and ca. 27% directly from an active porthole (J. M. Swart pers. obs.). The location of feeding sites appears to vary from one geographical region to another. For example, in Zimbabwe 45% of feedings are from tree bases and shrub bases and 29% on bare ground (Richer *et al.* 1997). In the Kruger N. P. region of South Africa only 3.7% of feedings are from tree and shrub bases and only 3.8% from bare ground and even though they forage mostly in densely wooded areas 93% of feedings are between grass tufts (J. M. Swart pers. obs.). The mean distance between feedings in this region is ca. 15 m (n = 7670 feedings).

Although most of their activity is devoted to foraging for ants and termites, only 16% of this time is spent actually feeding (Swart *et al.* 1999). However, this value could vary considerably according to the habitat occupied at the time. For example, in the Kruger N. P. region of South Africa 20% of their time was spent feeding whilst foraging in calc brack thicket and only 7% whilst foraging in riverine thicket (Swart 1996). Richer *et al.* (1997) observed an individual that spent 20% of the time feeding in non-mopane and 12% feeding in mopane habitat. The distance they cover each evening while searching for prey varies considerably depending on the habitat and prey availability. In general the distance covered by ♂♂ varies from 202 to 3791 m per night (mean = 1482 m, n = 50 nights) and ♀♀ from 40 to 2176 m per night (mean = 942 m, n = 126 nights) (J. M. Swart pers. obs.).

There is distinct geographical variation in diet. Coulson (1989) recorded nine species in Zimbabwe, Jacobsen *et al.* (1991) 16 species in the North West Province of South Africa, Richer *et al.* (1997) seven species in NW Zimbabwe, and Swart *et al.* (1999) 20 species in the Kruger N. P. region. Only one ant species, *Anoplolepis custodiens*, was recorded in all these studies and only three species were common to two of the above studies. Although a number of species are preyed on, Ground Pangolins predominantly seek out species larger than 5 mm (Swart *et al.* 1999). For example, in South Africa 50 species of ants and termites were recorded as potential prey; however, only 20 of these species were preyed on and only six species ranging from 5.6 to 11.6 mm contributed to 98% of their diet (Swart *et al.* 1999). These six species in order of relative importance were: *A. custodiens*, *Myrmecaria natalensis*, *Camponotus cinctellus*, *Polyrhachis schistacea*, *Hodotermes mossambicus* and *Camponotus* sp. – *maculatus*-group.

Anoplolepis custodiens contributed to 77% of their overall diet and is probably the key species in their diet within southern Africa. Although the relative importance of *A. custodiens* as a prey species decreased from 83% during winter to 72% during summer, *A. custodiens* was still the most important prey species throughout the year. Thus, the distribution of *A. custodiens* is possibly important in determining the distribution of Ground Pangolins in southern Africa. Richer *et al.* (1997) suggest that *A. custodiens* is important only to juveniles and diurnal foragers and not to nocturnal foragers; however, the importance of *A. custodiens* in their diet is clearly exemplified by the above studies. However, *A. custodiens* is never mentioned in the diet of pangolins from Sudan, where main prey selected were *Crematogaster*, *Odontotermes*, *Microcerotermes*, *Microtermes*, *Amitermes* and *Ancistotermes*

(avoiding 30 other ant and termite species present in the habitat, including *Macrotermes* and *Trinervitermes*; Sweeney 1956).

One would expect juveniles to learn the same prey preferences and foraging locations from their mothers while accompanying them as they feed and forage. However, since juveniles never appear to forage with their mothers this knowledge is probably acquired through instinct and by trial and error. The only time they accompany their mother is when being carried on her back while being moved from one den to another. The mother walks directly to the new den without stopping to feed and then leaves the juvenile in the den and comes out to forage alone (J. M. Swart pers. obs.). Juveniles then venture out of the den alone, primarily during daylight hours, and forage within close proximity to the den entrance. As they grow older they venture further away from the den and also start coming out later in the day until eventually as adults they switch from being predominantly diurnal to predominantly nocturnal.

Although essentially nocturnal foragers, adult Ground Pangolins are occasionally crepuscular, particularly during winter. Juveniles on the other hand are predominantly diurnal and subadults are often diurnal or crepuscular foragers (Swart 1996). Although crepuscular and diurnal activity is also documented in other studies there is no reference to the age group of individuals (Coulson 1989, Jacobsen *et al.* 1991, Heath & Coulson 1997a, Richer *et al.* 1997). However, judging by the weights of animals referred to in these studies it appears that the majority are juveniles or sub-adults lighter than 8 kg. Since juveniles and subadults forage within their natal ranges they do not appear to forage earlier to avoid competition with adults for foraging sites and thus probably forage diurnally to avoid predation by nocturnal predators such as Lions *Panthera leo* or Spotted Hyaenas *Crocuta crocuta*. Subadults are considerably smaller and their scales weaker than adults, making them more vulnerable to predation.

The onset of foraging activity for adults ranges from 14:34h to 02:15h (mean = 20:25h) and for subadults from 14:30h to 20:15h (mean = 18:02h) and the duration of foraging activity for adults and subadults ranges from 35 min to 8 h 20 min (mean = 3 h 51 min and 3 h 42 min, respectively) (Swart 1996). The time they remain active each evening appears to be directly related to their feeding intensity (feeding time per hour) such that on evenings when their feeding intensity is higher they are active for shorter periods.

Social and Reproductive Behaviour Besides ♂♂ and ♀♀ coming together to mate and ♀♀ nursing their young, individuals lead an entirely solitary existence. Males do not appear to be territorial since they do not actively defend a territory. However, they are intolerant of one another since they will attack aggressively by wrestling with the tail and scratching with the front claws and may remain engaged in battle for several hours until one relents and leaves the area (J. M. Swart pers. obs.).

In NW Zimbabwe the home-ranges of three adult ♂♂ (measuring 10.35, 10.68 and 11.07 km²) calculated from plots of their respective den locations were larger than the home-ranges of three adult females (5.65, 5.91 and 7.49 km²) (Heath & Coulson 1997a). These home-ranges are probably underestimated since the area utilized around the dens was not included. Home-ranges based on den locations of 14 Ground Pangolins in the Kruger N. P. region increased by 50.3% when the coordinates of foraging excursions were included (J. M. Swart pers. obs.). Home-ranges of adult ♂♂

in this region overlap the home-ranges of up to five adult ♀♀ and vary in size from 9.28 to 22.98 km² (mean = 16.33 km², n = 4). Home-ranges of adult ♀♀ in this region are overlapped by the home-ranges of up to three adult ♂♂ and vary in size from 0.65 to 6.66 km² (mean = 3.66 km², n = 8), ca. four times smaller than home-ranges of adult ♂♂. Adult male and female home-ranges are ca. 4% larger during the wet season.

Home-ranges of adult ♀♀ overlap each other by 0.3–24.9% (mean = 8.8%, n = 6) and the overall proportion of an adult female's home-range that is overlapped by other adult ♀♀ is 0.3–34.1% (mean = 14.6%, n = 6). In contrast, home-ranges of adult ♂♂ overlap each other by 19.5–51.1% (mean = 28.5%, n = 3) and the overall proportion of an adult male's home-range that is overlapped by other adult ♂♂ is 22.9–51.1% (mean = 38.0%, n = 3). The proportion of an adult female's home-range that is overlapped by the home-range of at least one adult ♂♂ varies from 31% to 100% (mean = 72.3%, n = 8) (J. M. Swart pers. obs.).

Males and ♀♀ scent-mark with urine. The soil is loosened with the sharp front claws before the animals urinate and roll in the urine-impregnated soil to spread it over the body. As they move off, their scent is transferred onto the vegetation so that their presence is announced to other conspecifics. Males also scent-mark by lifting a hindleg to squirt a small deposit of urine on an object such as a tree or rock.

Dens (mostly abandoned Aardvark *Orycteropus afer*, warthog *Phacochoerus* spp., or springhare *Pedetes* spp. burrows) are predominantly used for resting in during the day and since they are distributed throughout the home-range they are convenient sites for scent-marking. Males and ♀♀ often visit several abandoned burrows during their nightly excursions, which they use as marking posts. These burrows are not necessarily utilized as dens but are frequently used only as scent-marking posts (J. M. Swart pers. obs.).

In the Kruger N. P. area, ♂♂ utilized from 1.5 to 4.1 dens/km² (mean = 3.0, n = 4) and ♀♀ from 3.4 to 22.6 dens/km² (mean = 9.6, n = 8) within their home-range (J. M. Swart pers. obs.). Males spent 1–16 consecutive days (mean = 2.3 days, n = 4) in the same den whereas ♀♀ spent 1–75 consecutive days (mean = 5.0 days, n = 8) in the same den. Once dens were vacated after a period of occupation, ♂♂ returned to only ca. 18% and females to ca. 23% of dens previously utilized. A den described by Sweeney (1974) had an entrance 200–250 mm in diameter and a tunnel 3–5 m long that sloped steeply downward with the end of the tunnel about 1 m below the entrance level.

In the Kruger N. P. region, courtship and mating behaviour was only observed twice in the wild, where on both occasions the ♂ and ♀ only paired off for one day. On each occasion the ♂ approached the ♀ very cautiously hissing at her and sniffing all the time while circling and clambering over her. Coitus was achieved when the ♂ forced his tail beneath the ♀ and they remained in this position for ca. 30 min (J. M. Swart pers. obs.). A pair of captive Ground Pangolins was also observed copulating in the Bloemfontein Zoo, South Africa; the ♂ mounted the ♀ from the side and forced his hindquarters underneath the ♀ (Van Ee 1978).

Females conceal their young in a den for about one month and leave the den to forage alone. After this period the young are moved several times, each time to a new den. The mother and young often share the same den for over a year. A large adult ♀ of 14.1 kg was observed carrying a juvenile weighing 4.7 kg (ca. one year old) on her back (J.

Ground Pangolin *Smutsia temminckii*.

M. Swart pers. obs.). This juvenile was being moved to a new den but also frequently foraged independently and returned to the same den as her mother. If threatened, very young juveniles will take refuge underneath the ♀, who curls up around the juvenile as protection. As the juvenile grows too large to be completely enclosed, the head and shoulders are enveloped thus affording protection to the heads of both the ♀ and juvenile (Skinner & Chimimba 2005).

There are no vocalizations used to communicate between individuals; however, they do emit a soft purr-like growl that causes their body to vibrate when alarmed (J. M. Swart pers. obs.).

Reproduction and Population Structure Mating and birthing seasons have not been documented. However, the two incidences of mating recorded in the wild in Sabi Sand G. R. bordering Kruger N. P. in South Africa were during different seasons. One mating was observed at the end of the wet season in Mar and the other during the dry season in Aug (J. M. Swart pers. obs.). No births were recorded in the wild, but a ♀ killed in May (dry season) in Zimbabwe had a foetus of 8.1 g and a ♀ killed in Jul (dry season) had a ♂ foetus of 113.8 g. No foetuses were recorded in ♀♀ killed during the wet season (Coulson 1989). Other records include gravid ♀♀ taken in Jul (Smithers 1971), a captive birth recorded in Aug (Ansell 1960), and an injured ♀ that gave birth to a possibly premature neonate in Aug and which had a mass of 120 g (Jacobsen *et al.* 1991). A radio-tagged ♂ was found cohabiting with a ♀ in

mid-February after walking 12 km from its original home-range in less than one week. They were documented cohabiting for three days prior to the radio-tag falling off the ♂ (Heath & Coulson 1997a).

A single young of approximately 15 cm long and 340 g in weight is born after gestation of about 140 days (Van Ee 1966); ♀♀ give birth to one young per year (Van Ee 1966). Eyes are open at birth and the scales are soft. At four weeks old the young rode on the mother's back and was seen eating termites for the first time; by 35 days it began eating the artificial diet eaten by the captive adults (Van Ee 1978). Juveniles grow quickly initially, reaching up to 5 kg in the first year and are usually weaned at about five months old. A juvenile born in Bloemfontein Zoo weighed just over a kilogram after three months and 3.5 kg after one year (Van Ee 1978). Sweeney (1974) reported a ♀ still lactating a half-grown juvenile while carrying a well-developed foetus, indicating that ♀♀ mate and become pregnant while still nursing young from the previous year. Young may accompany the mother for a considerable period of time.

The longevity of Ground Pangolins is unknown but is estimated to be in excess of 19 years based on the recorded captive longevity of the Indian or Thick-tailed Pangolin *Manis crassicaudata* (Weigl 2005), which is approximately the same size.

Predators, Parasites and Diseases Lions *Panthera leo* and Spotted Hyaenas *Crocuta crocuta* are probably the major predators, although on most occasions the protection afforded by their scales

allows them to escape unharmed. A Ratel *Mellivora capensis* was observed attacking and killing a large ♀♀ by persistently clawing and biting at the smaller lateral scales close to the back legs until she eventually weakened, enabling the Ratel to penetrate the flesh (J. M. Swart pers. obs.). There is also one record of a Nile Crocodile *Crocodylus niloticus* killing a Ground Pangolin (Coulson 1989).

There is little information on parasites and disease in Ground Pangolins. An adult ♂ found covered with mites *Manitherionyssus heterotarsus* and tampans *Ornithodoros moubata* died two days later and the probable cause of death was diagnosed as progressive paralysis induced by the tampans (Jacobsen *et al.* 1991). Parasites such as these and ticks are removed by occasionally wallowing in mud or fresh herbivore dung.

Conservation IUCN: Least Concern. CITES: Appendix II.

Although present in a number of protected areas across their range, and protected by law in many range countries, numbers of Ground Pangolins may be declining due to the demand for their body parts and scales for medicinal purposes and superstitious value (Coulson 1985, Bräutigam *et al.* 1994, Swart 1996). In Tanzania they are sometimes referred to as the doctor, *Bwana mganga*, because every body part is believed to have some medicinal value (Wright 1954). Many East African people believe that burning pangolin scales keeps away Lions (Kingdon 1971). Other widely believed magical and medicinal properties are: their ability to converse with tribal chiefs; that smoke from burning scales improves the health of cattle and cures persistent nose bleeding; and scales are used as a medicine for good luck and to bring rain. In Zimbabwe it is traditionally a good omen to catch and present pangolins to a superior such as a local chief, and several were even captured and presented to the Prime Minister (Coulson 1985). Cunningham & Zondi (1991) found that overexploitation of Ground Pangolins for medicinal use is occurring in South Africa and is increasingly focused on core conservation areas. They are used as bushmeat in some parts of their range (South Africa, Zimbabwe, Namibia), but are generally unpopular since the meat is fatty; the skins are sometimes used to make leather goods. The species was formerly listed in Appendix I of CITES from 1975 to 1995, but then transferred to Appendix II. There have been reports of organized commercial poaching and export to Asia or other African countries (Bräutigam *et al.* 1994), but there is no or very limited international trade in this species included in CITES annual reports for the period 1996–2011 (www.cites.org).

Other threats to pangolins include pesticide usage, in particular those containing gamma-BHC (benzenehexachloride); death from very small quantities has been documented within 24 hours (Swart 1996). This substance has been used in the past to control locusts in South Africa and it is likely that Ground Pangolin populations are reduced in areas where this has occurred (Swart 1996). Pangolins have also been recorded killed on the lower strands of electric fences in South Africa (Swart 1996, Beck 2010), though this should not necessarily pose a major threat.

Confiscated pangolins are often released in areas far from their original home-ranges, apparently with grave consequences. Jacobsen *et al.* (1991) in South Africa reported that two pangolins released far from their home-ranges were found dead within 10 days after release; however, they also released a third pangolin, this time back in its original home-range, which survived only 14 days. Although the condition of these pangolins on the day of release is not known it can be assumed that they were probably under severe stress during the period of capture, which may have contributed to their deaths. Three other pangolin relocations into the Sengwa G. R. in Zimbabwe (Heath & Coulson 1997b) were met with limited success. One adult ♀ was released 5 km from her original home-range but returned back again after 10 days, a second adult ♀ was released 18 km from her home-range, but unfortunately the transmitter failed after 30 days and could not be followed further, and finally a third pangolin, a juvenile retrieved from a poacher, was released and followed for 85 days before the transmitter fell off. This relocation was apparently successful; however, being a juvenile, this pangolin would not have established a home-range before being relocated and would thus probably naturally settle wherever placed. Clearly, this is a field where more research is needed particularly since pangolins cannot be raised successfully in captivity because of specialized ant and termite dietary requirements (Van Ee 1966, 1978).

Measurements

Smutsia temminckii

HB (♂♂): 431 (297–565) mm, n = 18

HB (♀♀): 458 (350–677) mm, n = 15

T (♂♂): 405 (290–585) mm, n = 18

T (♀♀): 370 (223–440) mm, n = 15

HF c.u.: 60 (52–70) mm, n = 11*

E: n. d.

WT (♂♂): 9.4 (2.5–17.1) kg, n = 42**

WT (♀♀): 9.0 (4.6–15.8) kg, n = 40**

Zimbabwe (Coulson 1989)

*Zimbabwe (Smithers & Wilson 1979)

**South Africa and Zimbabwe (Coulson 1989, Jacobsen *et al.* 1991, Heath & Coulson 1997a, Swart *et al.* 1999, J. M. Swart pers. obs.)

Sweeney (1956) recorded a body mass of 27 kg in Sudan, but this may well refer to a record of the Giant Pangolin; Ansell (1964) reported a mass of 16.8 kg for a specimen from Kafue N. P. in S Zambia. The longest animal recorded in a series from Zimbabwe, including tail, was 1403 mm and had a weight of 15.5 kg (Heath & Coulson 1998)

SUPERORDER EUUNGULATA

Euungulata Waddell, Kishino & Ota, 2001. *Genome Informatics* 12: 148.

Cetartiodactyl and perissodactyl lower limbs, forefoot above, hindfoot below: (a) Common Hippopotamus *Hippopotamus amphibius* (cetartiodactyl); (b) *Phenocodus* (condylarth); (c) *Hyracotherium* (primitive perissodactyl); (d) *Diceratherium* (Miocene rhinoceros); (e) *Miohippus* (Miocene horse); (f) *Equus* (living equid).

For more than a hundred years zoologists have laboured to emphasize the differences between odd-toed and even-toed ungulates. Over much of this time palaeontologists have also charted separate histories for perissodactyls and artiodactyls, which both first appeared around 55 mya. Both morphological and molecular studies show that both lineages share a common origin within the Laurasiatheria (Zhou *et al.* 2012). In the light of contemporary knowledge a new taxon is called for to register a common ancestry that is exclusive of the other, extremely diverse, laurasiatheres. Superorder 'Euungulata' has been proposed (Waddell *et al.* 2001) and we follow Asher & Helgen (2010) in adopting this name.

The orders Perissodactyla and Artiodactyla were once distinguished at the superordinal level as Mesaxonia and Paraxonia: mesaxonian means that the axis of the foot passes through the middle toe, i.e. through digit 3; paraxonian means passing outside the middle, i.e. between digits 3 and 4. With the identification, by molecular scientists, of the Afrotheria and the exclusion of afrotherian paenungulates from any close association with perissodactyls, the former category of 'Mesaxonia' (which at one time embraced both paenungulates and perissodactyls) needs to be scrapped as a mere synonym for Perissodactyla. Further, with the discovery that whales

cluster *within* the former artiodactyls, the term Paraxonia, were it to be retained, would now have to include pelagic mammals with non-paraxonid flippers.

A convenient ancestral grouping might plausibly include some 'condylarths' (Palaeogene archaic ungulates) but this systematic issue has not yet been resolved. Both artiodactyls and perissodactyls were originally known from across the northern latitudes (North America and Eurasia). Artiodactyls were mainly small, somewhat omnivorous forms, rather like present-day chevrotains in both size and ecology. Perissodactyls, on the other hand, in general were larger (dog- to pony-sized), and were, from the start, more specialized browsers. A less obvious, but fundamental difference is that many artiodactyls digest their food by foregut fermentation, while perissodactyls employ the less derived mode of hindgut fermentation.

Contemporary perissodactyls, rhinos, horses and tapirs, are but vestiges of a very diverse array that flourished from the Eocene until the late Miocene. By contrast, their even-toed equivalents, cetartiodactyls (discussed in the next volume) have been hugely successful.

Christine Janis, Michael Hoffmann & Jonathan Kingdon

ABOVE: Foregut (bovid, on left) and hindgut (equid, on right) digestive system.

BELOW: Features influencing morphology in perissodactyla.

Archaic perissodactyl features

Vegetarian diet; relatively high-crowned molars, deep jaws. Increasing size trend. Well-developed olfaction in extended cylindrical skull.

Equid features

Medium to large size. Elongation of neck, legs and skull. Vision well developed; high head carriage. Diastema, molars with very high crowns with deep rooting. Incisors cut and pull grass. *Defence*: speed. *Weapons*: teeth and hooves.

Rhinocerotid features

Great size and weight. Heavy head, low carriage. Short plantigrade limbs. Vision poor; olfaction good. Incisors and diastema lost, lips gather food. *Defence*: size and horns. *Weapons*: nasal horns.

Order PERISSODACTYLA – Equids, Rhinoceroses, Tapirs

Perissodactyla Owen, 1848. Quarterly Journal of the Geological Society of London 4: 103–141.

Tentative phylogenetic tree of Perissodactyla (after Bininda-Emonds *et al.* 2007, Meredith *et al.* 2011)

| | | |
|--------------------------------------|---------------|--------|
| Equidae (1 genus, 4 species) | Asses, Zebras | p. 410 |
| Rhinocerotidae (2 genera, 2 species) | Rhinoceroses | p. 444 |

The perissodactyls are the order of herbivorous ‘odd-toed’ hoofed mammals that includes the living horses, zebras, asses, tapirs, rhinoceroses and their extinct relatives. They were originally named by Richard Owen (1848) as a group including horses, rhinos, tapirs and hyraxes, although no recent authors have accepted the inclusion of hyraxes in Perissodactyla. Perissodactyls are recognized by a number of unique specializations (Hooker 2005), but their single most diagnostic feature is the structure of their feet. Most perissodactyls have either one or three toes on each foot, and the axis of symmetry of the foot runs through the middle digit.

The perissodactyls are divided into three subordinal groups (Prothero & Schoch 1989): the Hippomorpha (horses and their extinct relatives); the Titanotheriomorpha (the extinct brontotheres, found in Asia and North America during the Eocene); and the Moropomorpha (tapirs, rhinoceroses, and their extinct relatives). The latter suborder includes, as an infraorder, the Ceratomorpha, uniting the extant tapirs and rhinoceroses.

Perissodactyls were once thought to have evolved in Central America from the phenacodonts, an extinct group of archaic hoofed mammals placed in the invalid taxon ‘Condylarthra’. However, in 1989, a specimen recovered from deposits in China dated to about 57 mya was described and named *Radinskya*. This specimen shows that perissodactyls originated in Asia at around this time and were unrelated to North American phenacodonts. By 55 mya the major groups of perissodactyls had differentiated, and migrated from Asia to Europe and North America. Before 34 mya the brontotheres and the archaic tapirs were the largest and most abundant hoofed mammals in Eurasia and North America. After these groups became extinct, horses and rhinoceroses became the most common perissodactyls, with a great diversity of species and body forms. Both groups were decimated during another mass extinction about 5 mya, and today only five species of rhinoceros, four species of tapir, and a few species of horses, zebras and asses cling to survival in the wild. The niches of large hoofed herbivores have, to a large extent, been taken over by the ruminant artiodactyls, such as cattle, antelopes, deer and their relatives.

From their Asian origin, the hippomorphs spread all over the northern continents. In Europe, the horse-like palaeotheres substituted for true horses. North America became the centre of evolution of true horses, which occasionally migrated to other continents. The descendants of *Protorohippus* (once called *Hyracotherium*; Froehlich 2002) evolved into many different lineages living side by side. The collie-sized three-toed horses *Mesohippus* and *Miohippus* (from beds dated about 37–30 mya) were once believed to be sequential segments on the unbranched trunk of the horse evolutionary tree. However, they coexisted for millions of years, with five different species of two genera living at the same time and place. From *Miohippus*-like ancestors, horses diversified into many different ecological niches. One major lineage, the anchitherines, retained low-crowned teeth, presumably for browsing soft leaves in the forests. Some anchitherines, such as *Megahippus*, were almost as large as the living horse. *Anchitherium* migrated from North America to Europe about 20 mya and was the first true horse to reach Europe.

About 15 mya there were at least 12 different lineages of three-toed horses in North America, each with slightly different ecological specializations, a situation analogous to the diversity of modern antelopes in East Africa. The ancestors of this great radiation of horses are a group of three-toed, pony-sized beasts that have long been lumped into the ‘wastebasket’ genus ‘*Merychippus*’. However, recent analyses have shown that the species of ‘*Merychippus*’ are ancestral to many different lineages of horses. True *Merychippus* was a member of the hipparion lineage, a group of three-toed horses that developed highly specialized teeth, and had a distinctive concavity in the bone on the front of the face. Hipparions were a highly diverse and successful group of horses, with seven or eight different genera spread not only across North America, but also migrating to Eurasia. *Merychippines* were also ancestral to lineages such as *Calippus* (a tiny dwarf horse), *Protohippus* and *Astrohippus*.

On two different occasions (*Pliohippus* and *Dinohippus*), three-toed horses evolved into lineages with a single toe on each foot. About 5 mya most of these three-toed and one-toed horse lineages became extinct, leaving only *Dinohippus* to evolve into the modern horse *Equus*. The main lineage of horses that survived the extinctions 5 mya were known as

Hyracotherium skeleton.

the equines. The living genus *Equus* first appeared about 3 mya and was widespread throughout the northern hemisphere. When the Isthmus of Panama rose about 2.5 mya, horses also spread to South America. There they evolved into distinctive horses with a short proboscis known as the hippidions. At the end of the last Ice Age (about 10,000 years ago), horses became extinct in the New World. They were reintroduced to their ancestral homeland by Columbus in 1493. Feral horses that have escaped from domesticated stock are known as mustangs.

The earliest moropomorphs, such as *Homogalax*, occur in strata about 55 mya. They are virtually indistinguishable from the earliest horses, such as *Protorohippus*. From this unspecialized ancestry, a variety of archaic tapir-like animals diverged. Most retained the simple leaf-cutting teeth characteristic of tapirs, and like brontotheres they died out about 34 mya when their forest habitats shrank. Only the modern tapirs, with their distinctive long proboscis, still survive in the jungles of Central and South America (three species) and South-East Asia (one species). All are stocky, pig-like beasts with short stout legs and oval hooves, and a short tail. They have no natural defences against large predators, so they are expert at fleeing through dense brush and swimming to make their escape.

The horse-like clawed chalicotheres are closely related to some of these archaic tapirs. When chalicotheres were first discovered, there was general disbelief that the claws belonged to a hoofed mammal related to horses and rhinos. However, many specimens have clearly shown that chalicotheres are an example of a hoofed mammal that has secondarily developed claws. To begin with, claws were considered useful for digging up roots and tubers, but the fossilized claws show no sign of the characteristic scratches due to digging. Instead, chalicotheres are now thought to have used their claws to haul down limbs and branches to eat leaves (much as ground sloths did). *Chalicotherium* had such long forelimbs and short hindlimbs that it apparently knuckle-walked with its claws curled inward. Chalicotheres were always rare throughout their history in North America and Eurasia, but nevertheless survived until the late Pleistocene in Africa.

Rhinoceroses have been highly diverse and successful throughout the past 50 million years. They have occupied nearly every niche available to a large herbivore, from dog-sized running animals, to several hippo-like forms, to the largest land mammal that ever lived, *Paraceratherium*. Most rhinoceroses were hornless. Unlike the horns of cattle, sheep and goats, rhino horns are made of cemented hair fibres, and have no bony core, so they rarely fossilize. Therefore, the presence and size of the horn must be inferred from the roughened area on the top of the

skull where it once attached. Even without horns, rhino fossils are easy to recognize by a number of anatomical features in the skeleton, skull and braincase. One of the easiest to spot is the crests on the crowns of the upper molars, which look like the Greek letter 'pi'.

The earliest rhinos, known as *Hyrachyus*, were widespread over Eurasia and North America about 53 mya. They apparently crossed back and forth between Europe and North America using a land bridge. From *Hyrachyus*, three different families of rhino diverged. Long before hippos evolved, one family of Rhinocerotidae, the amynodonts, evolved into hippo-like amphibious forms, with stumpy legs and a barrel chest for living in ponds and rivers. The last of the amynodonts, which had a short trunk like an elephant, died out in Asia about 15 mya.

The second family was known as the hyracodonts, or 'running rhinos,' because they had unusually long slender legs compared with other rhinos. They were particularly common in Asia and North America between 42 and 34 mya. The biggest of all was *Paraceratherium* (once called *Baluchitherium* or *Indricotherium*), which was 6 metres tall at the shoulder and weighed 20,000 kg. It must have browsed leaves from the tops of trees, as giraffes do today. Indricotheres were also the last of the hyracodonts, vanishing from Asia about 15 mya.

The third family is the true rhinoceroses, or family Rhinocerotidae. They first appeared in Asia and North America about 40 mya, and lived side by side with the hyracodonts and amynodonts on both continents. Rhinocerotids can be distinguished from hyracodonts and amynodonts by their distinctive molars, and by the development of a tusk-like lower incisor that occluded against a chisel-like upper incisor. In the late Eocene and early Oligocene (about 37–28 mya), there were several different genera of rhinocerotids. When the brontotheres died out about 34 mya, rhinocerotids were the largest land mammals in North America, and remained so until mastodonts arrived about 16 mya.

Up until this point, all the rhinoceroses we have mentioned were hornless. Rhinos with horns first appeared about 28 mya; two different lineages independently evolved paired horns on the tip of the nose. Both of these groups went extinct about 18 mya, when two new subfamilies immigrated to North America from Asia: the browsing (leaf-eating) aceratherines, and hippo-like grazing teleoceratines. Between 18 and 5 mya, browser-grazer pairs of rhinos were found all over the grasslands of Eurasia, Africa and North America. The teleoceratine *Teleoceras* was remarkably similar to hippos in its short limbs, massive barrel-shaped body and high-crowned teeth for eating gritty grasses. We know these animals were aquatic because they are usually found in ancient lake or river sediments, and some extraordinary specimens buried in volcanic ash preserve the grass seeds of their last meal.

A mass extinction event that occurred about 5 mya wiped out North American rhinos, and decimated most of the archaic rhino lineages (especially the teleoceratines and aceratherines) in the Old World. The surviving lineages diversified in Eurasia and Africa, and even thrived during the Ice Ages. Woolly rhinos are known from numerous mummified specimens that give us detailed information about their hair, tissues and even stomach contents. The only surviving descendant of the woolly rhino lineage is the Sumatran Rhinoceros *Dicerorhinus sumatrensis*, of which only a few hundred individuals survive in the mountainous regions of Sumatra. Four other species of rhino survive in Asia and Africa, of which the Javan Rhinoceros *Rhinoceros sondaicus* is the most threatened, numbering fewer than 50 individuals in the wild.

Family EQUIDAE
ASSES, ZEBRAS

Equidae Gray, 1821. London Med. Repos. 15: 307.

Tentative phylogenetic tree of extant equids (after Orlando *et al.* 2009). Numbers indicate likely sequence of arrivals in Africa.

| <i>Equus</i> | | |
|--------------------------------|------------------|--------|
| <i>Asinus</i> (1 species) | African Wild Ass | p. 414 |
| <i>Hippotigris</i> (3 species) | Zebras | p. 417 |

The family Equidae contains the horses, asses and zebras, as well as numerous and diverse extinct forms. Like the rhinoceroses and tapirs, they belong to the order Perissodactyla, or Odd-toed Hoofed Mammals, which rest their weight on a single central toe on each foot. In fact, the Equidae have taken this to its logical conclusion, losing all side toes and retaining just the central, third one. All that remains of the side toes are a pair of sliver-like bones, called splint bones, at the ‘knee’ (really, the wrist) and hock (the ankle). On the forelegs, the ulna is greatly reduced and has fused with the very robust radius, such that all the weight is effectively borne by the radius. In the hindlegs, the reduced fibula is fused to the tibia and it is the latter that bears the weight of the animal.

A single genus, *Equus*, is commonly recognized, with seven species (four African) currently divided into three (but sometimes more) subgenera (Groves & Ryder 2000). The number of species recognized in the family depends on whether the Quagga is considered conspecific with the Plains Zebra *Equus quagga* (the approach followed here, but not, for example, by Grubb 2005), whether Cape and Hartmann’s Mountain Zebras are considered separate species (as proposed by Groves & Bell 2004), whether Przewalski’s Horse is considered distinct from *Equus ferus* (see extensive discussion in Grubb 2005), and species relationships of the taxa *onager*, *kiang* and *khur* relative to *E. hemionus*.

Modern equids are fast-running diurnal grazers of open plains country in north-east, East and southern Africa, as well as arid and semi-arid country in Asia. They do not extend into the West African grasslands or Sahel. Species living in more mesic environments live in harem herds, while in the more arid-adapted species small groups of females and young live apart from the males, which are territorial.

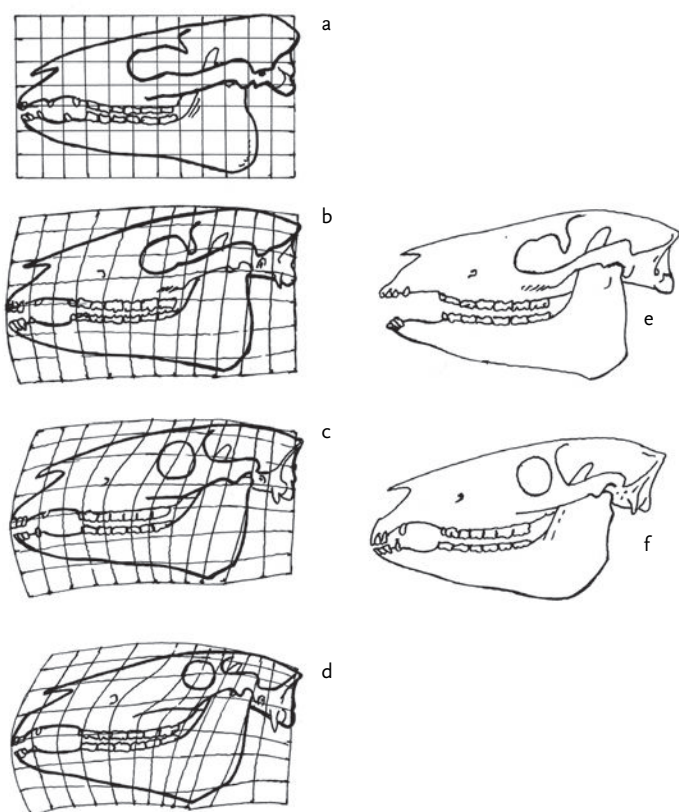

Equids have a long skull, and the jaws are powerfully developed, with a broad angle at the back where the masseter muscle is attached to the mandible. The braincase, although much shorter than the face, is large. The orbits (eye-sockets) are large and face to the side, and are entirely ringed by bone; the visual fields do not overlap, instead equids have all-round vision, and their pupils are even oblong, increasing the width of the visual field. There is a battery of high-crowned premolar and molar teeth with complex folds of enamel,

Functional zones in skulls of equids. From top: Plains Zebra *Equus quagga*, African Wild Ass *Equus africanus*, Grévy’s Zebra *Equus grevyi*.

increasing their wearing life, and chisel-like incisor and canine teeth separated from the cheekteeth by a long gap, the diastema. The typical dental formula is $I^{3/3} C^{0-1/0-1} P^{3-4/3} M^{3/3} = 36-42$. Equids, unlike most other medium-sized ungulates, have virtually no sexual dimorphism, except that the canines, well developed in adult males, are reduced or absent in ♀♀. The deciduous first premolars are rudimentary and soon shed, although the first upper premolar sometimes persists as a reduced tooth. The incisor teeth have an enamel-lined hollow or depression (the infundibulum) that runs down the centre for a variable length; as teeth wear down, the shape of the infundibulum can be used in age determination (e.g. Smuts 1974a, Penzhorn & Grimbeek 1987). The infundibulum is, however, absent in some Plains Zebras, especially many from north of the Zambezi R. Equids have a simple stomach in which the passage of food is not as delayed as it is in bovids (Alexander 1952). Glover & Duthie (1958) determined that horses consume approximately twice the amount that a similar-sized cow does and suggested that this might compensate for inferior levels of protein-assimilation.

The genetics of the Equidae have been investigated and discussed by various authors (e.g. Ryder *et al.* 1978, George & Ryder 1986, Oakenfull *et al.* 2000, Groves & Ryder 2000, Moodley & Harley 2005, Lorenzen *et al.* 2008, Orlando *et al.* 2009). Chromosome number in the equids varies from $2n = 32$ (*E. zebra*) to $2n = 46$ (*E. grevyi*) in the subgenus *Hippotigris*, and $2n = 54$ to $2n = 66$ in other species. The first extinct form to have its DNA cloned was, in fact, the Quagga *Equus quagga quagga*, when traces of DNA from a

Hyracotherium (a), *Equus* (d), and two intermediate skulls (b and c) constructed on coordinate transformations (from Thompson 1917). (e) *Mesohippus* for comparison with hypothetical skull (b) and (f) *Merychippus* for comparison with (c).

museum specimen were extracted and sequenced, an event achieved even before the development of techniques such as PCR (polymerase chain reaction) (Higuchi *et al.* 1984).

The evolutionary history of the Equidae is very well known and has been discussed in detail by several authors (e.g. Mathew 1926, Simpson 1951, Groves 1974, MacFadden 1988, 1992, 2005; and see Prothero & Schoch 1989). The family has been successful throughout its existence, and has left abundant fossils. The earliest members lived in the early Eocene, about 54 mya, at which time they are difficult to distinguish from the earliest rhinos and tapirs and members of other, now extinct, perissodactyl groups. Previously known as 'eohippus' or *Hyracotherium*, recent work reveals that these Eocene 'hyracothere' horses include an early diversification of a half-dozen genera (Froehlich 2002). These very early, primitive perissodactyls were small animals, less than 30 cm high, with four toes on the forefoot and three on the hindfoot, short skulls, simple low-crowned cheekteeth and small brains with small frontal lobes. The equid fossil record documents in great detail the successive loss of side toes, the lengthening of the legs and feet, lifting the wrist and ankle high off the ground, the increasing complexity of the cheekteeth, the development of the diastema, the enlargement of the brain, and all the many changes that have led to the modern horse, one of the glories of the world of modern mammals.

Hyracothere horses date from the earliest Eocene of America and Eurasia. They lived in forest and probably had a mixed but mainly herbivorous diet (Radinsky 1969). During the later Eocene and Oligocene, equids were apparently restricted to North America where *Orohippus* (approximately 50 mya), *Epihippus* (47 mya),

Grévy's Zebra *Equus grevyi*, skeleton and myology.

Mesohippus (40 mya) and *Miohippus* (36 mya) became more herbivorous, with concomitant changes in dentition. For example, in *Orohippus*, the last premolar became more molar-like, giving *Orohippus* one more grinding tooth, and in *Epihippus* the last two premolars were like molars, giving *Epihippus* five grinding cheekteeth. *Mesohippus*, and all subsequent horses, had six grinding cheekteeth, and, like *Epihippus*, had well-formed crests on the cheekteeth. In addition, *Mesohippus* was very slightly larger in size at the shoulder, and had three toes on both hind- and on forefeet, the fourth front toe vestigial. *Miohippus* split off from early *Mesohippus* and again was slightly larger, with longer skull.

The early Miocene saw a massive radiation of equids, which ranged from small, duiker-sized browsers, such as *Archaeohippus*, to rhino-sized 'anchitheres' such as *Megahippus* (Simpson 1951). A particularly

successful form, *Anchitherium*, lived in Asia and has been recorded through the Miocene. Lineages that survived into the Pliocene include *Neohipparion* and *Nannippus*, but it was the Miocene *Merychippus* (which arose about 17 mya) or *Protohippus* lineage that seems to have given rise to the extant equids. In *Merychippus*, the brain was notably larger, and overall recognizable as a horse. *Merychippus* also displayed some of the modifications of the lower limbs indicative of progressive adaptation to a more cursorial type of locomotion. It was still three-toed, and the side toes were still complete, though of varying sizes; some species had full-sized side toes, while in others they were smaller and only touched the ground during running. The legs became longer, the radius and ulna fused (eliminating leg rotation), and the fibula was greatly reduced. *Merychippus* had an elongated muzzle and high-crowned cheekteeth, and the teeth were bulked out with cement that surrounded less complex precursors of the crenellated lamellae so typical of living horse and zebra teeth (Simpson 1951).

Merychippus gave rise to a line of large equines with small side toes, which in turn gave rise to *Pliohippus*, *Astrohippus* and *Dinohippus*, all of which had lost their side toes. *Dinohippus*, which arose around 12 mya, eventually graded into the modern day genus *Equus*. Members of this radiation only reached Africa in the mid-Pliocene. Within *Equus* there was a radiation that various authors (Hopwood 1936, MacGrew 1944, Groves 1974) have suggested branched into a zebrine lineage living under relatively warm, humid climates (and the living forms of which can be placed under the subgenus *Hippotigris*), *Equus*, a Eurasian subgenus that, after adapting to the onslaught of cold conditions, entered North America (where it displaced the zebrine *E. (H.) simplicidens*), and the subgenus *Asinus*, which evolved in near desert conditions.

GENUS *Equus*

Asses, Zebras

Equus Linnaeus, 1758. Syst. Nat., 10th edn, 1: 73.

Plains Zebra *Equus quagga* myology.

Equid incisors exposed
(Plains Zebra *Equus quagga*).

During the Miocene, grasses became a dominant plant form (see illustration in MacFadden 2005) such that in North America by the beginning of the Pliocene (5 mya) savannas and grasslands were more extensive than woodlands. Grazing equids and ruminants expanded into these habitats: the genus *Equus* appeared in North America during the Pliocene, about 4.5 mya, and evolved into 25–30 species, of which seven survive today. A ‘zebrine’ form (*E. stenonis*) colonized the old world by crossing the Bering Strait in the early Pleistocene, 2–3 mya. These animals were replaced in Eurasia by ‘caballine’ and ‘asinine’ species by the late Pleistocene, but descendent forms are thought to have survived in sub-Saharan Africa.

The living members of the genus are divided into three subgenera (Groves & Ryder 2000, Groves & Bell 2004): *Equus*, *Asinus* and *Hippotigris*. Grévy’s Zebra *Equus grevyi* has been included in the subgenus *Dolichohippus* (e.g. Lydekker 1916, Groves 2002), but molecular and morphological evidence reveal its close affiliation with other zebras

(Groves & Ryder 2000). The inclusion here of discussion on the subgenera permits us to explore contentions surrounding the topic of how and why striping evolved in some equids while being lost in others.

The subgenus *Equus* contains the horses, which do not occur naturally in Africa. The only wild horse is the Asian Przewalski’s Horse, *E. ferus przewalskii*, which survived in zoos and has been reintroduced into Mongolia; Przewalski’s Horse is sometimes considered a distinct species (see discussion in Grubb 2005). Subgenus *Asinus* contains the hemionies or onagers, which are strictly Asian, as well as the true asses or donkeys, which includes the African Wild Ass *E. africanus* that was formerly indigenous to an extensive area of northern Africa, but now only survives in sandy and stony deserts in Ethiopia, Eritrea and Somalia. In *Asinus*, the metacarpus is short compared with the metatarsus, and the biischial breadth is high compared with the biacetabular. The coat is striped only on the limbs, or on the shoulder and then only in some populations.

The three species in the subgenus *Hippotigris* (Zebras) are now exclusively African: the *E. quagga* group (Plains Zebra) has the widest range, occurring in mesic savannas and grasslands from the South-West Arid Biotic Zone in southern Africa to the Somalia–Masai bushland Biotic Zone in the Horn. The *E. grevyi* group (Grévy’s Zebra) is confined to the arid and semi-arid savannas of the Horn of Africa (now mainly Ethiopia and Kenya). The *E. zebra* group (Mountain Zebra) contains two subspecies, *E. z. zebra* (Cape Mountain Zebra) and *E. z. hartmannae*

Head of Grévy's Zebra *Equus grevyi* (above); Plains Zebra *Equus quagga* (below).

(Hartmann's Mountain Zebra), which Groves & Bell (2004) regard as distinct species. Members of *Hippotigris* have the metacarpus long compared with the metatarsus, and biischial breadth low compared with biacetabular. Externally, members are distinctly striped at least on head and neck, usually on the whole body. Some authorities regard each of the species groups as forming a separate subgenus (Groves 2002), and the subgenus *Asinus* is occasionally given full generic status.

The living equids are well adapted to eating grasses, have high crowned, very durable teeth, and have survived competition with the highly evolved grazing bovids, such as wildebeest *Connochaetes* spp. and African Buffalo *Syncerus caffer*. In a few systems, like the Makgadikgadi Pans (Botswana), the Plains Zebra is the most abundant medium-sized ungulate. The digestive system of horses (and probably zebras) is more effective at extracting nutrients from grasses than cattle since they eat half again as much grass per day (Ménard *et al.* 2002). Ruminants, however, eat a wider range of plants, and appear to be better adapted for dealing with plant chemical defences, such as terpenes. Zebra populations can be limited by resources (Georgiadis *et al.* 2003); however, at least in ecosystems with high predation pressure, they may suffer heavier predation than do comparable ruminants, wildebeest and buffalo, from the large cursorial predators, such as Lions *Panthera leo* and Spotted Hyenas *Crocuta crocuta*. Equid populations 'turn-over' more slowly than comparable ruminants, which breed earlier in their lives and have shorter gestation lengths (Grange *et al.* 2004).

Stomach and secum of *Equus*.

Equids have contrasting mating systems: in species like Grévy's Zebra, ♂♂ show area-restricted dominance, which resembles the territoriality shown by many ungulates. Plains Zebras and Mountain Zebras have an unusual mating system, which is also found in a few primates like gorillas: dominant ♂♂ acquire and defend harems whose members may stay together for many years. In such harem-forming species, young zebras of both sexes disperse from their natal harem. Feral domestic and Przewalski's Horses show the same social structure and dynamics, and the young ♀♀ leave to avoid incestuous matings. The function of this unusual harem-based mating system is debated: it may allow the ♀♀ to enlist the help of the father of their offspring to combat group hunting predators (like Lions) and/or other breeding ♂♂, which are a potential source of serious harassment. However, functional explanations of variations in equid social and spatial organization and behaviour are today under debate (e.g. Linklater 2000). Equid ♀♀ are polyoestrus, gestation is around 12 months, and parturition tends to be aseasonal, with young being born throughout the year. Maximum longevity in captivity for the various species has been given at between 30 and 60 years, but is typically on the order of 20–25 years for zebras in the wild.

All equid species can interbreed in captivity, including hybrids among zebra species as well as with other Equidae, and produce offspring that, depending on chromosome number, are generally sterile (Roberts 1929, Benirschke *et al.* 1964, Gray 1972, Ryder *et al.* 1978). In the wild, several F1 hybrids and one suspected F2 hybrid between Grévy's Zebra and Plains Zebra are known from ranches in Laikipia, N Kenya. The stripe pattern as well as the behaviour of these specimens exhibits elements of both parent species (Cordingley *et al.* 2009, J. Cordingley pers. comm., H. Klingel pers. obs., and see Grubb 1981). In some areas, such as parts of Zimbabwe, Zebdonks, i.e. hybrids between zebras and donkeys, are not uncommon.

There has, in recent years, been much debate surrounding efforts to bring the extinct Quagga back from extinction, the last individual of which died in Amsterdam Zoo in 1883. Genetic evidence reveals that the Quagga is little more than a subspecies of the extant Plains Zebra *Equus quagga* (Higuchi *et al.* 1984, Leonard *et al.* 2005). Twenty-three preserved skins remain of the extinct Quagga, which reveal that the population displayed much individual variation. Extant Plains Zebra populations also display individual variation, with some individuals displaying characteristics of Quaggas. The project attempts to breed by selection individuals of Plains Zebra, which in external appearance, and possibly genetically as well, will be closer to the Quagga.

Patrick Duncan & Colin Groves

Subgenus *Asinus*

African Wild Ass

Asinus Gray, 1824. Zool. Journ. 1: 244.

The subgenus *Asinus* embraces both the true ass, which is exclusively African (although also claimed from archaeological deposits in the south-western Arabian peninsula) and the Asiatic hemiones, kiangs and onagers. All species inhabit sandy and stony deserts and show some specialization of the hooves, apparently for the particularly tough wear that lower limbs must endure from consistently hard, unyielding substrates. The metacarpus is short compared with the metatarsus, and the biischial breadth is high compared with the

biacetabular. The hoof itself is vertical-sided and leaves a distinctive track. The Asiatic asses (sometimes included in the subgenus *Hemionus*; Groves 2002) have somewhat redder coats than the African ass, which is mainly grey and white and is striped on the lower legs and shoulder (but only in some populations). Such striping could be seen as incipient or vestigial (but see Subgenus *Hippotigris* profile).

Colin Groves

Equus africanus AFRICAN WILD ASS (SOMALI WILD ASS)

Fr. Âne sauvage; Ger. Wildesel

Equus africanus von Heuglin & Fitzinger, 1866. Systematische Übersicht der Säugethiere Nordost-Afrika's mit Einschluss der arabischen Küste, des rothen Meeres, der Somali- und der Nilquellen-Länder, südwärts bis zum vierten Grade nördlicher Breite. Sitzungsberichte der kaiserlichen Akademie der Wissenschaften. Mathematisch-Naturwissenschaftliche Classe, 54: 537–611. Ain Saba, Eritrea (as fixed by Schlawe 1980).

African Wild Ass *Equus africanus*.

Taxonomy The African Wild Ass is the ancestor of the domestic donkey *Equus asinus*. Analyses of ancient DNA (Kimura *et al.* 2011) demonstrate that there are two distinct mitochondrial haplogroups (clades) of domestic donkeys. The Nubian Wild Ass is the ancestor to one of these mtDNA haplogroups; however, the Somali Wild Ass exhibits significant mitochondrial divergence from the Nubian Wild Ass, and both domestic donkey haplogroups, leaving the second ancestor of the domestic donkey undetermined. The earliest archaeological evidence for the donkey, in the Sudan, is dated to 5000 years ago, and only slightly later in Syria and Iran. Phylogenetic analyses suggest that north-east Africa is the most likely location of domestication, and that the donkey might be the only ungulate domesticated solely in Africa (Beja-Pereira *et al.* 2004, Vilà *et al.* 2006). From 4000 years ago, domestic donkeys were brought to Europe by the Greeks in their colonies along the north-east coast of the Mediterranean, and later the Romans distributed them to all parts of their empire.

The International Commission on Zoological Nomenclature ruled (Opinion 2027, March 2003) *Equus africanus*, as the first available name based on a wild population, to be valid for the wild North African ass, and Gentry *et al.* (2004) recommended that *E. asinus* be used for the domestic donkey. Gentry (2006) criticized the incorrect use of the name *E. asinus* for the wild ass by Grubb (2005).

There are two recognized extant subspecies, although there is disagreement as to whether the African Wild Ass is one continuously distributed species exhibiting clinal variation, or if these represent valid subspecies (Ansell 1974, Groves & Willoughby 1981, Groves 1986, Yalden *et al.* 1986). Groves (1986) showed that there is some clinal change from the Atbara population (colour more buffy and shoulder cross thick) via the Red Sea coastal populations (colour greyer, and shoulder cross nearly always thin) to Somalia, and a marked change between N and S Eritrea. A subspecies from North Africa, the Atlas Wild Ass, is depicted in rock paintings and Roman mosaics (such as those from Hippone near Annaba, where one depicts an ass being captured with a lasso by mounted hunters) as having distinct leg stripes and shoulder stripe (often doubled) (Hufnagl 1972, Kowalski & Rzebik-Kowalska 1991, Groves 2002). The name *atlanticus*, often assigned to this form, is unavailable. Groves (2002) lists a third unnamed subspecies, *Equus africanus* ssp. (Saharan Wild Ass), authenticated for Ahaggar, Tibesti and Fezzan, and which is similar to *E. a. africanus*, but smaller and greyer, and with long, thin shoulder cross, but these may actually represent domesticated feral animals (see Kowalski & Rzebik-Kowalska 1991). The nomenclature of African Wild Ass is reviewed in detail by Groves & Smeenk (2007).

Synonyms: *aethiopicus*, *africanus*, *atlanticus* (unavailable), *dianae*, *hippagrus* (unavailable), *nubianus*, *sahariensis* (unavailable), *somalicus*, *somaliensis*, *taeniopus*. Chromosome number: 2n = 62–64, with the most frequently occurring diploid number being 63 (Benirschke & Malouf 1977, Ryder *et al.* 1978, Houck *et al.* 1998). This chromosomal variation is the result of a centric fission accompanied by a heterochromatic deletion. Karyotypes consisted of 34–36 metacentric/telocentric autosomes; the X chromosome is a large

Lateral, palatal and dorsal views of skull of African Wild Ass *Equus africanus*.

Equus africanus

submetacentric, and the Y chromosome a small acrocentric (Houck *et al.* 1998). Hybrids between the two subspecies are fertile.

Description Lean and muscular, grey to reddish-buff in colour with a contrasting white underside and white muzzle with dark grey shading on the nostrils and upper and lower lips. Ears are long and possibly play an important role in heat dissipation. Coat of hair is short and slick and reflects the sun. Both subspecies have an erect, thin mane that is usually pale in colour with a dark terminal border. Thin black dorsal stripe (sometimes absent in *E. a. somaliensis*); the Somali subspecies has distinct leg stripes (less marked, and sometimes absent in Nubian subspecies). Tail tufted. Hooves small and narrow. One pair of nipples.

Groves (2002) describes the skull as being characterized by a very long cranium, short palate, long diastema, squared upturned occipital crest, and wide external auditory meatus. Orbit is high and rounded (not anteroposteriorly elongated as in other species – with the exception of Mountain Zebra *Equus zebra*).

Geographic Variation

E. a. somaliensis (Somali Wild Ass): E Eritrea, NE and E Ethiopia, Somalia. Dorsal stripe sometimes absent (and when present sometimes incomplete); occasionally short, thin shoulder stripes (sometimes absent); and individually distinct leg stripes; ears short; apparently longer legged and shorter bodied than Nubian.

E. a. africanus (Nubian Wild Ass): N Eritrea and NE Sudan. Dorsal stripe present (and nearly always complete from mane to tail-tuft); shoulder stripe only thick in some populations (e.g. Atbara), and sometimes absent; leg stripes sometimes present (and then only restricted to a few bands at the fetlocks); ears longer and thinner.

Similar Species Domestic and feral donkeys often are found in the same habitat as the African Wild Ass. However, domestic donkeys are about two-thirds the size of the African Wild Ass, their coat colour varies from grey to brown to black and they tend to have a longer coat

of hair giving them a 'rough' rather than 'slick' appearance. Domestic donkeys have proportionally shorter legs and cranial length.

Distribution

Historical Distribution During the Pleistocene, the African Wild Ass may have existed in Israel and Syria. Historically, the Atlas Wild Ass was found in the Atlas region of NW Algeria, and adjacent parts of Morocco and Tunisia. It survived in this area until about 300 AD (Antonius 1938). In recent times, there have been reports of wild asses in N Chad and the Hoggar Massif of the C Sahara (e.g. Dupuy 1966; and see Kowalski & RzebiK-Kowalska 1991), but it is doubtful whether these are true wild asses.

The Nubian Wild Ass *E. a. africanus* lived in the Nubian desert of NE Sudan, from east of the Nile R. to the shores of the Red Sea, and south to the Atbara R. and into N Eritrea. During aerial flights in the 1970s, wild asses were seen in the Barka Valley of Eritrea and in the border area between Eritrea and the Sudan.

The Somali Wild Ass *E. a. somaliensis* was found in the Denkelia region of Eritrea, the Danakil Desert and the Awash River Valley in the Afar region of NE Ethiopia, W Djibouti, and into the Ogaden region of E Ethiopia. In Somalia, they ranged from Meit and Erigavo in the north to the Nugaal Valley, and as far south as the Shebele R. A comprehensive review of the historical literature concerning African Wild Ass distribution can be found in Yalden *et al.* (1986) and Bauer *et al.* (1994).

Current Distribution The African Wild Ass is found in Eritrea, Ethiopia and possibly in Somalia. Some animals may persist in Djibouti, but recent surveys have not recorded their presence (Künzel *et al.* 2000). African Wild Asses may still be found in Sudan and Egypt, but their presence has not been documented. In Ethiopia and Somalia the population has been severely reduced, both in population size and range.

Habitat In Ethiopia and Eritrea, African Wild Asses live in arid grass and bushlands of the Great Rift Valley. They are found in a volcanic

landscape and range from rocky mountains (as high as 1500 m) to below sea level in the Dalool Depression.

Abundance In Ethiopia, during the 1970s, African Wild Asses could be found from Yangudi-Rassa N. P. to Mille-Serdo Wild Ass Reserve. At that time there were between 15 and 30 individuals per 100 km². Currently, there are few African Wild Asses left in Yangudi-Rassa and less than 1/100 km² are left in Mille-Serdo Wild Ass Reserve. Even if as many as one individual per 100 km² exists throughout the species' former range (16,000 km²), the population in Ethiopia probably numbers fewer than 160 individuals (Moehlman 2002).

Due to Eritrea's 30-year war for independence, there are no long-term data on African Wild Ass populations for this country. However, recent surveys indicate that viable populations exist in the Northern Red Sea Zone. In this area, the population density is estimated at roughly 47 individuals per 100 km². This is the highest population density found anywhere in the present range of the species and is similar to population densities recorded in Ethiopia in the early 1970s. Given the absence of guns among rural people and the conservation ethic among local Afar pastoralists, the African Wild Ass has good potential for recovery in Eritrea (Moehlman 2002).

In Somalia, in 1997, local pastoralists said that there were fewer than ten African Wild Asses left in the Nugaal Valley; an earlier ground survey in 1989 in the Nugaal Valley yielded population estimates of roughly 135–205 animals or approximately 2.7–4.1/km² (Moehlman 1998). Some animals may remain near Meit and Erigavo, but this area has not been surveyed since the 1970s.

Adaptations Research on domestic donkeys (descendants of the African Wild Ass) has shown that they are physiologically well adapted to life in arid habitats. They can sustain a water loss of up to 30% of their body weight and can drink enough water in two to five minutes to restore fluid loss (Maloij 1970). Tomkiewicz (1979), using temperature-sensitive implants, determined that feral asses varied their body temperature from 35.0 to 41.5°C, depending on air temperature. In hot summer months, ♂♂ had lower mean body temperatures (36.5°C) than ♀♀ (38.2°C). Females maintained higher body temperatures and presumably lost less water due to sweating. A 2°C increase in body temperature could provide a 2% daily water saving in a hydrated 150 kg feral ass. Tomkiewicz (1979) also found that the biological half-life of water for ♀♀ was one day longer than for ♂♂, indicating that their water use was more efficient. Such information indicates that the ancestral species, the African Wild Ass, is probably even more physiologically adapted to life in the deserts of Eritrea, Ethiopia and Somalia. However, the African Wild Ass still needs access to surface water and the movements of lactating ♀♀ are constrained by water availability. During aerial surveys in the Danakil Desert of Ethiopia, most African Wild Asses were observed within 30 km of known water sources.

In a gradient of mesic to arid habitat, the Plains Zebra *Equus quagga* is in the most mesic habitat, Grévy's Zebra *Equus grevyi* is in the drier habitat, and the African Wild Ass survives in the hottest, driest habitat, which also has the lowest plant biomass (Bauer *et al.* 1994). The physiological adaptations of this species allow this equid to live in one of the most extreme habitats in Africa.

Foraging and Food In Eritrea and Ethiopia, limited observations indicate that the African Wild Ass is primarily a grazer, but will also

Male African Wild Ass *Equus africanus* performing 'flehmen' while galloping.

utilize browse (Moehlman *et al.* 1998, Kebede 1999). In Mille-Serdo Wild Ass Reserve the preferred forage is *Aristida* spp., *Chrysopogon plumulosus*, *Dactyloctenium schindicum*, *Digitaria* sp., *Lasiurus scindicus* and *Sporobolus iocladius*.

Social and Reproductive Behaviour In the deserts of Eritrea and Ethiopia, African Wild Asses live in temporary groups that are small and typically comprise fewer than five individuals. The only stable groups are composed of a ♀ and her offspring. Female foals often stay with their mother and are residents in their natal area. Females do associate with other ♀♀ or with ♂♂, but even temporary groups are small. In temporary groups, the sex and age-group structure varies from single-sex adult groups to mixed groups of ♂♂ and ♀♀ of all ages. Adult ♂♂ are frequently solitary, but also associate with other ♂♂. Some adult ♂♂ are territorial, marking (by means of dung piles) and defending large areas for several weeks, and are dominant over conspecifics; only territorial ♂♂ have been observed copulating with oestrous ♀♀. Thus, African Wild Ass exhibit a social organization typical of equids living in arid habitats (Klingel 1977a, Moehlman 1998).

Individuals will form groups when benefits exceed costs in terms of feeding, predation, disease and reproduction. The density, continuity of distribution, and biomass of forage are key factors in the stability of association and the spacing of equids. When forage and water availability allows ♀♀ to be gregarious and form stable groups, then a ♂ can attempt to control access to these ♀♀. Large stable groups are more likely to form when one individual's foraging does not adversely affect a conspecific's foraging. Consequently, closer spacing and larger aggregations are possible when food is abundant. Conversely, low vegetation biomass and food shortages tend to limit group size and stability. This is the case with the African Wild Ass, which lives in an arid, low primary productivity habitat.

In more arid environments, limited food availability (both spatially and temporally) usually does not permit ♀♀ to forage in close proximity and/or to be associated consistently. In dry habitats, equids exhibit the same nutritional and reproductive characteristics (e.g. ♀♀ provide nutrition and ♀♀ tend to come into oestrus asynchronously), which allow ♂♂ to attempt multiple matings, but 'indirectly' control access to the ♀♀. In most cases, they actually control access to a critical resource, i.e. water. In these territorial mating systems, the only stable social group is a ♀ and her offspring.

Thus, the African Wild Ass has a resource-defence polygynous mating system (Klingel 1977a, Moehlman 1998).

Reproduction and Population Structure The African Wild Ass is polyoestrus and foals are usually born from Oct to Apr after a gestation period of 12–13 months. Natality and foal survivorship correlate positively and significantly with rainfall. A known-age African Wild Ass had her first live foal at six years, although ♀♀ are sexually mature much earlier. Females typically have a surviving foal every other year and natality correlates with rainfall during the period of gestation. In captivity the African Wild Ass can live up to 28.5 years (Weigl 2005).
